About the Editors

Lisa Feldman Barrett, PhD, is University Distinguished Professor of Psychology and Director of the Interdisciplinary Affective Science Laboratory at Northeastern University, with research appointments at Harvard Medical School and Massachusetts General Hospital (MGH), and is a faculty member at the MGH Center for Law, Brain and Behavior. Dr. Barrett's research focuses on the nature of emotion from both psychological and neuroscience perspectives, and incorporates insights from anthropology, philosophy, linguistics, and the history of psychology. She is the recipient of a Pioneer Award from the National Institutes of Health, among numerous other awards, and is a Fellow of the Royal Society of Canada, the American Association for the Advancement of Science (AAAS), and the Association for Psychological Science (APS). Dr. Barrett was a founding editor-in-chief of the journal *Emotion Review* and cofounder of the Society for Affective Science. She has published more than 170 journal articles and book chapters.

Michael Lewis, PhD, is University Distinguished Professor of Pediatrics and Psychiatry and Director of the Institute for the Study of Child Development at Robert Wood Johnson Medical School. He is also Professor of Psychology, Education, Nursing, Cognitive Science, Biomedical Engineering, and Social Work at Rutgers, The State University of New Jersey, where he serves on the Executive Committee of the Center for Cognitive Science and is an Associate of the Center for Mathematics, Science, and Computer Education. Dr. Lewis is a Fellow of the New York Academy of Sciences, the American Psychological Association (APA), the AAAS, and the Japan Society for the Promotion of Science, and is currently in the top 1.5% of scientists referenced in the Social Science Index. He is a recipient of the Urie Bronfenbrenner Award for Lifetime Contribution to Developmental Psychology in the Service of Science and Society from the APA, the Hedi Levenback Pioneer Award from the New York Zero-to-Three Network, and the Distinguished Scientific Contributions to Child Development Award from the Society for Research in Child Development. Dr. Lewis has published over 450 journal articles and book chapters and 35 books, including *The Rise of Consciousness and the Development of Emotional*

Life, which won the 2014 William James Book Award from the APA; *Social Cognition and the Acquisition of Self*; *Children's Emotions and Moods*; *Shame: The Exposed Self*; and *Altering Fate*.

Jeannette M. Haviland-Jones, PhD, is Professor Emerita of Psychology at Rutgers, The State University of New Jersey, where she is Codirector of the Center for Sensory Science and Innovation and former Director of the Human Emotions Lab. Dr. Haviland-Jones has written extensively about emotional development for over 25 years. She is coauthor of *The Hidden Genius of Emotion: Lifespan Transformations of Personality* and has published over 60 journal articles, chapters, and books on emotion and related issues. Her long-time research interests have included lifespan changes in displays of emotion, gender differences in emotions, and the organizing effects of emotion on cognition and personality. Recently she has initiated research on the chemosensory aspects of emotion communication, called "olfactics."

PREFACE

Since the first edition of the *Handbook of Emotions* was published in 1993, the field of affective science has expanded significantly, becoming ever more vibrant and interdisciplinary. Several new journals were founded (*Emotion* in 2001; soon followed by *Cognitive, Affective, and Behavioral Neuroscience*; *Social Cognitive and Affective Neuroscience*; and *Emotion Review*), and a new scientific society, The Society for Affective Science, emerged to complement the International Society for Research on Emotion. According to PsycINFO, the number of journal articles related to the study of affective phenomena has skyrocketed over 600% over the past 40 years, with the growth rate accelerating markedly over the past 15 years as publications on affect and emotion have grown faster than other historically comparable topics. New fields of study have emerged, such as affective computing, affective neuroscience, neuroeconomics, and positive psychology. So much research is conducted on emotion regulation that it is virtually its own field of study. The topic of emotion has seen a resurgence in humanities fields like history and philosophy. Even legal scholars are getting into the act with an entirely new field of emotion and law. The success of our second and third editions of the *Handbook* (published in 2000 and 2008, respectively) testifies to the surging interest in emotions and related phenomena. Research in affective science is a hub for many other sciences, owing to the increasing recognition that affective phenomena play a central role in every facet of life.

This fourth edition of the *Handbook* reflects this excitement. Several third edition chapters have been revised to include new material from pioneers in the field, and many new chapters reflect the changing focus and theoretical innovations of a vibrant scientific field. Virtually every section has expanded with the inclusion of cutting-edge work on novel topics. This edition breaks new ground with chapters on the mechanisms, processes, and influences that contribute to emotions, such as genetics, the brain, neuroendocrine processes, language, eating, and exercise; on the changes in emotion across the lifespan, from childhood into adolescence and older age; on neurodegenerative disorders; on methodological innovations like computational modeling of emotion; and on the ways in which emotion is related to closely allied topics such as stress, health, and empathy. We have also captured an emerging dialogue on the nature of emotion perception with three chapters reviewing different points of view. Prior editions of the *Handbook* have showcased the broad interdisciplinary scope of our field, and this edition is no different. Whether you are a scientist, a clinician, or an interested student of human nature, we hope you find this fourth edition as generative and instructive as we did while assembling it.

Interdisciplinary Perspectives

CHAPTER 1

THE PHILOSOPHY OF EMOTIONS AND ITS IMPACT ON AFFECTIVE SCIENCE

Andrea Scarantino

Philosophers' fascination with the emotions is as old as philosophy itself. A great many leading philosophers since Ancient Greece and throughout the Middle Ages, the Early Modern Period and up to the present time have proposed complex theories of emotions and of their value or disvalue with respect to knowledge, the good life, and morality, three historically dominant philosophical concerns. What has changed over time is the degree to which philosophical and scientific investigations of the emotions have differed from one another.

Many of the major figures in the history of Western philosophy were philosopher–scientists, namely pioneers of *natural philosophy*, the subfield of philosophy devoted to the inquiry into nature that in the 19th century started being singled out as "science." Since the 19th century, science and philosophy have differed in their methods, conceptual tools, and research questions, and the extent to which they should be separate intellectual pursuits is itself a topic of continuing philosophical reflection.

At first blush, there are some differences between the research programs of contemporary philosophers of emotions and affective scientists. Philosophers of emotions seem more inclined than affective scientists to engage in the armchair analysis of emotion concepts. They often explicitly aim to vindicate common-sense ideas about emotions, and find inspiration in the history of philosophy or in literary texts. Philosophers' standard method is to rely on reflective intuitions, developed through personal experiences of emotions and thought experiments, and try to come up with a theory of emotions that is all-encompassing, elegant, intuitively compelling, and capable of shedding light on other concepts of philosophical interest.

Affective scientists, on the other hand, generally do not consider the preservation of common-sense ideas about emotions to be a valuable objective, citing a litany of cases in which science has proven common sense wrong, as exemplified for instance by the conflict between folk physics and modern physics. The standard operating procedure of affective scientists is to form and test scientific hypotheses, typically modest in scope, through intersubjectively available empirical methods. When they engage in more general theorizing about emotions, affective scientists are often content to formulate theories of emotions that accommodate a particular set of empirical data, and are helpful for scientific explanation, prediction, and control in a given subfield of inquiry.

Despite these prima facie differences, it would be a mistake to conclude that the philosophy of emotions is not relevant to the present-day concerns of affective scientists. First, a sizable proportion of contemporary philosophers of emotions are self-described *naturalists*, in the sense that they reject the pertinence of the broad methodological divide I have outlined so far, suggesting instead that the type of knowledge about the world revealed by philosophy should not differ in kind from the type revealed by affective science.

These naturalistic philosophers consider the empirical data about emotions to be both a constraint on, and an inspiration for, philosophical theorizing. Unlike specialized affective scientists, who favor depth over breadth, naturalistic philosophers of emotions tend to become conversant in a variety of empirical literatures, learn to translate their disciplinary concerns and terminologies into a common language, and try to mediate among competing scientific viewpoints, often with the ultimate objective of integrating them into a coherent whole.

Second, many of the questions contemporary philosophers ask about emotions overlap with questions asked by affective scientists. Principal among those is the question of what emotions are. But several more specific issues at the forefront of affective science are attracting the attention of philosophers of emotions as well, including the nature of emotional experience (e.g., Ratcliffe, 2008), the structure of collective emotions (e.g., von Scheve & Salmela, 2014), the influence of emotions on decision-making (e.g., Elster, 2010), the impact of emotions on action (e.g., Döring, 2007), the role of emotions in morality and art (e.g., Prinz, 2007; Matravers, 1998), the possibility of unconscious emotions (e.g., Lacewing, 2007), the power of music to elicit emotions (e.g., Robinson, 2005), the use of emotions in film (e.g., French, Wettstein, & Saint, 2010), the influence of emotions in the law (e.g., Nussbaum, 2004), the natural kind status of folk emotion categories (e.g., Charland, 2002; Griffiths, 2004a), the ability of emotions to deliver epistemic information (e.g., Brady, 2013), the connection between emotional expressions and the origins of language (e.g., Green, 2007; Bar-On, 2013), and the nature and value of specific emotions (e.g., Haybron, 2008, on happiness; Steuber, 2006, on empathy; Brogaard, 2015, on love; Kelly, 2011, on disgust; D'Arms, 2013, on envy; Deigh, 1999, on guilt; Clark, 2010, and Velleman, 2001, on shame; Macnamara, 2012, on gratitude; Martin, 2014, on hope).

We can make significant progress on all these topics by applying theoretical tools developed in various areas of philosophy (see also Deonna, Teroni, & Tappolet, 2015). Just to mention a few examples, distinctions between dispositions and occurrences developed in metaphysics can help draw more refined emotion taxonomies, distinctions among varieties of consciousness developed in philosophy of cognitive science can clarify the various senses in which an emotion can be unconscious, distinctions between historical and forward-looking notions of function developed in philosophy of biology can provide a solid foundation for functional accounts of emotions, and theories of mental content developed in philosophy of mind can shed light on whether and how emotions have representational qualities.

Finally, the history of the philosophy of emotions, intertwined as it is with the history of affective science up to the 19th century, is a key resource for reconstructing where the "big ideas" that shape contemporary emotion research come from. A historical approach can help us better articulate and evaluate these ideas, and develop a sharp understanding of the costs and benefits of alternative theories of emotions. In this chapter, I trace the origin of the three ideas that have historically constituted the primary attractors in the project of defining emotions: the idea that emotions are *feelings*, the idea that emotions are *motivations*, and the idea that emotions are *evaluations*.

I begin by illustrating how these ideas have been introduced and developed by philosophers, and then highlight a few examples of how they continue to influence debates in emotion theory writ large. In the course of this exploration, it will become apparent that the science and the philosophy of emotions are deeply interconnected and can put their proprietary theoretical tools at the service of projects of common interest. It will also emerge that, although the area of consensus on the distinctive characteristics of emotions has increased over time, we are far from having reached consensus on what emotions are. I suggest in conclusion that failure to define emotions despite centuries of cross-disciplinary efforts demands significant changes in the methodological presuppositions of emotion research.

As we consider theories introduced at different times and in different languages, a caveat on terminology is in order. A variety of terms have been used over the centuries to designate what we now call "emotion," a term that came into use in the English language during the 17th and 18th centuries as a translation of the French term *émotion* but did not designate "a category of mental states that might be systematically studied" until the mid-19th century (Dixon, 2012, p. 338; see also Dixon, 2003; Solomon, 2008). Such alternative terms include, among others, "passion," "sentiment," "affection," "affect," "disturbance," "movement," "perturbation," "upheaval," "appetite," and their Greek, Latin, German, or French cognates.

None of these terms was used precisely as we use it today, none overlaps completely with our contemporary "emotion" category, and none was used in the exact same way by different authors. In the interest of simplicity, I disregard the nuances of translation between alternative terminologies, and count as emotion theories all theories that focus on affective categories that are "close enough" to what we call emotions today, in the sense that they comprise a sufficient number of the more specific states (e.g., joy, anger, fear) we count as emotions in contemporary taxonomies.

Emotions as Feelings, Motivations, and Evaluations

Theorists of emotions disagree vigorously on what emotions are, but they tend to concur on what I call the *diagnostic features* of emotions. These are the features we commonly use to infer that an emotion is under way, and they involve causes, constituents, and effects of emotions. An example can help us draw out our intuitions. Suppose the chair of your department pops by your office one day to nonchalantly tell you that you were denied tenure, after 6 years of strenuous efforts and despite having met all publicly stated tenure requirements. Further suppose that this piece of dreadful news makes you extremely angry. Which features are involved in this episode of anger?

First, it seems likely that you engaged in a certain type of *evaluation* of the events that unfolded: you appraised them as constituting a major slight to you. Second, a sequence of *physiological changes* is likely to take place, involving, say, slight tremors, decrease in saliva flow, and increases of heart rate, blood pressure, rate of respiration, and gastric activity. Third, your face, body, and voice are likely to manifest distinctive *expressions*: eyes locked on the department chair, eyebrows lowered and pulled together, expanded chest, stiff posture, and loud and high-pitched voice. Fourth, you are likely to undergo an unpleasant *subjective experience* that involves feeling hot and ready to engage in aggressive action. Fifth, your *mental processes* and *behavioral dispositions* are likely to change from their baseline states.

You immediately interrupt whatever else you were doing and focus your attention on the interaction at hand, first heatedly stating that denying you tenure is completely unfair and misguided and then, as soon as the department chair urges you not to take it personally, yelling at him to get out of your office. You then briefly close your eyes, try to calm down your breathing, imagine what your spouse's reaction to the news is going to be, consider where else you could apply, and immediately form an intention to appeal the decision. Your judgment of your department as a whole changes ("What a snake pit!"), and you come to realize how deeply you cared about tenure, despite your prior claims to the contrary.

Which of the many features of this prototypical anger episode *is* your anger? Is it the evaluation, the subjective experience, the expressions, the physiological changes, the disposition to engage in mental and physical actions, or a combination of all such features, plus perhaps some other ingredient? Furthermore, is getting angry beneficial or detrimental to you? These are some of the questions that have divided emotion theorists for centuries, leading to a plethora of competing accounts of emotions and their functions. Although such accounts differ across multiple dimensions, they can be usefully sorted into three broad traditions with deep philosophical roots, which I call the *feeling tradition*, the *motivational tradition*, and the *evaluative tradition*. Such traditions identify emotions with, respectively, distinctive conscious experiences, distinctive motivational states, and distinctive evaluations of the eliciting circumstances.

Each tradition comes in several varieties, and some theories do not fit comfortably within any one tradition. Furthermore, most theories combine aspects of several traditions. Nevertheless, it is helpful to sort theories into traditions of primary membership. This can allow us to highlight similarities among theories over time and across disciplines, and to unveil persistent theoretical challenges faced by each tradition. Most importantly, the historical investigation reveals that no tradition has developed a clear lead over its competitors. As a result, no view about what kind of psychological structures emotions are has gained widespread consensus. This remarkable fact sets affective science apart from other scientific pursuits, and it demands an explanation I provide in the chapter's methodological coda.

Aristotle at the Crossroads among Traditions

A good place to start our historical journey is Aristotle's account of emotions, which anticipates many of the themes of the three traditions I wish to distinguish and has exerted a major influence on the subsequent history of emotion theory. Aristotle's account is a rich hybrid that could be slotted into either the *feeling tradition, motivational tradition, or evaluative tradition*, depending on which aspect one decides to emphasize. This is due in part to the fact that Aristotle never provided a systematic theory of emotions (Cooper, 1999, pp. 406–407), offering instead a number of insightful but disjointed reflections on the nature and function of emotions throughout his ethical treatises (*Nicomachean Ethics*, *Eudemian Ethics*), his book on the nature of the soul (*On the Soul*), his writings on poetry (*Poetics*), and most prominently, his work on the art of public speaking (*Rhetoric*).

Aristotle's discussion of the emotions begins with a distinction between passions (*pathê*) and actions (*praxeis*) that has been taken for granted by most emotion theorists ever since (but see the section "The Motivational Tradition" for a discussion of some important exceptions). Whereas actions are things we *do*, Aristotle tells us, "in respect of the passions we are said to be moved" (*Nicomachean Ethics*, 1106a4–5). As pointed out by Kosman (1980, p. 105), the distinction between *praxeis* and *pathê* in Aristotle is a "special instance of a more general structural duality, that of *poiein* and *pashein*, doing and being done," which are for Aristotle distinct "categories of being." The identification of emotions with things that happen to us, or things by which we are acted upon, or things we undergo, is one of the most enduring legacies of Aristotelianism.

It strongly influenced early modern accounts of emotions (James, 1997) and it is still embedded in the very metaphors we use to speak about emotions in ordinary language. For example, "we 'fall' in love, are 'consumed' by envy, 'haunted' by guilt, 'paralyzed' by fear" (Averill, 1980, p. 267). Many of the adjectives we deploy to refer to the emotions are "derived from participles" (Gordon, 1987, p. 373)—"frightened," "surprised," "joyed," "irritated," "upset"—another sign of how ingrained the idea of passivity is in our folk conceptualization of emotions.

Initially, Aristotle may seem to be a straightforward founder of the *feeling tradition*. Besides emphasizing that the passions are things that happen to us, as feelings do, Aristotle explicitly identifies passions with feelings. As he puts it, the "passions [are] all those feelings that so change men as to affect their judgments, and that are also attended by pain [*lupe*] or pleasure [*hedone*]" (*Rhetoric*, 1378a19–21). Pain and pleasure must be understood here as having bodily underpinnings, since Aristotle tells us that "all the affections of soul involve . . . a concurrent affection of the body" (*On the Soul*, 403a16–19). Examples of passions discussed in some detail by Aristotle include anger, calmness, friendliness, hatred, fear, confidence in the face of danger, shame, kindness, pity, indignation, envy, and emulation.[1]

Aristotle's interest in how feelings "change men as to affect their judgments" was related to his primary rationale for studying them. His most detailed account of the passions is in the *Rhetoric*, whose practical objective was to help public speakers become more persuasive, especially in the context of political oratory and lawsuits. The ability to control one's own and the audience's passions, Aristotle thought, would make the orator more effective.

This makes Aristotle an early emotion regulation theorist, and a sophisticated one at that. He implicitly distinguishes between what regulation theorists now call *extrinsic regulation* (the regulation of other people's emotions) and *intrinsic regulation* (the regulation of one's own emotions; Gross, 1998). With respect to intrinsic regulation, Aristotle recognizes that we cannot choose our passions the way we choose our actions, but adds that the dispositions to undergo the passions can be chosen. This is because such dispositions are associated with *character*, something that according to Aristotle can be voluntarily shaped over time by means of a process of *habituation*. The objective of the sage should be for Aristotle *metriopatheia*—namely, moderation in the passions—which requires experiencing them with respect "to the right person, to the right extent, at the right time, with the right motive, and in the right way" (*Nicomachean Ethics*, 1109a25).

Concerning extrinsic regulation, Aristotle suggests that the regulation of other people's passions demands learning what kind of frame of mind is typical of people who experience a certain passion, what kinds of people are such that a certain passion is experienced toward them, and what kinds of circumstances characterize the experience of a passion.

This explains Aristotle's interest in the *evaluations* associated with the passions, which are for him ultimately feelings caused, and possibly partially constituted by, distinctive evaluations. For example, fear is "pain or disturbance due to imagining some destructive or painful evil in the future" (*Rhetoric*, 1382a23); shame is "pain or disturbance in regard to bad things, whether present, past or future, which seem likely to involve us in discredit" (1383b15); and envy is "pain excited by the prosperity of . . . people who are like us or equal with us" (1387b21).[2]

Aristotle insightfully points out that since emotions have both an evaluative dimension and a bodily dimension underlying the feelings of pleasure and pain, two options are available for defining them. For example, a "physicist would define an affection of soul differently from a dialectician; the latter would define e.g. anger as the appetite for returning pain for pain, or something like that, while the former would define it as a boiling of the blood or warm substance surrounding the heart. The latter assigns the material conditions, the former the form" (*On the Soul*, 403a29–403b2). For Aristotle, an emotion is a combination of *matter* and *form*, where the matter is what makes up the entity, and the form is the structuring principle that shapes the matter to constitute a certain type of entity.

Aristotle's distinction between types of interest-dependent definitions raises the question of whether being caused by a particular evaluation is essential to being a passion, or whether a passion can just be a feeling of pleasure and pain with its attendant bodily underpinnings. I do not take a position on this thorny issue here, but note that whether evaluations merely cause the emotions or partially constitute them matters for establishing whether Aristotle can be counted as one of the founders of the *evaluative tradition*, which is also often traced back to his work (e.g., Power & Dalgleish, 2008; Nussbaum, 2001).

Finally, passions are for Aristotle closely associated with actions, although once again, whether being a motive for action is constitutive of being a passion is up for debate. At the very least, we can count Aristotle as an early sympathizer of the *motivational tradition*. In some cases, Aristotle makes the tie with action explicit. For example, he tells us in the *Rhetoric* that (as defined by the dialectician) anger is "an impulse, accompanied by pain, to a conspicuous revenge for a conspicuous slight directed without justification towards what concerns oneself or towards what concerns one's friends" (*Rhetoric,* 1378a31–1378b1). Similarly, a friendly feeling toward someone amounts to "wishing for him what you believe to be good things, not for your own sake but for his, and being inclined, so far as you can, to bring these things about" (1380b36–1381a2). This being said, it is notable that no other accounts of the passions in the *Rhetoric* include explicit mention of an impulse or motivation (*orexis*) for action (Cooper, 1999, p. 420).

In the rest of this chapter, I explore how different authors have articulated the identification of emotions with feelings, motivations, and evaluations, and highlight a handful of especially interesting contributions. I emphasize from the beginning that in some cases a different reading of the multiply interpretable textual evidence is possible with respect to specific authors. Historical scholarship will have to be the ultimate arbiter of where various theories of emotions stand in terms of their tradition of primary membership. My main interest here is not to contribute to historical scholarship, but to sketch in broad strokes a historically plausible family tree in light of which contemporary attempts to define emotions in philosophy and affective science can be better connected and understood. I present the resulting family tree in Figure 1.1, and will proceed to illustrate its various parts in what follows.

The Feeling Tradition

The *feeling tradition* holds that emotions are feelings of a distinctive type, where a feeling is a conscious experience or a sensation or a subjective quality or a quale or a what-it-is-likeness. This view has largely dominated the study of emotions from Ancient Greece to the 20th century, and it has never stopped being influential, in part because it seems to capture folk intuitions about emotions better than its alternatives. When asked to rank in order of importance five "attributes" of emotion—facial expressions, vocal expressions, feeling states, cognitive changes, and autonomic changes—English speakers reliably pick feelings as most important (Panksepp, 2000).[3]

Although many emotion theorists since Aristotle have identified emotions with feelings, I begin my discussion of the modern feeling tradition with René Descartes. Besides having formulated what became the orthodox theory of emotions from the 17th century to roughly the end of the 19th century (with some exceptions along the way), Descartes offers the first rigorous formulation of one of the two main approaches to the *feeling tradition* that still influence contemporary research. I characterize the approach followed by Descartes, and later by Hume, Locke, and several other early modern philosophers, as the *atomistic perceptualist approach*. This approach identifies emotions with types of perceptual feelings, and assumes that such feelings are, as William James later put it, "psychic atoms."

The second approach of contemporary relevance is James's *constructionist approach*, according to which emotions are feelings that can be further

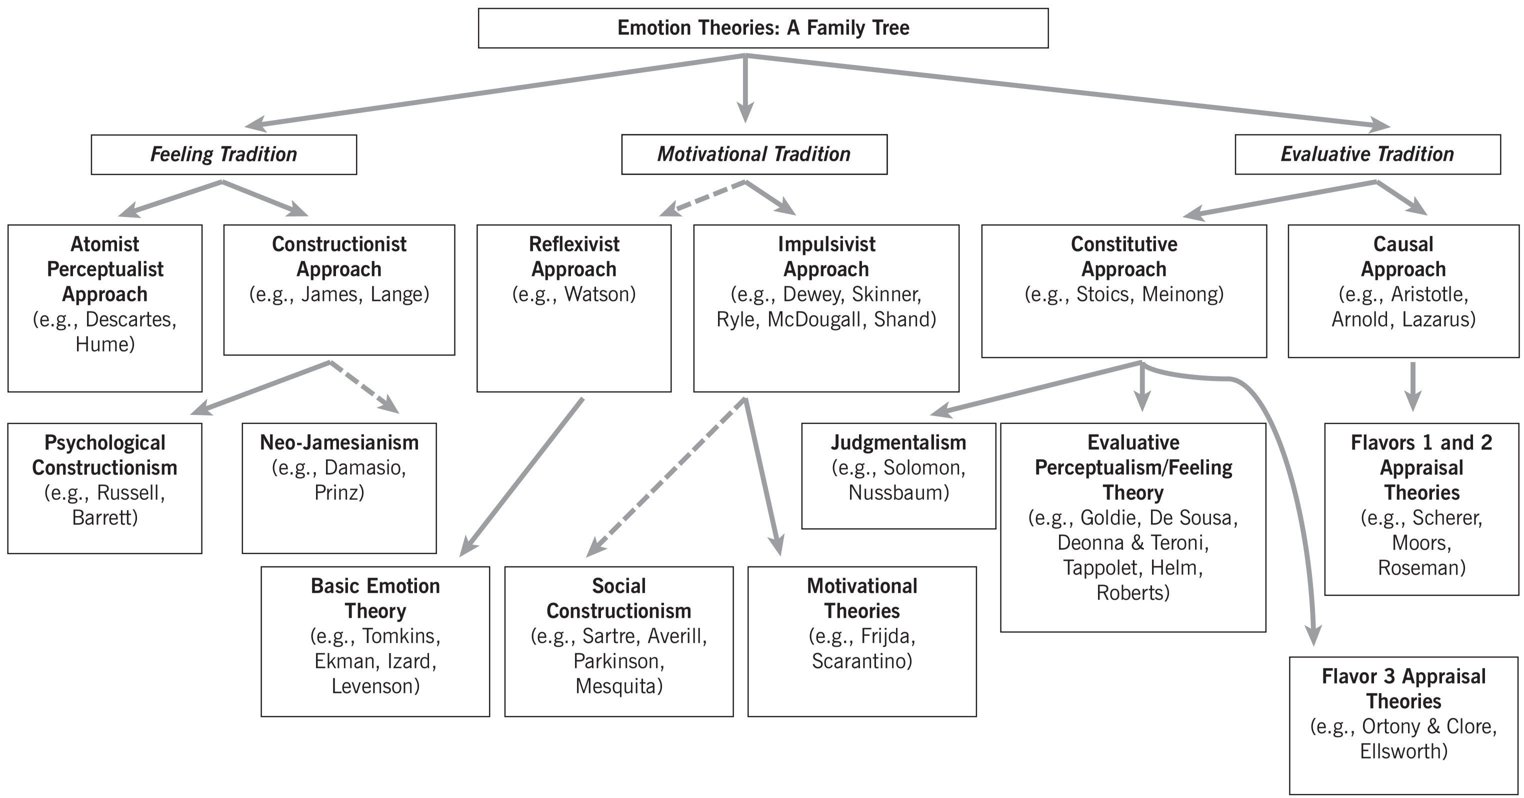

FIGURE I.1. A family tree for theories of emotions. Dashed lines are meant to signal more tenuous connections among traditions, approaches, and research programs than solid lines.

decomposed into building blocks, a view meant to usher psychology into a new scientific phase. I first illustrate these two approaches, and then consider two research programs in contemporary affective science which carry the Jamesian torch in different ways—namely, psychological constructionism and neo-Jamesianism (see Figure 1.2).

Cartesian Passions: The 17th- to 19th-Century Orthodoxy

Descartes presents his theory in *The Passions of the Soul* (1984), a treatise that begins with a sweeping dismissal of all emotion theories that came before: "the defects of the sciences we have from the ancients are nowhere more apparent than in their writings on the passions" (PA, a.1). Descartes, a dualist, decries their failure to distinguish between soul and body as distinct substances, and to investigate separately the functions of each. The functions of the body are for Descartes motion and heat. The function of the soul is the production of thoughts, of which two varieties can be distinguished: actions and passions. The actions of the soul are "acts of will" (e.g., the will to love God, the will to go for a walk), whereas the passions of the soul—in the broadest sense—are "perceptions . . . found in us," rather than willed.

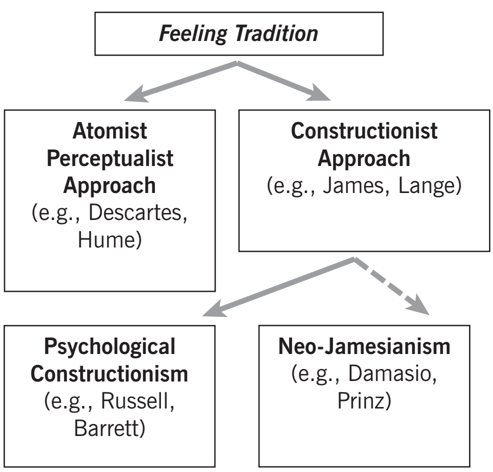

FIGURE 1.2. The *feeling tradition* and some related contemporary developments. The dashed line between the *constructionist approach* and *neo-Jamesianism* indicates that, although neo-Jamesianism is inspired by James's analysis of emotions, it is not a variety of constructionism.

Perceptions found in us come in two varieties: some are caused by the soul (e.g., the perception of an act of will) and some are caused by the body. And here we come to the key distinction: for Descartes, some of the perceptions caused by the body are referred to external objects, some are referred to the body, and some are referred to the soul itself. The first are sensory perceptions (e.g., visual perceptions, auditory perceptions), the second are bodily perceptions (e.g., pain, thirst, hunger), and the third are the passions properly understood. Cartesian passions in this narrower sense are "perceptions we refer only to the soul [and] whose effects we feel as being in the soul itself" (PA, a.25). The idea is that whereas our sensory experiences are of external objects (e.g., we perceive red apples) and our bodily experiences are located in the body (e.g., we perceive a pain in the foot), we experience our passions directly in the soul. For example, we may be afraid of a tiger and facial movements may accompany our fear, but for Descartes the feeling of fear is in the soul itself rather than in the external world or in the body.

As a result, Descartes thinks, emotions are "so close and so internal to our soul that [we] cannot possibly feel them unless they are truly as it feels them to be" (PA, a.26). What he means is that, since the passions do not involve implicit causal hypotheses about which external objects caused them or where in the body they are located, they cannot be felt in the soul without actually being in the soul. A corollary of this view is that the passions become objects of infallible introspective access: we may be wrong about what causes our passions, but we cannot be wrong about the very existence of our passions (see Kenny, 1963).

Descartes distinguishes among six primitive passions (admiration, love, hatred, desire, joy, and sadness) and an open range of nonprimitive passions, which are species of primitive passions (e.g., cheerfulness is a species of joy) or compounds of primitive passions (e.g., pride is a compound of joy and love). Since animals, unlike humans, do not have a soul, Descartes concludes that none of these passions is available to them.

Descartes makes it clear that the distal cause of the passions is an *evaluation*, whereas their proximal cause is the motions of the pineal gland brought about by "animal spirits" (the finest particles of matter). For instance, Descartes tells us that "wonder" is a "sudden surprise of the soul" which is caused by "an impression in the brain . . . which represents the object as something unusual and consequently worthy of special consideration"

(PA, a.70).[4] Love and hatred are instead caused by evaluating an object as, respectively, "agreeable" or "harmful" (PA, a.79). Descartes also emphasizes that the passions have an important function: "they move and dispose the soul to want the things for which they prepare the body." So the feeling of fear "moves the soul to want to flee," the feeling of courage "to want to fight," and so on (PA, a.40). But neither the evaluative nor the motivational elements, although part of the causal chain from perception of external objects to behavior, are part of the passions. For Descartes, "only the final, culminating, reactive, simple and unitary mirror-feeling in the soul of all that [is] going on in the body, could be called 'the emotion' " (Lyons, 1999, p. 28). It is the very idea of feelings as *simple* and *unitary* "atoms" that James's constructivist psychology called into question at the end of the 19th century.

Hume's Rejection of the Reason–Passion Dichotomy

As Anthony Kenny (1963) put it, "it was Descartes' formulation of the problems concerning the emotions which was to influence the later history of philosophy and the early attempts to make psychology into an experimental science" (p. 11). Descartes' influence on the philosophy of emotions is revealed by the fact that most early modern philosophers, despite significant differences in their overall philosophy, thought of emotions as species of perception (e.g., Locke, 1690/1975, describes them as "internal sensations"; Hume, 1739/1992, describes them as "secondary impressions"; Hutcheson, 1728/2002, describes them as "perceptions of pleasure and pain"). Classical British empiricists like David Hume, and especially John Locke, strongly emphasized the atomistic aspect of the passions, trying to show that, just like all other mental states, they are either simple mental states or reducible to a combination of simple mental states (see Deigh, 2010, for further discussion).

Hume's analysis is especially notable because it calls into question the divide between reason and passion that most emotion theorists had taken for granted until then. Hume begins by describing the passions as "impressions of reflection"—namely, perceptions caused either by other impressions or by ideas, which are copies of impressions. But the passions themselves are not ideas and consequently have "no more a reference to any other object, than when I am thirsty, or sick, or more than five foot high" (T 2.3.3.5).[5] What follows is that the passions cannot be "contradictory to truth and reason." For Hume, "this contradiction consists in the disagreement of ideas, considered as copies, with those objects, which they represent" (T 2.3.3.5). But since the passions are not copies of anything, the conflict between reason and passions cannot take place.[6]

And since the passions are for Hume the only psychological entities that can direct the will to action, reason cannot affect actions except by courtesy of the passions. This is what lies behind Hume's trademark claim that "reason is, and ought only to be the slave of the passions, and can never pretend to any other office than to serve and obey them" (T 2.3.3.4). Reason can determine what is the best means for achieving a practical end picked out by the passions, but it cannot pick out a practical end of its own, because it has no access to the direction of the will.

Notably, this approach to action explanation is still dominant in contemporary philosophy, and it has been enshrined in the so-called *Humean theory of motivation*, according to which all intentional actions are caused and rationalized by pairs of beliefs and desires, which are regarded as distinct, mutually irreducible kinds of mental states (Smith, 2010). Beliefs have a mind-to-world direction of fit, because their aim is to fit what the world is like (cognitive direction of fit), and desires have a world-to-mind direction of fit, because their aim is to change the world so as to be satisfied (conative direction of fit; Searle, 1983).

The dominance of this model is testified by the attempt made by several philosophers to explain *emotional actions* in terms of beliefs and desires, on the assumption that the only way for emotions to affect actions is by causing, or by being constituted by, belief and desire pairs. This Humean model has been influentially criticized by Hursthouse (1991), who focuses on the counterexample offered by "arational actions"—namely, "weird" emotional actions like jumping up and down out of joy or kicking a door out of anger or gouging the eyes out in someone's picture out of hatred.

In such cases, Hursthouse (1991) argues, the Humean model collapses, because we cannot find any belief–desire pair that would cause and rationalize such emotional actions. In Hursthouse's view, a better explanation of arational actions is that they are performed because one is in the grip of an emotion, which has a distinctive motivational force irreducible to belief and desire psychology. The debate on whether the *Humean theory of motivation* can explain emotional actions has flourished in recent philosophy of emotions, and a number of proposals, both in favor of and against Humeanism, are available (see Smith, 1998; Goldie, 2000; Döring, 2003, 2007; Kovach & De Lancey, 2005; Scarantino & Nielsen, 2015).

Descartes' assumption that the mind consists in what lies within one's consciousness also had a profound impact on the emerging science of psychology. Early champions of experimental psychology like Wilhelm Wundt and Edward Titchener took it for granted that introspection offers us privileged access to the inner world of conscious experience, and they defined psychology as the science that studies consciousness through properly trained introspection, a view that oriented the young science of psychology until the rise of behaviorism in the early 20th century.

The Jamesian Revolution: Feelings as Constructions

The second approach I distinguish within the *feeling tradition* is the *constructionist approach* associated with James's theory of emotions, presented in "What Is an Emotion?" (1884), in the 25th chapter of *The Principles of Psychology* (1890), and in "The Physical Basis of Emotion" (1894).[7] James believed that a truly scientific theory of the emotions required understanding their *physiological* causes rather than treating them as *psychic* and *atomic* phenomena that take place in the soul, a characterization applicable to the theories offered by Descartes, Hume, Locke, and many other early modern philosophers.

James complained that emotions had been described until then as "the internal shadings of emotional feeling," where feelings were understood as "psychic entities" whose bodily underpinnings, although perhaps typical, were not essential. "The trouble with the emotions in psychology," he wrote, "is that they are regarded too much as absolutely individual things. So long as they are set down as so many eternal and sacred psychic entities, like the old immutable species in natural history, so long all that *can* be done with them is reverently to catalogue their separate characters, points, and effects" (1890, p. 449).

James judged the "merely descriptive literature of the subject, from Descartes downwards, [as] one of the most tedious parts of psychology" (James, 1892, p. 374). Besides being tedious, James (1890) believed that theorizing about the emotions in terms of internal shadings of emotional feeling resulted in endless classification lacking in scientific rigor. What the scientific theory of emotion needed was a "generative principle" that could only be discovered by regarding the emotions as "products of more general causes" rather than individual psychic entities to be introspectively distinguished and labelled (1890, p. 449).

Since "the general causes of the emotions are indubitably physiological," James concluded that focusing on physiology offered emotion theorists the promise of a generative principle that could do for the understanding of emotions what the generative principle of heredity and variation had done for the understanding of species—namely, allow it to get "on to another logical level" (1890, p. 448).

According to Mandler (1990, p. 180), James developed "the first constructionist psychology, attempting to understand the processes that generate and construct behavior and conscious experiences." Mandler notes an important change in scientific psychology between the 19th and the 20th century. Nineteenth-century psychology was "generally atomistic—mental phenomena were seen as the concatenation of nuclear ideas, feelings, and thoughts," whereas 20th-century psychology was interested in the "mechanisms and processes that produced or generated feelings and thoughts, and when there was an interest in basic building blocks, it rarely invoked ideas, feelings, or thoughts" (1990, p. 179).

James pioneered this very transition, suggesting that emotional feelings are not "simple and unanalyzable," as generally assumed within the *feeling tradition*, but rather constructed out of more basic ingredients. For James (1884), an emotion is a "secondary feeling indirectly aroused" when organic changes occur in a reflex-like fashion as a result of being exposed to an exciting stimulus. This approach makes it possible to conceive of emotions "as something other than individual sensations or feelings each identifiable by a distinctive sensory tone or quale" (Deigh, 2001, p. 1249). Most importantly, this approach allows James to explore how these secondary feelings are *constructed* out of the combination and integration of more basic processes not specific to emotions.

On James's original account, there is no *psychic entity* (e.g., no evaluation) that mediates between the mental perception of some exciting fact and the bodily expression. Rather, "*the bodily changes follow directly the PERCEPTION of the exciting fact*" and "*our feeling of the same changes as they occur IS the emotion*" (1884, p. 190).[8] This amounts to a reversal of common sense, according to which we cry because we are sorry, we run because we are afraid, and we strike because we are angry. On the contrary, according to James, "we feel sorry because we cry, angry because we strike, afraid because we tremble" (p. 190). On this view, since emotions are feelings resulting from perceiving changes in expressions, physiology and behavior, and such changes must occur prior to being perceived, emotions do not cause the diagnostic changes associated with them (see Deigh, 2014, for further discussion).

In developing his theory, James makes a distinction between what he calls the *standard* or *coarser* emotions and the *intellectual* or *subtler* emotions. The former are those in which the bodily disturbance is clear, and they include surprise, curiosity, rapture, fear, anger, lust, greed, grief, rage, and love. However, James acknowledges that there are also emotions "whose organic reverberation is less obvious and strong" (1890, p. 449). For these subtler emotions, which include "moral, intellectual, and aesthetic feelings," as well as "feelings of pleasure and displeasure, of interest and excitement," James's theory seems at first sight less apt. However, James insists that, although muted, the bodily sounding board must be at work for the *subtler* emotions as well, lest they simply amount to "a cold and neutral state of intellectual perception" (p. 451). To support his claim that bodily feelings are necessary for emotions, James simply argues that nothing emotional is left once we subtract bodily changes from emotions. As he puts it, "emotion dissociated from all bodily feeling is inconceivable" (p. 452).

Contemporary Developments: Neo-Jamesianism and Psychological Constructionism

James's theory has arguably had a more profound impact on 20th-century emotion theory and research than any other previous theory, either as an inspiration or as a foil. Contemporary neo-Jamesians and psychological constructionists have both singled out James as a central predecessor, but they have found inspiration in different aspects of his work. Neo-Jamesians like Antonio Damasio and Jesse Prinz have focused on the *bodily side* of James's theory, whereas psychological constructionists like James Russell and Lisa Feldman Barrett have focused on the *constructionist side*. Let us briefly consider these developments in turn.

James thought of bodily changes primarily in terms of autonomic bodily changes, which comprise physiological reactions such as changes in heart rate, blood pressure and blood flow distribution, respiration, and activity of the sweat glands (but note that James, 1890, had also included changes in expressions and emotional actions). Neo-Jamesians have added to this list *hormonal changes* such as changes in the catecholamine hormones epinephrine and norepinephrine, *musculoskeletal changes* such as changes in muscle tension and feedback from facial expressions of emotion, and, most importantly, *neural changes* consisting of the activation of the somatosensory brain areas. On this view, emotional feelings need not be caused by feedback from peripheral bodily changes, and can (at least in some cases) simply consist of brain activations (Damasio, 1994, calls these "as-if" bodily changes).[9]

An additional difference is that many neo-Jamesians have rejected James's identification of *emotions* with *feelings*, and suggested that emotions and feelings have importantly different functions. Damasio argues that "an emotion is a collection of changes in body state connected to particular mental images" (1994, p. 145), with the function of initiating automatic and stereotyped bodily responses. Feelings are instead the "experience of such changes in juxtaposition to the mental images that initiated the cycle [emphasis removed]" (p. 145) and their function is to "open the door for some measure of willful control of the automated emotions" (Damasio, 2003, p. 80). They do so through their role in practical reasoning. When deliberative options are considered, they elicit memories of past emotions experienced in comparable situations. Such memories activate *somatic markers*—namely, "gut feelings" that mark options as positive or negative in light of their expected emotional consequences, and aid the decision process.

Damasio (1994) posits somatic markers to explain the intriguing correlation between ventromedial (VM) prefrontal cortex damage and the incapacity to make rational decisions in a variety of domains. Patients with VM damage have been characterized as irrationally Hamlet-like when faced with trivial decisions such as choosing a date for their next doctor's appointment, irrationally risk prone when faced with gambling decisions, irrationally impatient when faced with decisions demanding deferred gratification, and irrationally antisocial when faced with decisions involving respect for norms.

Damasio's (1994) *somatic marker hypothesis* is that all these forms of irrationality are due to the loss of the ability to "mark" options as positive or negative in the prefrontal cortex. The debate on whether the empirical evidence supports Damasio's somatic marker hypothesis is still ongoing (see, e.g., Dunn, Dalgleish, & Lawrence, 2006; Reimann & Bechara, 2010). Another important recent advance is Prinz's addition to the neo-Jamesian toolbox of a theory of intentionality applicable to perceptions of bodily changes, a development I discuss in the section "Contemporary Developments I: Evaluative Theories in Philosophy and Their Challenges."

A second descendant of James's theory is *psychological constructionism*, which has followed James in emphasizing that emotions are put together out of building blocks that are not specific to emotions (Gendron & Barrett, 2009). Constructionists deviate from James in assuming more (and partly different) building blocks. One is especially common: *core affect*. As Russell (2003, p. 147) puts it, core affect is a "neurophysiological state that is consciously accessible as a simple, nonreflective feeling that is an integral blend of hedonic (pleasure–displeasure) and arousal (sleepy–activated) values." Different constructionists describe how affective episodes are built out of core affect and other ingredients in different ways.

For example, in the work of Barrett (2006, 2009, 2012, 2015), conceptualization plays a key role. On her view, being afraid amounts to categorizing a core affective state of high arousal and high displeasure under the "fear" concept. Being happy amounts to categorizing a core affective state of high arousal and high pleasure under the "happiness" concept. This view has been criticized for conflating emotions with verbal labeling, for making it impossible for adult humans to mislabel their own emotions, and for preventing infants and animals from having emotions in the first place (e.g., Scherer, 2009; Scarantino, 2015; see Barrett, 2015, for a reply).

Russell, another prominent psychological constructionist, allows emotion episodes to be constructed without the involvement of categorization, since on his view conceptualization only affects the *meta-experience* of emotion, that is, the experience corresponding to the realization that one is afraid (see Scarantino, 2012a; Russell, 2012a, 2012b, for further discussion).

What most varieties of psychological constructionism accept is James's view that emotions do not *cause* their diagnostic features but rather *emerge* from them. This shift corresponds to a transition between measurement models of emotions. The traditional *latent variable model*, according to which emotions precede and cause the variation in their diagnostic indicators, is replaced by psychological constructionists with an *emergent variable model*, which "posits that emotions do not cause, but rather *are caused by*, their measured indicators" (Coan & Gonzalez, 2015, p. 213).

For example, Russell (2003) criticizes the "traditional view of an emotion episode," according to which the "antecedent [stimulus] causes the emotion, which causes all its various 'manifestations'" (p. 151). If emotions were internal entities with such causal powers, Russell (2009, p. 1262) continues, it would follow that "because the various components stem from a single [causal] entity, they [would] cohere in tight packages." The empirical evidence tells us that they do not, and that there is major variability with respect to each component (see the section "Contemporary Developments I: Basic Emotion Theory and Social Constructionism"). Russell concludes that this calls into question the view that emotions are "internal entities [with] certain powers, such as the power to cause their own components" (2015, p. 432).

Some Challenges for the Feeling Tradition

As we have seen, various elements of the *feeling tradition* have been incorporated into contemporary research programs in affective science. Yet, the *feeling tradition* as a whole progressively lost its dominance in the course of the 20th century. Many challenges were raised to the idea that emotions are essentially feelings, but three stand out for their long-term impact and for how they are shaping contemporary attempts to revive the feeling tradition (see the section "The Evaluative Tradition").

The first is the *problem of differentiation*—that is, the problem of distinguishing among different emotions. Against James's bodily feeling theory, for example, Cannon (1929) objects that "the responses in the viscera seem too uniform to offer a satisfactory means of distinguishing emotions" (pp. 351–352; see also Baldwin, 1894). More generally, critics of feeling theories argue that—regardless of the nature and origin of the emotional feelings postulated by different feeling theories—not all differences among distinct emotions are reflected in differences among the subjective experiences associated with them.

One reason for this is that different emotions like, say, indignation and annoyance may involve indistinguishable feelings (Bedford, 1957). Another reason is that some emotions may not be felt in the first place, and so cannot differ from other emotions in light of the quality of the subjective experiences associated with them. This possibility became prominent when Freud (1915/1997) rejected the Cartesian assumption that the mind consists of what we are conscious of, and proposed instead that consciousness is just the tip of an iceberg, with the bulk of mental processes occurring below the surface of consciousness.

Specifically with regard to emotions, Freud points out that "in psychoanalytic practice we are accustomed to speak of unconscious love, hate, anger, etc." (1915/1997, p. 126). Notably, however, Freud himself does not recommend a literal interpretation of this way of speaking, because "it is surely of the essence of an emotion that we should feel it, i.e. that it should enter consciousness" (1915/1997, p. 126).[10]

On Freud's view, an unconscious emotion is a feeling that is "perceived, but misconstrued" (1915/1997, p. 126), in the sense that "by the repression of its proper presentation it is forced to become connected with another idea, and is now interpreted by consciousness as the expression of this other idea" (1915/1997, p. 110). An example of such a misconstrued feeling would be an episode of romantic love for a first-degree cousin with its attendant feelings but whose phenomenology is mistaken for one of, say, friendly attachment. In such case, there are feelings associated with being in love with one's cousin, but the *idea* that one loves one's cousin never gets a "proper presentation" to the person's conscious mind, due to repression. Later theorists have argued that emotions themselves, rather than just ideas connected to emotions, can be unconscious, although the debate on the possibility of unconscious emotions is still unsettled in both philosophy and affective science (e.g., Lacewing, 2007; Winkielman & Berridge, 2004; Winkielman, 2013).

The second problem for feeling theories of emotion is the *problem of intentionality*. I consider this problem to comprise two related subproblems. The first is the problem of *aboutness*: emotions appear to be about objects. For example, we are not just angry, sad, or afraid, but angry, sad, or afraid *about* particular things. The second is the problem of *correctness*: emotions appear to be *correct* or *incorrect* with respect to the objects they are about. For example, it seems correct to be angry about having been cheated on by one's spouse, sad about the death of one's mother, and afraid of a deadly snake nearby. This view of intentionality conceives of the relation between the emotion and what the emotion is about as a representation relation: emotions are about objects in the sense that they *represent* them in a particular way and can do so correctly or not.

As several analytic philosophers argued in the late 1950s and early 1960s (and as was argued in the 19th century by Franz Brentano and his students, such as Alexius Meinong and Carl Stumpf), Hume was simply wrong about the fact that an emotion "contains not any representative quality." If being afraid were just like being "thirsty, or sick, or more than five foot high" (T 2.3.3.5), as Hume had put it, it would be mysterious why fear is *about*, say, a tiger and what makes it *appropriate* with respect to it. One is not "thirsty, sick, or more than five foot high" about anything, and being thirsty, sick, or more than five feet tall are not the sorts of things that can be appropriate or inappropriate. The attempt to explain why emotions are about objects that they can represent correctly or incorrectly—the problem of intentionality as I understand it in what follows—was one of the primary reasons for the emergence of the evaluative tradition in emotion theory (see the section "The Evaluative Tradition").

The third problem is the *problem of motivation*—namely, the problem of accounting for how emotions can motivate actors to pursue certain ends (e.g., to flee danger in the case of fear, to help a needy person in the case of pity). This problem was especially significant for James's theory. According to James, emotions are caused by bodily changes, but they have no causal influence on action. James gave the job of motivating action to *instincts*, where an instinct is "defined as the faculty of acting in such a way as to produce certain ends, without foresight of the ends, and without previous education in the performance" (1890, p. 383).

Once actions are brought about by instincts, the bodily changes they involve are perceived, giving rise to emotions. From this it follows that "every object that excites an instinct excites an emotion as well."[11] But "the emotional reaction usually terminates in the subject's own body," James adds, whereas "the instinctive reaction is apt to go farther and enter into practical relations with the exciting object" (1890, p. 442). This very assumption was called into question by the proponents of the *motivational tradition*, who argued that if emotions terminated in the subject's own body and had no practical relations with the exciting object, they would lack the significance that we commonly ascribe to them (e.g., Dewey, 1894, 1895; McDougall, 1908; Shand, 1920).

The final straw for the *feeling tradition* was the emergence of behaviorism in the early 20th century, which undermined the core idea at the foundation of the tradition—namely that emotions should be conceptualized as special states of consciousness. As Watson put it in a brusque putdown, "nearly 40 years ago James gave the psychology of the emotions a setback from which it has only recently begun to recover" (1925, p. 140). But feeling theories have since become fashionable again and are making a comeback in new and more powerful forms, as contemporary feeling theorists try to answer the challenges of explaining how emotions as feelings can be differentiated, intentional, and motivationally powerful (see the section "The Evaluative Tradition").

The Motivational Tradition

The *motivational tradition* holds that emotions are motivational states of a distinctive type, or patterns of behavior of a distinctive type. I distinguish two approaches within the *motivational tradition*. The *impulsivist approach*, which identifies emotions with behavioral impulses (i.e., states of being set or disposed or ready for a certain pattern of behavior), and the *reflexivist approach*, which identifies emotions with reflex-like behaviors (see Figure 1.3). Generally speaking, talk of motivation is appropriate only when the reflex connection between stimulus and response is broken. But since *reflexivist* and *impulsivist* approaches both identify emotions as "modes of behavior" in a broad sense of the term, it makes sense to discuss them as members of the same tradition.

After introducing some highlights from the history of the *motivational tradition*, I explore how it has inspired various developments in contemporary emotion theory, most significantly the emergence of basic emotion theory, of motivational theories of emotions and of social constructionism.

Dewey between Darwin and James: Emotions as State of Action Readiness

Many in the history of emotion theory have emphasized that emotions involve impulses to behave, starting as we have seen with the Aristotelian accounts of anger and friendly feelings. Philosophers throughout the Middle Ages were especially keen on developing the "motivational side" of Aristotle's theory, characterizing emotions as types of "willings" (Augustine), "wantings" (Anselm, Abelard), or "motions" (Aquinas), although the extent to which such accounts give primacy to motivations over feelings and evaluations is up for debate (see King, 2010; Lyons, 1980; Power & Dalgleish, 2008).

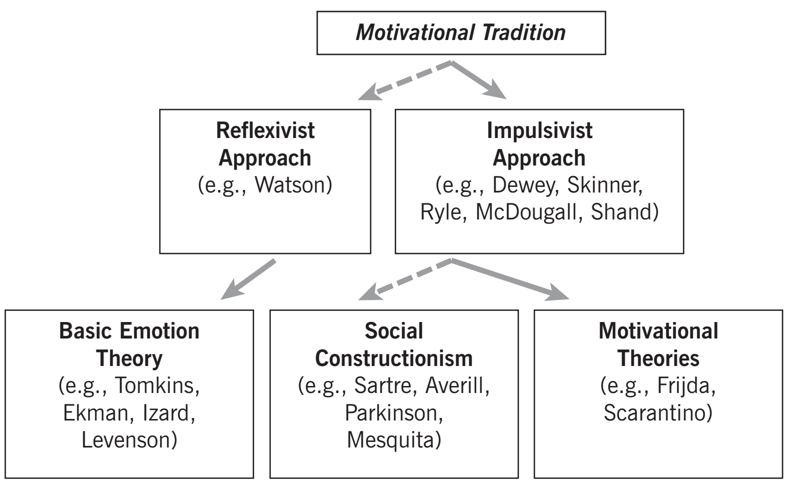

FIGURE 1.3. The *motivational tradition* and some related contemporary developments. The dashed line between the *motivational tradition* and the *reflexivist approach* is meant to signal that talk of motivation is strictly speaking inappropriate when it comes to reflexes. The dashed line between the *impulsivist approach* and *social constructionism* indicates that, although social constructionists are inspired by the idea that emotions have an active side, they do not necessarily identify emotions with motivational states.

The first to provide a detailed theory of emotions as motivational states is arguably John Dewey (1894, 1895), with whom I associate the beginning of the *impulsivist approach*. Dewey's general aim in his "The Theory of Emotion. (I) Emotional Attitudes" (1894) and "The Theory of Emotion. (2) The Significance of Emotions" (1895) was to propose a synthesis of Charles Darwin's (1872) theory of emotional expressions with William James's (1884) theory of emotions.

Darwin, in *The Expressions of the Emotions in Man and Animals* (1872/1965), had proposed three principles for explaining emotional expressions, suggesting that they often operate in concert. A great many emotional expressions emerge for Darwin according to the principle of *serviceable associated habits*. Consider the baring of the teeth, produced by various species when in anger. For Darwin, this expression is an involuntary vestige of a voluntary action—biting—that used to be serviceable in the ancestral past of the species and kept being associated to the state of mind that brought it about by force of habit or by reflex.

Once an expression has been established through the principle of serviceable associated habits, other expressions can be generated through the subsidiary principle of *antithesis*. According to it, states of mind opposed to those that elicited expressions according to the principle of serviceable associated habits recruit expressions in morphological antithesis to them. For example, if a dog in an angry state of mind displays a fixed stare, walks tall, and holds its tail stiff and upright, a dog in a placid state of mind will not look intently, crouch, and lower and wag its tail. Finally, according to the principle of the *direct action of the nervous system*, some emotional expressions are the direct result of the excitation of the nervous system. Darwin cites as examples the "trembling of the muscles, the sweating of the skin, the modified secretions of the alimentary canal and glands" (Darwin 1872/1965, p. 81).

Dewey (1894) notes that Darwin's theory of expressions is incompatible with James's theory of emotions. According to James, an emotion emerges once an expression (and other bodily changes) is perceived: the agent first bares his or her teeth, and then anger ensues. According to Darwin, the emotion comes first, and the expression follows: the agent first gets angry, and then the teeth are bared as a means of expressing anger. Dewey makes two main suggestions to improve upon both accounts and make them compatible.

In opposition to Darwin, Dewey rejects the view that we should "start from the emotion and attempt to derive the movements as its expression" (1894, p. 564). Expression for Dewey only makes sense from the point of view of the observer, which takes facial and postural movements to be *signs* of the emotion. Since Darwin's principles do not assume that being a sign of emotion relative to an observer explains the origin of the sign, Dewey suggests focusing on facial movements *qua* movements, and explore how such movements relate to practical ends.[12] As Dewey notes, in the case of serviceable associated habits the "principle of explanation *actually* used . . . is that of survival . . . of acts originally useful not *qua* expressing emotion, but *qua* acts—as serving life" (p. 555, emphasis in original).

The principle of antithesis poses a bigger challenge, because movements are alleged to have emerged simply because they are opposite of movements that used to be serviceable, without having been serviceable themselves. Dewey rejects this interpretation, because it turns antithesis into a mysterious causal force. As an alternative, Dewey argues that the movements Darwin proposes to explain through the principle of antithesis can also be explained in light of the practical ends they serve. For example, he suggests that the movements of a dog in a placid state of mind were serviceable because they helped the dog receive "favor and food" from the master. Dewey acknowledges that the kinds of facial movements Darwin explained through the principle of direct discharge are a "breakdown of . . . teleological coordination" (p. 560), thereby allowing for exceptions to the rule that facial movements must be serviceable as portions of some useful activity.

The second suggestion, contra James, is to stop thinking of emotions merely in terms of how they feel, and construe them instead as "modes of behavior." As Dewey puts it, emotions "are too important and too relevant in our lives to be in the main . . . the 'feel' of bodily attitudes which have themselves no meaning" (1894, p. 563). For Dewey, an emotion "in its entirety" is "a mode of behavior which is purposive" (an idea Dewey gets from his revision of Darwin) and "which also reflects itself into feeling" (an idea Dewey gets from his revision of James; Dewey, 1895, p. 15).

Since James focuses only on the phenomenological dimension of emotions while neglecting the teleological one, Dewey concludes that James never intended to deal with "emotion as a concrete whole of experience, but with an abstraction from the actual emotion of that element which gives it its differentia—its feeling *quale*" (1895, p. 16). This interpretation allows Dewey to remove from

James's theory its "paradoxical air." When James tells us that "we feel sorry because we cry, angry because we strike, afraid because we tremble," Dewey points out, "the very statement brings out the idea of *feeling* sorry, not of *being* sorry" (p. 15). But when we say that someone is sorry or angry or afraid, Dewey continues, "we do not simply, or even chiefly, mean that [such person] has a certain 'feel' occupying his consciousness." Rather, "[w]e mean he is in a certain practical attitude, has assumed a readiness to act in certain ways" (pp. 16–17).

Dewey adds that there is yet another important element in emotions, besides feelings and modes of behavior, namely, the "'object' or intellectual content" of the emotion, which is "always 'about' or 'toward' something" (1895, p. 17)—for instance, an episode of fear may be about a frightening bear. But Dewey emphasizes that "the mode of behavior is the primary thing," in the sense that it "carrie[s] with it the—concept of the bear as a thing to be acted towards in a certain way, and of the 'feel' of our reaction" (p. 24). This is to say that the mode of behavior of running away from a bear at the same time endows the bear with the property of being an object to be run away from, and it generates the feeling of fear.

McDougall, Shand, and the Emergence of Evolutionary Accounts

The *impulsivist approach* was further articulated by William McDougall in *An Introduction to Social Psychology* (1908/2001) and by Alexander Shand in *The Foundations of Character* (1920 see also Stout, 1899; Mead, 1934; Young, 1943; Leeper, 1948; Bull, 1951). These two monographs share the distinction of being the first book-length accounts to characterize emotions as evolutionary adaptations selected for their ability to motivate behavior toward ends.

McDougall and Shand reaffirm the tight connection between emotions and instincts already proposed by James and Dewey, but formulate two different accounts of how emotions and instincts relate. Shand argues that instincts are subordinate to emotions, which are "penetrated throughout by an impulse" (1920, p. 179) that organizes the instincts and directs them to an end (e.g., the instincts of flight and concealment are directed by fear toward protection from danger). Shand adds that, as we "cannot understand the organs of the body without a knowledge of their functions," so we cannot understand "the emotions without a knowledge of their ends" (p. 197). He singles out six primary emotions (fear, anger, disgust, curiosity, joy, and sorrow), and describes them in ways that are very reminiscent of contemporary accounts of basic emotions (Ekman, 1999): they appear early in ontogeny, they are present in animals, they are independent of other emotions, they can be evoked by innate stimuli, and they are manifested in instinctive behaviors.

McDougall (1908/2001) understands emotions as "emotional excitement[s] of specific quality" that emerge as a result of the operation of instincts already "directed to some particular mode of action" (p. 285; e.g., fear is the emotional excitement associated with the instinct to flee, which is directed toward protection from danger). For McDougall, there are seven primary emotions (fear, anger, tender-emotion, disgust, positive self-feeling, negative self-feeling, and wonder) and they are primary because they are the "immediate inevitable result and subjective expression of the excitement of an instinct, an innate disposition specifically directed to some particular mode of action" (p. 285). McDougall (1923, pp. 316–317) eventually distinguishes between a broad and narrow meaning of "emotion." According to the narrow meaning, the emotion is the feeling; according to the broad meaning, the emotion is the complete instinctive process.

The relevance of the pioneering efforts of McDougall and Shand is that they added an evolutionary dimension to the *motivational tradition* and opened the door for functionalist accounts of emotions, which characterize emotions not just in terms of their diagnostic features but also in terms of the evolutionary problems they solve. This research program came to maturity with the emergence of basic emotion theory in the 1970s (see the section "Contemporary Developments I: Basic Emotion Theory and Social Constructionism").

The Behaviorist Detour: Emotions as Behavior Patterns

Behaviorism dominated psychology roughly from the second decade of the 20th century to the cognitive science revolution in the 1960s (see Bechtel, Abrahamsen, & Graham, 1998). Its core commitment was that psychology is the science of behavior rather than the science of consciousness. As a result, psychology should change its methodology, and replace introspection of conscious states with observation of behaviors. In the initial phase of behaviorism, it was assumed that facts of behavior can be wholly explained without invoking internal psychological processes. This is the sort of behaviorism championed for instance by John B.

Watson, the first pioneer of *classical behaviorism*, and by B. F. Skinner, arguably the most influential developer of the research program and the father of what came to be known as *radical behaviorism*.

In the later *neo-behaviorist* phase of the movement, behaviorists like Edward Tolman and Clark Hull rejected the blanket opposition to internal states advocated by classical and radical behaviorists, and allowed the positing of internal states understood as "intervening variables" that mediate the stimulus–response connection (see, e.g., Mowrer, 1947; Miller, 1951, for a neo-behaviorist analysis of emotions as motivations). Behaviorism also had a philosophical wing focused on the meaning of mental terms (*analytical behaviorism*). This variety of behaviorism, best represented by Gilbert Ryle's (1949/2009) work, held that sentences ascribing mental states can be translated into sentences ascribing behavioral dispositions (see also Carnap, 1959; Hempel, 1935/1980; Wittgenstein, 1953).

Although I am including all behaviorist accounts within the *motivational tradition*, it is clear that classical and radical behaviorism are at best *sui generis* members of the tradition because of their staunch opposition to internal states. The rationale for including not only neo-behaviorism but classical and radical behaviorism as well into the *motivational tradition* is that even ruthlessly anti-mentalistic theories such as the ones offered by Watson and Skinner tried to identify emotions with behavior patterns, which is what motivational states predispose one to. It consequently seems fitting to consider such theories closer to the *motivational tradition* than to either the *feeling tradition* or the *evaluative tradition*.

With these caveats in mind, we can distinguish two approaches to the study of emotions within behaviorism. The *reflexivist approach*, paradigmatically associated with Watson, identifies emotions with reflexive behavioral patterns (on a broad interpretation of what counts as behavior). The *impulsivist approach*, best exemplified by the convergent work of Ryle and Skinner, identifies emotions with, respectively, behavioral dispositions or changes in the probabilities of operant behaviors.

According to Watson, emotion is a "hereditary 'pattern-reaction' involving profound changes in the bodily mechanism as a whole, but particularly of the visceral and glandular systems. By pattern reaction we mean that the separate details of response appear with some constancy, with some regularity, and in approximately the same sequential order each time the exciting stimulus is presented" (1919a, p. 195). In this model, emotions are inherited physiological pattern reactions, which are basically Jamesian emotions without the attendant feelings. Watson contrasts reflexive *emotional* reactions with *instinctive* reactions, which are not "internal and confined to the subject's body" but lead to "adjustment of the organism as a whole to objects" (p. 197). Watson therefore limits the notion of emotional behavior in two important ways: the "behavior" consists primarily of physiological changes (but see below), and such changes are reflexive in nature.

The problem Watson had to face is that emotions in adults rarely if ever manifest such distinctive physiological patterns. So he focused on the emotions of infants, for which he thought reflexive patterns are more easily detectable. Watson distinguishes between three emotional stimulus–response patterns allegedly present in infants: fear, rage, and love, where love is understood "in approximately the same sense that Freud uses sex" (1919a, p. 199). He proposes that all kinds of adult emotions result from infant fear, rage, and love through complex processes of classical conditioning, although his suggestions on this point remained very vague.

For example, fear in an infant is the pattern of responding to loud sounds and loss of support with the unconditioned emotional responses of "catching of the breath, clutching randomly with the hands (the grasping reflex invariably appearing when the child is dropped), blinking of the eyelids, puckering of the lips . . . crying" (1919b, p. 170). Rage is the pattern of responding to restraint with "crying . . . quickly followed by screaming . . . [while] the body stiffens and . . . slashing or striking movements of the hands and arms result; the feet and legs are drawn up and down; the breath is held" (p. 170). Love is the pattern of responding to the striking of the skin or sex organs or to patting and rocking with "a smile . . . attempts at gurgling, cooing" (p. 171).

But Watson is not entirely consistent on limiting emotional reactions to physiological changes. For example, he tells us that in "older children" the reactions of fear include "flight and hiding" (1919b, p. 170), those of rage include "kicking, slapping, and pushing" (p. 171), and those of love include "the extension of the arms which we should class as the forerunner of the embrace" (p. 171). This enlargement in the scope of behavior beyond mere physiological changes was brought to fruition by other behaviorists, who included physical actions in the class of emotional behaviors, and abandoned the assumption that such reactions had to be reflexive.

Whereas Watson acknowledges that ordinary emotion terms refer to mental states (feelings) but argues that psychology, if it wants to be a true science, must redefine emotions in terms of behaviors and the stimuli that cause them (Watson 1913, 1919a), philosophical behaviorists like Ryle (1949/2009) argue that a close study of emotion ascriptions in ordinary language reveals that emotion terms in most cases do not refer to feelings at all, but rather to dispositions to behave. This claim, which Ryle generalizes to all mental state ascriptions, becomes the centerpiece of his attack on Cartesian dualism, grounded in the idea that the language of mental states does not (at least not primarily) refer to a realm of private mental occurrences.

To have a disposition, Ryle (1949/2009, p. 31) tells us, "is not to be in a particular state, or to undergo a particular change; it is to be bound or liable to be in a particular state, or to undergo a particular change, when a particular condition is realized." The dispositions to which (most) emotion terms refer, Ryle emphasizes, are "indefinitely-heterogeneous," in the sense that they have an open range of manifestations of different kinds.[13] For example, "When Jane Austen wished to show the specific kind of pride which characterized the heroine of 'Pride and Prejudice,' she had to represent her actions . . . thoughts and feelings in a thousand different situations" (p. 32). Being proud involves being disposed to engage in actions like rejecting an invitation from someone who slighted us in the past, in thoughts like reminiscing about one's own successes, in painful feelings when one is snubbed, plus innumerable other manifestations depending on the circumstances. On this view, describing a person as proud is not saying that he or she is having a feeling (or any other kind of occurrent mental state), but that he or she is disposed to engage in an open range of actions, thoughts, and feelings.[14]

Skinner (1953, 1957) offers an account of emotions that combines reflexivist and impulsivist elements. He suggests that emotions either consist of behavioral reflexes or behavioral dispositions, where the latter are understood as "change[s] in probability that the organism will behave in a given way" (1957, p. 158). For example, a stimulus can either elicit "the emotional reflex pattern of anger" or "a predisposition to attack someone," which amounts to an increase in the "probability of abusive, bitter, or other aggressive behavior" and a "decrease [in] the probability of generous or helpful behaviour" (1957, p. 215). The behaviors to which emotions predispose are operant behaviors, that is "active behaviors that *operate* upon the environment to generate consequences" (1953, p. 65, emphasis in original). In another reminder of the fact that classical and radical behaviorists belong to the motivational tradition only in an "inverted commas sense," Skinner concludes by describing the emotions as "excellent examples of the fictional causes to which we commonly attribute behavior" (1953, p. 160).

Behaviorism collapsed as a research program in the 1950s. Already in the 1920s and 1930s psychologists such as Edward C. Tolman and Wolfgang Köhler had argued against the stimulus–response paradigm for its dismissal of intervening variables, pointing out that the mentalistic notion of *purpose* was constitutive of the very notion of behavior. However, the nail in the coffin of behaviorism came with an influential review of Skinner's (1957) *Verbal Behavior* by Chomsky (1959), who argued that "verbal behavior" (i.e., the production of speech) cannot be explained without reference to the mental mechanisms generating it, more specifically to a "mental grammar" (a set of rules that specify syntactically correct utterances). Chomsky's critique of Skinner generalizes to all behaviors that were the focus of behaviorist psychology: it seems impossible even to characterize behaviors as being of the same kind without making at least implicit assumptions about the mental states and processes that cause them (e.g., intentions).

Contemporary Developments I: Basic Emotion Theory and Social Constructionism

Following the demise of behaviorism, the *motivational tradition* was soon revived by several authors, in particular by Robert Plutchik (1962, 1970; Plutchik & Kellerman, 1980), who proposed an emotion theory rather similar to that of McDougall, as well as by other psychologists such as Silvan Tomkins (1962–1992/2008), Paul Ekman (1980, 1992a, 1992b, 1994, 1999, 2003; see also Ekman & Friesen, 1969), and Carrol Izard (1969, 1971, 1977, 1980, 1992).

Tomkins offers a theory of *affects* intended to show that "the primary motivational system is the affective system," whereas "the biological drives have motivational impact only when amplified by the affective system" (2008, p. 4). Tomkins suggests that the motivational power of affects comes from their feeling pleasurable or painful. His core assumption is that such hedonic feelings emerge from the perception of facial changes providing "motivating feed-back."

Reminiscent of James, Tomkins claims that "affect is primarily facial behavior [and] [s]econdarily bodily behavior, outer skeletal and inner visceral behavior" (2008, p. 114). These behaviors, Tomkins proposes, are organized by subcortical *affect programs*, which evolved partly because the facial behaviors they produce are communicative. Note that this is an important departure from Darwin's (1872/1965) original proposal that facial changes are vestiges of serviceable actions that did not evolve in order to communicate.

The task of providing empirical evidence for the claim that affects are associated with distinctive facial expressions was left largely to Ekman and Izard, who were then Tomkins's students and developed contemporary basic emotion theory. Basic emotion theory's core commitment is that basic emotions are solutions to recurrent evolutionary tasks: "each basic emotion prompts us in a direction that, in the course of our evolution, has done better than other solutions in recurring circumstances that are relevant to our goals" (Ekman & Cordaro, 2011, p. 364).

This is an idea that, although already present in Shand and McDougall, became especially prominent in emotion theory with Plutchik's (1970) work. "In order to provide a general definition of emotion," Plutchik argued, "we need to use the functional or adaptational language." On his view, "an emotion is a patterned bodily reaction of either protection, destruction, reproduction, deprivation, incorporation, rejection, exploration or orientation, or some combination of these, which is brought about by a stimulus" (p. 12). These eight biological functions individuate Plutchik's eight primary emotions (fear, anger, joy, sadness, acceptance, disgust, anticipation, and surprise), from which all other emotions can be derived as "all colors can be considered to result from a mixture of just a few primary colors" (p. 9).

Ekman (1980, 1992, 1994) further develops the idea that emotions must be defined in adaptationist terms, and starts referring to a subset of the emotions we distinguish in folk psychology (happiness, sadness, anger, fear, disgust, and surprise) as *basic emotions*, to emphasize that he regards them (or more precisely, the mechanisms that underlie them) as "biologically basic"—that is, as domain-specific evolutionary adaptations. Over time, Ekman expands the roster of basic emotions, suggesting that evidence of biological basicness is likely to also be found for amusement, contempt, embarrassment, excitement, guilt, pride in achievement, relief, satisfaction, sensory pleasure, and shame (Ekman & Cordaro, 2011).

But Ekman (1999) also adds, "I do not allow for 'non-basic' emotions" (p. 57), implying that he is unwilling to regard anything as an emotion if its generating mechanisms did not develop during evolutionary time as a solution to a fundamental life task. Accordingly, other items commonly called "emotions" in folk psychology are reclassified by Ekman as belonging to other psychological categories that, while having affinities to emotions, are not themselves emotions. These other categories include "emotional plots" (e.g., love), moods (e.g., depression), and affective personality traits (e.g., hostility).

To illustrate his understanding of evolutionary life tasks, Ekman (1992b) started relying on evolutionary psychologists Tooby and Cosmides, who give the following examples: "fighting, falling in love, escaping predators, confronting sexual infidelity, experiencing a failure-driven loss in status, responding to the death of a family member" (Tooby & Cosmides, 2008, p. 117; see also Keltner & Haidt, 2001). Besides being defined as domain-specific evolutionary adaptations, basic emotions are associated by Ekman with 11 diagnostic characteristics. They include distinctive universal signals, distinctive physiology, automatic appraisals tuned to distinctive universals in antecedent events, distinctive developmental appearance, presence in other primates, quick onset, brief duration, unbidden occurrence, distinctive thoughts, memories and images, and distinctive subjective experiences (Ekman 1999).[15] However, with the possible exception of distinctive universal signals, none of these characteristics is deemed to be a necessary feature of a basic emotion (see, e.g., Russell, Bachorowski, & Fernández-Dols, 2003; Matsumoto, Keltner, Shiota, Frank, & O'Sullivan, 2008; Cordaro, Fridlund, Keltner, Russell, & Scarantino, 2015, for a summary of the debate on facial expressions).

Ekman's crucial assumption is that, as soon as the basic emotion program is activated, a "cascade of changes (without our choice or immediate awareness) occurs in split seconds in: the emotional signals in the face and voice; preset actions; learned actions; the autonomic nervous system activity that regulates our body; the regulatory patterns that continuously modify our behavior; the retrieval of relevant memories and expectations; and how we interpret what is happening within us and in the world" (Ekman & Cordaro, 2011, p. 366).

These changes, Ekman emphasizes, are "inescapable," in the sense that "the instructions in the affect programs run until they have been executed" (Ekman & Cordaro, 2011, p. 367). Although the list of behaviors activated is broader than the list invoked by Watson, the assumption of inescapability makes Ekman a member of the reflexivist strand of the motivational tradition. This connection must be qualified, however, because Ekman explicitly denies that basic emotions are full-fledged reflexes. This qualification emerges in his discussion of the difference between surprise (a basic emotion) and startle (a physical reflex; Ekman, Friesen, & Simons, 1985). Ekman tells us that reflexes such as startle, unlike emotions such as surprise, are easy to elicit, are shown reliably by every subject, cannot be totally inhibited, and cannot be simulated with the correct latency.

Yet, the differences posited by Ekman are differences of degree rather than kind. The inescapable responses activated by affect programs are reflex-like, as they manifest the very features singled out by Watson in his description of emotional reflexes: they "appear with some constancy, with some regularity and in approximately the same sequential order each time the exciting stimulus is presented" (Watson, 1919a, p. 195). An important qualification is that, in the case of basic emotions, an *appraisal process* mediates between the stimulus and the cascade of responses, which for Ekman follow inescapably only after the stimulus is appraised as exciting. A corollary is that in the case of basic emotions, unlike in the case of physical reflexes, a stimulus that elicits a basic emotion in one subject may not elicit it in another due to differences in the appraisal processes.

In addition, Ekman makes it clear that the inhibition of basic emotions is never complete, from which it follows that neither full-fledged reflexes nor basic emotions can be totally inhibited. Rather, the cascade of inescapable behavioral changes can be *regulated* after it has occurred, with a swiftness that depends on the feature under consideration. Facial changes, Ekman suggests, can be regulated within less than a second. But "the changes in our respiration, perspiration, and cardiac activity . . . have a longer time line, some stretching out to 10 or 15 seconds" (Ekman & Cordaro, 2011, p. 367), during which they cannot be interrupted.[16]

This assumption—that basic emotions are associated with an inescapable cascade of bodily changes—has been heavily criticized by psychological constructionists, who have pointed out that the empirical evidence does not support it (Russell, 2003; Barrett, 2006). Specifically, psychological constructions have argued that, contrary to what the hypothesis of an inescapable cascade of changes would predict, there is no one-to-one correspondence between anger, fear, happiness, sadness, or any other basic emotion, and any neurobiological, physiological, expressive, behavioral, or phenomenological responses, and that such diagnostic markers are not strongly correlated with one another. This variability, psychological constructionists conclude, calls into question the very idea that "emotions have ontological status as causal entities [and that they] exist in the brain or body and cause changes in sensory, perceptual, motor, and physiological outputs" (Barrett, 2005). As we have seen in the section "Contemporary Developments: Neo-Jamesianism and Psychological Constructionism," skepticism about the causal powers of emotions has motivated emergent models of emotions, according to which emotions are the effects of changes in sensory, perceptual, motor, and physiological outputs, rather than their causes (Coan & Gonzalez, 2015).

The social constructionist approach found its first advocates in the 1920s, 1930s, and 1940s, when a number of anthropologists and social scientists started questioning Darwin's (1872/1965) evidence for the universality of emotional expressions (e.g., Allport, 1924; Landis, 1924; Klineberg, 1940). These researchers initiated what we may call the "cultural variability" strand of social constructionism, related to the thesis that emotions are different in several essential respects in different cultures. These differences have since been shown with respect to both the emotion lexicon (e.g., Russell, 1991; Wierzbicka, 1999) and the diagnostic features of emotions (Mesquita & Frijda, 1992), which vary to some extent across cultures.

The strand of social constructionism that is more germane to the *motivational tradition* is the "social role" strand, related to the thesis that emotions fulfill social functions by virtue of which they should be considered actions or roles or moves rather than passions.[17] Jean Paul Sartre (Sartre & Frechtman, 1948) can be considered the first to offer a general, although idiosyncratic, theory of emotions as social roles, a view further developed in the early 1980s by philosophers (e.g., Harré, 1986; Armon-Jones, 1986), psychologists (e.g., Averill, 1980), and anthropologists (e.g., Lutz, 1980). In recent times, Parkinson (1995, 2008, 2009), Parkinson, Fischer, and Manstead (2005), Griffiths (2004b), Mesquita and Boiger (2014), and Van Kleef (2009) and others have developed sophisticated social constructionist proposals that add to the social constructionist approach themes from the evolutionary tradition.

Sartre argues that an emotion is "an organized system of means aiming at an end" (Sartre & Frechtman, 1948, p. 32). This "finality" gives emotions their significance and it is what physiological accounts in the style of James miss out on, because "physiological facts . . . taken by themselves and in isolation . . . signify almost nothing" (p. 17). What distinguishes emotions from straightforward actions is for Sartre the way they go about fulfilling their ends: they do so in a *masked* or *covert* fashion. As Sartre puts it, "[emotion] is called upon to mask, substitute for, and reject behavior that one cannot or does not want to maintain. By the same token, the explanation of the diversity of emotions becomes easy; they represent a particular subterfuge, a special trick, each one of them being a different means of eluding a difficulty" (p. 32). Sartre's central idea is that we emote when the opportunity to pursue our ends in nonemotional ways turns out to be unavailable or unappealing. On this view, we emote by substituting a behavior that is openly instrumental with one that is covertly instrumental. Emotion researchers have since explored this Machiavellian aspect of emotions from a variety of research perspectives (e.g., Frank, 1988; Solomon, 1980; Griffiths & Scarantino, 2009; Slaby & Wüschner, 2014).

The idea that emotions are covertly instrumental was further developed within the social constructionist camp by Averill, who argues that "an emotion is a transitory social role (a socially constituted syndrome) that includes an individual's appraisal of the situation, and is interpreted as a passion rather than as an action" (1980, p. 139). The idea here is that emotions are means of resolving conflicts among norms at the social level, and they do so in part because of the widely shared Aristotelian assumption that we are overcome by our passions. This is what Averill calls the "myth of passions," a self-deceiving assumption that comes from having "limited self-awareness" about the social functions of emotions (see also Peters, 1962). For example, Averill tells us that anger is a way to solve the conflict between societal norms that prohibit violence, and societal norms that demand protection of one's own rights from wrongdoers. By being "overcome" by anger, individuals manage to protect their rights by inflicting violence, and they are justified in doing so because they inflict violence while being acted upon by a passion that partially suspends responsibility (Averill, 1980, p. 66).

In more recent times, social constructionism has shifted from an understanding of emotions as solutions to *social-level* problems to an understanding of emotions as solutions to *interpersonal* problems. These efforts are inspired in part by influential work on the strategic dimension of emotional expressions by Fridlund (1994), Russell (1997), Fernández-Dols and Carroll (1997), and Fernández-Dols and Ruiz-Belda (1997) among others. Parkinson (1995) states for instance that "many of the occasions for emotion arise from local negotiations in the course of everyday personal interaction and do not directly reflect societally prescribed norms" (p. 162). On this view, anger is not a solution to a conflict between societal norms but a solution to a local problem of negotiation between parties who are interfering with each other's goals. The social transaction relies on emotional expressions that convey assessments (you are to blame) and behavioral intentions (I will hurt you unless you stop). This shift from the societal to the interpersonal is accompanied by a new attention to the dynamic unfolding of emotions, understood as open-ended interactive processes in which emotional responses are not preordained at the beginning of the sequence, but rather shaped over time by each interactant's ongoing responses.

Contemporary Developments II: Motivational Theories of Emotions

The *impulsivist approach* has been further articulated by Nico Frijda (1986, 2007, 2010), who has described emotions as "modes of relational action readiness, either in the form of tendencies to establish, maintain, or disrupt a relationship with the environment or in the form of mode of relational readiness as such" (1986, p. 71; see also Frijda, Ridderinkhof, & Rietveld, 2014; Ridderinkhof, 2014). The first mode of *relational action readiness* is that of an *action tendency*, which is a state of readiness "to execute a given kind of action." What *kind* of action it is will depend on what *kind* of "end result" is being pursued. For example, fear is associated with the action tendency of "avoidance," characterized by the end of achieving one's "own inaccessibility" with respect to a certain stimulus. Disgust is associated with the action tendency of "rejecting," characterized by the end of "removal of object."

States of "readiness as such," the second variety of modes of relational action readiness, come in two flavors: "null states" and "activation modes." According to Frijda (1986), sadness is a *relational null state* [emphasis added], namely, a state of "explicit absence of relational activity" (p. 22). Joy, on the other hand, is the "manifestation of *free activation* [emphasis added]" (p. 38). Frijda emphasizes that "null states, activation modes, and action tendencies proper . . . all are modifications of action tendency in a general sense: they all represent modes of readiness, unreadiness included, for relational action" (p. 71).

Frijda's (1986) most distinctive contribution is his claim that emotions should be identified not just with generic states of action readiness but with states of action readiness that have *control precedence*. Emotion, he tells us, "has action control precedence in two senses." First, "it can interrupt other processes and block access to action control for other stimuli and other goals." Second, "it invigorates action for which it reserves control and invests that control with the property of indistrability or persistence" (p. 460).

Scarantino (2014) has developed a self-described "motivational theory of emotions" that is in many ways similar to Frijda's own, but is more closely integrated with basic emotion theory, and, most importantly, includes a theory of intentionality suitable for motivational theories. On Scarantino's view, emotion systems are behavioral programs that are flexible on the input and output sides, and provide solutions to recurrent evolutionary problems in the form of "motive states" with control precedence—namely, states of readiness to achieve a prioritized goal while allowing for some degree of rational control.

Emotion episodes correspond to the activations of such programs. Such episodes are shaped over time by the interaction between prioritized modes of action readiness (a domain-specific adaptation) and rational control (a domain-general capacity). This interaction can lead either to the inhibition of the action readiness or to its variable and context-dependent manifestation.

This proposal aims to combine two insights: (1) the idea that (a great many) emotions are evolved solutions to fundamental life tasks, and (2) the idea that the distinctive design advantage of emotions stems from their ability to combine speed and flexibility of execution. Scarantino (2015) argues that basic emotion theory in its traditional, Ekman-inspired formulations only heeds to the first insight while neglecting the second.

As a result, a fundamental tension is created within the research program, because it makes little evolutionary sense to assume both that basic emotions are solutions to abstract problems like avoiding dangers or removing obstacles and that they elicit responses in a reflex-like fashion (see also Scarantino & Griffiths, 2011).

This is because abstract problems like avoiding dangers or removing obstacles require different adaptive responses in different circumstances. To account for this fact, the traditional assumption that affect programs activate a cascade of inescapable responses (Traditional BET) must be replaced by the assumption that they inescapably activate "motive states" with control precedence (the New BET; Scarantino, 2015).

A motive state is a goal-oriented "general direction for behavior [that operates] by selectively potentiating coherent sets of behavioral options" (Gallistel, 1980, p. 322; see also Morgan, 1957; Pacherie, 2001). The determination of which behavioral option, if any, is ultimately chosen is left to rational control, which operates under the constraints of urgency and limited informational access that define control precedence.

In addition, Scarantino (2014) argues that emotion systems can have intentionality, or the capacity to represent, by virtue of their functions. The background philosophical theory of representation being assumed here is *teleosemantics*, according to which traits represent what they have the function of indicating (Dretske, 1988; Prinz, 2004b). On this view, the fly detection system in a frog represents flies or edible objects because it has the function of indicating them. By the same token, fear represents danger because it has the function of selectively potentiating avoidance options in the presence of danger. Similarly, anger represents slights because it has the function of selectively potentiating attack options in the presence of slights (see Scarantino, 2014, 2015, for further examples and discussion).

Some Challenges for the Motivational Tradition

While the *motivational tradition* continues to influence the contemporary emotion debate in the ways described and others, it faces its own share of problem cases. Some critics have questioned whether defining emotions as modes of behavior, or states of action readiness, can solve the problem of differentiation. As Bedford (1957, p. 84) puts it, "the same, or similar, behavior, can be differently, yet correctly, interpreted in different circumstances, for example as anger, indignation, annoyance, exasperation, or resentment." The idea, once again, is that behaviors are not sufficiently fine grained to distinguish among different emotions. This problem is especially biting for the *reflexivist approach*, which is committed to the assumption that behavioral responses are reflex-like, but has failed to marshal convincing evidence for the existence of biobehavioral signatures for different discrete emotions.

But the problem also affects the *impulsivist approach*, which faces a variety of potential counterexamples to the claim that any two emotions are differentiated by the action tendencies they involve. First, many emotions do not appear to motivate actions at all. Grief and depression, for example, seem to involve a general depotentiation of the will to act. Second, regarding "backward-looking" emotions like regret, it is unclear which action tendency they could elicit, because they focus on what happened in the past, which cannot be changed. Third, emotions like existential joy involve the selective potentiation of behavioral options, but the range of these options is so wide that it is difficult to pinpoint which action tendency is associated with them. Fourth, it seems possible for the same action tendency to be associated with different emotions (e.g., avoidance may be associated with both anger and unrequited love), and for different action tendencies to be associated with the same emotion (approach and avoidance may both be associated with anger), provided such tendencies are described at a sufficiently abstract level of analysis.

One option for dealing with some of these problem cases, as mentioned before, is the one suggested by Frijda (1986), who introduced the hypothesis of modes of "relational readiness as such." Frijda's proposal can in principle take care of the cases of grief and depression, arguably associated with a "null state" and existential joy, arguably associated with a state of "free activation." A second option is to include mental actions along with physical actions. Depression and regret may lack distinctive physical action tendencies, but they appear to be associated with distinctive mental action tendencies that have control precedence. For example, one of the symptoms of depression is compulsive mental rumination, and regret is strongly associated with a tendency to counterfactually think about what would have happened had one made different choices. A third option is to allow multiple action tendencies to be comprised within the same emotion, as proposed in Frijda and Parrott's (2011) recent theory of action tendencies as universal and biologically based *ur-emotions*. Whether or not a combination of these proposals can solve the problem of differentiation remains to be seen (see, e.g., Reisenzein, 1996; Prinz, 2004b; Tappolet, 2010; Eder & Rothermund, 2013, for critiques of motivational approaches).

The other significant liability for the *motivational tradition* is that in many of its versions it does not solve the problem of intentionality (but see Scarantino, 2014). If fear were simply a tendency to avoid, why would it be inappropriate in the absence of danger? If anger were simply a tendency to remove obstacles, why would it be inappropriate in the absence of a slight? And in what sense would fear and anger be about objects, if they were merely modes of behavior? Answering these questions requires giving evaluations a more central role in the identification of emotions, since evaluations seem to be precisely the sorts of things that are about objects and can be appropriate and inappropriate with respect to them.

These problems led the *motivational tradition* to lose ground in the 1960s and 1970s in favor of the *evaluative tradition*. The transition from one research tradition to the other was facilitated by the general shift in the understanding of minds ushered in by the cognitive revolution, which replaced the understanding of mind as behavior proposed by behaviorism with a new understanding of mind as a computer that processes information according to rules. The cognitive revolution made internal cognitive states and processes respectable again, and sent emotion theorists in search of alternatives to both behaviorist theories and feeling theories of emotions.

The Evaluative Tradition

The *evaluative tradition* holds that emotions are essentially distinguished from one another by the evaluations they involve, where an evaluation is a cognition, or an interpretation, or a judgment, or a thought, or a construal or some other kind of mental representation of the eliciting circumstances. I distinguish between two approaches within the *evaluative tradition*: the *constitutive approach*, which takes emotions to *be* evaluations of a distinctive type, and the *causal approach*, which takes emotions to be *caused by* evaluations of a distinctive type (always or typically; see Figure 1.4).

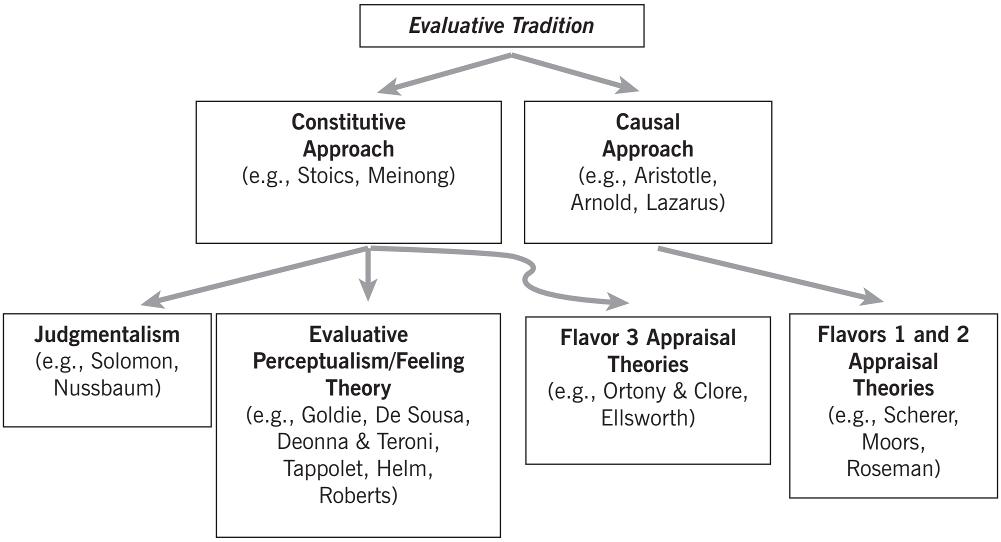

FIGURE 1.4. The *evaluative tradition* and some related contemporary developments.

The two approaches are often conflated, but they differ in their historical origins, objectives, and implications. Importantly, only the *constitutive approach* is a direct competitor of the *feeling* and *motivational traditions*. The *causal approach*, on the other hand, is at least in principle compatible with the idea that emotions are essentially feelings or motivations, because it only claims that emotions are caused by evaluations while (at least potentially) remaining agnostic on what emotions are. I illustrate some highlights from the history of the *evaluative tradition*, and then discuss some related contemporary developments, most significantly the transition from judgmentalism to other evaluative research programs in philosophy, and the emergence of appraisal theories in psychology.

The Stoics on the Passions

The *constitutive approach* has attracted most of the work in recent philosophy of emotions, and it has its roots in the Stoic theory of the passions. Although Stoicism offered a variety of views on the nature of emotions, what we now call the Stoic theory of the passions is the theory of emotions introduced by Chrysippus, the third head of the Stoic school of Athens (ca. 206 BC), and prominently defended by the Roman Stoic Seneca (4 BC–65 AD; see Sorabji, 2000). According to Chrysippus, passions are false judgments of appropriateness, a position that clearly identifies emotions with evaluations of a special type—namely, judgments.

The Stoics understood judgments as assents to impressions (*phantasiai*), and assumed that the capacity to give assent requires reason, which emerges in humans at age 14 and is not available to nonhuman animals. Unlike judgments, impressions do not require reason. An impression is that by virtue of which the world *appears to be a certain way*, prior to, and in potential opposition with, what one judges the world to be like. Chrysippus distinguishes between two forms of assent involved in undergoing a passion. First, the assent to the impression that something good or bad is happening or will happen, and second, the assent to the impression that it is appropriate to react in a certain way.

According to Chrysippus, there are four primary passions: distress (*lupe*), pleasure (*hedone*), fear (*phobos*), and appetite (*epithumia*). All other passions are subspecies of the four primary ones. Sorabji (2000) describes the primary passions as follows:

> Distress is the judgment that there is bad at hand and that it is appropriate to feel a sinking. Pleasure is the judgment that there is good at hand and that it is appropriate to feel an expansion. Fear is the judgment that there is a bad at hand and that it is appropriate to avoid it. Appetite is the judgment that there is good at hand and that it is appropriate to reach for it. (p. 30)

On this view, what is judged to be appropriate to the goodness or badness at hand are what the Stoics called *movements of the soul*, which are either bodily changes (sinking or expansion, as in the case of distress and pleasure) or action tendencies (avoiding and reaching, as in the case of fear and appetite). This indicates that the Stoics made room for diagnostic features other than evaluations, but also that they held a very peculiar notion of passion, because they assimilated having a passion with engaging in a complex evaluative judgment to the effect that something is good/bad and it is appropriate to reach for it/avoid it.

Suppose you detect a tiger, start trembling, manifest increased heart rate, develop an impulse to flee, and have feelings associated with such bodily changes and action tendency. On all theories of emotions we have considered so far, under such circumstances you would be afraid. Not so on the Stoic theory: you are not afraid as long as you do not judge avoiding getting mauled by the tiger to be good. And you should not do so, the Stoics added, because judging avoiding getting mauled by the tiger to be good would amount to considering your own life and health to be good. Nothing for the Stoics is good or bad except the presence or absence of a virtuous character. Alleged goods like life, health, wealth, honor, power, beauty, and strength, and alleged bads like death, disease, poverty, dishonor, powerlessness, ugliness, and weakness are in reality "indifferents," because they are not good or bad in all circumstances and whether we obtain or avoid them is not in our power.

The Stoic sage selects appropriately and virtuously among the indifferents, aiming at things such as health, or honor, or the well-being of one's friends. But the sage never thinks that goodness or badness are at stake in achieving the aims of these actions, so he or she reaches a state of *apatheia*, or freedom from the passions. Since the passions consist of erroneously judging these indifferents as being good or bad, they should be avoided.[18]

The Stoic doctrine of *apatheia* has exerted a major influence on debates on the value of emotions ever since, but the doctrine of emotions as evaluations was much less influential until recently, and even some of its sympathizers misrepresented it throughout the centuries (Sorabji, 2000, pp. 375–384). There were of course exceptions, constituted by theorists who, at various historical junctures, tried to understand emotions in more "cognitive" terms. A prominent example of a Stoic-inspired theory that gives pride of place to "ideas" in the identification of emotions is Baruch Spinoza's (1677/1955) theory of the passions as presented in *Ethics*. On Spinoza's view, passions are "the modifications of the body, whereby the active power of the said body is increased or diminished, aided or constrained, and also the ideas of such modifications" (p. 130). Such ideas are "confused" for Spinoza, from which it follows (on his view) that the mind entertaining them is passive rather than active, a point analogous to the Stoic proposal that emotions are false judgments. Spinoza distinguishes three primary passions: desire, joy, and sadness. All secondary passions are derived from desire, joy, and sadness in combination with ideas that distinguish one passion from the other. For example, love is joy accompanied by the idea of external cause, hatred is sadness (or pain) accompanied by the idea of external cause, and regret is desire to possess something kept alive by the remembrance of other things that exclude the existence of what is regretted.

The Rise of the Evaluative Tradition

A turning point for the *evaluative tradition* was the publication of Franz Brentano's *Psychology from an Empirical Standpoint* (1874/1995), which brought the challenge of explaining the intentionality of emotions center stage. Brentano (1874/1995, p. 88) influentially argued that "every mental phenomenon is characterized by what the Scholastics of the Middle Ages called the intentional (or mental) inexistence of an object, and what we might call, though not wholly unambiguously, reference to a content, direction toward an object." Among the paradigmatic examples of intentional states, Brentano lists the emotions: "in love [something is] loved, in hate hated, in desire desired."[19]

Brentano's (1874/1995) views mark the beginning of an important transition in psychology. For Brentano and his followers, psychology is no longer simply the science of consciousness, but also as the science of intentional or representational states. This view eventually led to modern cognitive psychology and its consuming concern with mental representations (Reisenzein, 2006). In the aftermath of Brentano's claim that all and only mental states are intentional states, the challenge of explaining why and how emotions can be about objects acquired new urgency.

In a discussion of precursors of the *evaluative tradition* of emotion theorizing in the 19th century, Reisenzein (2006) points to Stumpf (1899) and particularly Meinong (1894) (see also Reisenzein & Schönpflug, 1992). Meinong, a student of

Brentano, proceeds from Brentano's (1874/1995) assumption that emotions are object-directed. This assumption, Meinong argues, implies that emotions presuppose a "cognitive representation of [their] object" (Reisenzein, 2006, p. 923).

Meinong (1894) goes on to propose that the "cognitive representations" of emotions can be used to differentiate emotions from one another, and thereby provide an alternative solution to the problem of emotion differentiation that had plagued feeling theories and motivational theories of emotion. Although the cognitive theory of emotion developed by Meinong went largely unnoticed at the time, he indirectly influenced modern cognitive emotion theory in psychology (e.g., Weiner, 1986) through his student Frizu Heider (1958), who incorporated Meinong's analysis in his reconstruction of common-sense psychology (see Reisenzein & Mchitarjan, 2008).

However, the heyday of the *evaluative tradition* only came in the late 1950s and early 1960s, and it was the result of the convergent work of philosophers like C. D. Broad (1971), Errol Bedford (1957), George Pitcher (1965), Anthony Kenny (1963), Irvin Thalberg (1964), and R. S. Peters (1970), and psychologists like Magda Arnold (1960) and Richard Lazarus (1966). Philosophers focused on the inability of previous theories of emotions to explain how they can be object-directed and normatively assessable, whereas psychologists focused on the inability of previous theories to explain how emotions are caused. The first project led to the emergence of modern evaluative theories of emotions in philosophy, and the second project led to the emergence of appraisal theories in psychology. Let us consider these two developments in turn.

The first analytic philosopher in the English-speaking world to brand emotions as cognitions by virtue of their object-directness was Broad (1971). He argues that there are two kinds of experiences: those that have an "epistemological object" and those that do not. Experiences of the first sort are directed toward something, whereas experiences of the second kind are such that undergoing them is not being "*aware of a certain object*, real or fictitious," but rather "feeling in a certain way" (p. 283). Broad concludes that "emotions . . . are *cognitions*" because they are experiences with an epistemological object (p. 283; emphasis in original).

A related theme becomes prominent at around the same time, and it is the idea that emotions are normatively assessable, in the sense that they can be appropriate or inappropriate with respect to the objects toward which they are directed (Broad, 1971; Pitcher, 1965). Broad distinguishes between two dimensions of normative assessment: (1) an emotion is *misplaced* just in case it is felt toward an object that either does not exist or does not exist with the attributes under which it is emotionally responded to; and (2) an emotion is *inappropriate* just in case it is felt toward an object that the emotion does not fit, either in kind or in intensity.

To illustrate the first dimension of normative assessment, Broad (1971) argues that an emotion directed toward a nonexistent murderer that is the object of a *hallucinatory perception* would be *totally* misplaced, because there is no real ontological object corresponding to it. An emotion toward an existing person *falsely believed* to be an assassin would instead be *partially* misplaced, because there is a real ontological object—an existing person—but it does not have the attributes under which it is emotionally responded to.

These considerations bring to the fore an important characteristic of the emotions—namely, that they presuppose for their existence the presence of a perception, belief, memory, or other mental representation of the objects toward which they are directed. To fear a tiger, one must perceive it, or believe it about to appear, or remember it, or mentally represent it in some other way. Deonna and Teroni (2012) have referred to this as the *nonevaluative cognitive basis* of emotions. As Broad (1971) emphasizes, the cognitive basis of emotions is one possible object of normative assessment for emotions (misplacement), even though it focuses on mental states that are distinct from emotions.

With respect to the second dimension of normative assessment (inappropriateness), Broad (1971) states that once we have cognized a particular object as having certain characteristics, there is an appropriate and an inappropriate way to respond emotionally to it. For example, if an object has been cognized as threatening, fear rather than joy is the appropriate emotion toward it. If an object has been cognized as a man experiencing undeserved pain, amusement or satisfaction are not the appropriate emotions toward it. These examples raise a potential ambiguity concerning Broad's notion of appropriateness, which I illustrate by focusing on the second example.

The most likely interpretation of what Broad (1971) is suggesting is that it is *epistemically inappropriate* (or *unfitting*) to be amused or satisfied when a man experiences undeserved pain, in the sense that these forms of amusement or satisfaction violate standards that are internal to the emotions of amusement and satisfaction themselves (in a sense to be specified). But there are other ways in which these emotions may be inappropriate. For example, it is *morally inappropriate* to be amused or satisfied at another's undeserved pain, because these forms of amusement or satisfaction violate moral standards. In addition, it may be *prudentially inappropriate* to be amused or satisfied at another's undeserved pain (at least with public manifestations) because one would come across as a nasty person and possibly be sanctioned for it. One of the challenges in current philosophy of emotions is to articulate a clear and principled distinction between these varieties of appropriateness, a project that is at the core of the contemporary debate on emotions and values (see the section "Contemporary Developments II: Sentimental Values and the Situated Affectivity Movement").

Kenny on the Material and Formal Objects of Emotions

The difference between epistemic appropriateness or fittingness and other forms of appropriateness became clearer with Kenny's (1963) influential distinction between *material* and *formal* objects of emotions. Kenny's distinction is derived from scholastic philosophy, and it applies not only to emotions but also to perceptions and actions. Kenny (p. 132) introduces the distinction as follows: "Anything which can be φ-d is a material object of φ-ing . . . The formal object . . . is the object under that description which *must* apply to it if it is to be possible to φ it. If only what is P can be φ-d, then "thing which is P" gives the formal object of φ-ing." Let us unpack this philosophical mouthful.

First, the definition states that "anything which can be φ-d is a material object of φ-ing." For example, anything that can be seen, stolen, or feared is a *material object* of such perceptions, actions, and emotions. Since you can see a car, the car is a material object of seeing. Since you can steal a phone, the phone is a material object of stealing. Since you can fear a tiger, the tiger is a material object of fearing. But now ask yourself: "Which 'description . . . must apply to [a material object] if it is to be possible to φ it?'" For example, which description must apply to the car for it to be possible to see it, to the phone for it to be possible to steal it, and to the tiger for it to be possible to fear it? Kenny (1963) would answer that only what is *visible* can be seen, and only what *does not belong to you* can be stolen, and only what is *believed to be a threat* can be feared. But "if only what is P can be φ-d, then 'thing which is P' gives the formal object of φ-ing." So "thing which is visible," "thing which does not belong to you," and "thing which is believed to be a threat" describe the *formal objects* of, respectively, seeing, stealing, and fearing.

To sum up, formal objects place restrictions on what the material objects of perceptions, actions, and emotions can be, and they do so in a way that is "internal" to the mental attitude under consideration. Kenny's way of spelling out the sense in which they are internal is to suggest that the appropriateness of, say, an emotion to its formal object is *logical*: "each of the emotions is appropriate—logically, and not just morally appropriate—only to certain restricted objects" (1963, p. 134).

Kenny (1963) here is referring to the logic of the *concepts* involved, or to their conceptual entailments. For example, one may say that the very concepts of seeing, stealing, and fearing determine what the formal objects of such mental attitudes can be. It is the very concept of seeing that determines that you can only see what is visible. And it is the very concept of stealing that entails that you cannot steal what is already yours. And it is the very concept of fear, Kenny concludes, that entails that one must believe the stimulus feared to be bad.[20] As we shall see, the idea that there are conceptual connections between emotions and appraisals is at the core of one of the varieties of contemporary appraisal theory (see the section "Contemporary Developments III: Three Flavors of Appraisal Theory and Their Challenges").

The idea that emotions have material and formal objects has since become widely accepted in the philosophy of emotions. Each emotion can have an open range of material objects, which vary all the time and can be the same for different emotions. We can be afraid of different things at different times, and the same material object can be feared or admired by two different people, or by the same person at different times. The material object can be an individual (e.g., we can be afraid of Tom), or a proposition describing an event or a state of affairs (e.g., we can be afraid that Tom will try to kill us).

Formal objects, often referred to as *core relational themes* or *evaluative properties* or *values*, have found a semi-canonical formulation in Lazarus's (1991) description of core relational themes for emotions. Figure 1.5 illustrates some examples.

As pointed out by Fabrice Teroni (2007), formal

Emotion	Formal Object
Sadness	Having experienced an irrevocable loss
Anger	A demeaning offense against me and mine
Fear	Danger
Guilt	Having transgressed a moral imperative
Shame	Failing to live up to an ego ideal
Pride	Enhancement of one's ego identity by taking credit for a valued object or achievement, either one's own or that of someone or group with whom we identify

FIGURE 1.5. A representative list of *formal objects/core relational themes* (Lazarus, 1991).

objects have been assigned three main jobs in the philosophy of emotions: individuating different emotions, making emotions intelligible from the point of view of the emoter, and accounting for the conditions of epistemic appropriateness for emotions (see also Mulligan, 2007). First, formal objects can tell us how any two emotions differ from one another. For example, we may say that sadness is different from fear because the formal object of the former is having suffered an irrevocable loss, whereas the formal object of the latter is danger.

Second, formal objects can make an emotion intelligible (or justified or warranted or reasonable) from the point of view of the emoter by informing us about how the emoter describes the material object toward which his or her emotion is directed. For example, if we wonder why John responded with shame to being complimented for his degree, learning that John interpreted being complimented for a degree that he in fact had acquired using improper means as a failure to live up to an ego ideal makes shame intelligible from his point of view.

Third, formal objects provide the criteria for deciding whether emotions are epistemically appropriate or fitting. For example, when we wonder about whether it was epistemically appropriate for Jennifer to get angry at her boss's compliment on her skirt, the question we are asking is whether her boss' compliment on her skirt constitutes a demeaning offense against her. If it is, then Jennifer's anger is epistemically appropriate or fitting with respect to the unsolicited compliment.[21]

Contemporary Developments I: Evaluative Theories in Philosophy and Their Challenges

A great many contemporary philosophers of emotions are convinced that the reason why emotions are so tightly connected with formal objects is that an emotion *is* essentially an evaluation that a given formal object is instantiated by a given material object.[22] This is the core thesis of modern evaluative theories of emotions in philosophy, which hark back to the Stoic suggestion that emotions are judgments. But whereas for the Stoics emotions are judgments that a certain movement of the soul is appropriate, for contemporary philosophers emotions are evaluations to the effect that a formal object is instantiated (by some material object).

Various proposals have been made concerning what type of evaluation an emotion is. Until quite recently, the most popular option was *judgmentalism*, developed by Robert Solomon (1976, 2003) and Martha Nussbaum (2001) among others. "I still hold the claim that emotions are judgments," states Solomon (2003, p. 210), and Nussbaum (p. 4) writes that "emotions are appraisals or value judgments." Solomon gives the following examples: "'I am angry at John for taking . . . my car' entails that I believe that John has somehow wronged me . . . My anger is that judgment . . . If I do not find my situation awkward, I cannot be ashamed . . . If I do not judge that I have suffered a loss, I cannot be sad . . . to have an emotion is to hold a normative judgment about one's situation" (Solomon 2003, p. 8).

Judgmentalism became popular because it seemed to solve most of the problems that had afflicted previous traditions of emotion theorizing. Most significantly, it provided a straightforward solution to the problem of intentionality, explaining both why emotions are about objects and what makes them appropriate or inappropriate to such objects. If emotions *are* judgments, then they are about whatever the judgments with which they are identified are about, and they are appropriate whenever such judgments are true.[23] In addition, judgmentalism appeared to solve the problem of differentiation: emotions can be distinguished in terms of the *content* of the judgments with which they are identified.

These advantages notwithstanding, judgmentalism is now considered to be flawed. First, it does not provide a satisfactory solution to the problem of motivation. If emotions simply were judgments to the effect that a certain formal object is instantiated, they would lack independent motivational force. This is because judgments have a mind-to-world direction of fit, as their objective is to "fit" what the world is like rather than to motivate action directed at changing the world, as in the case of desires (Searle, 1983).

To this objection, judgmentalists have replied that desires to act are either conceptually connected to (e.g., Solomon, 2003) or caused by (e.g., Lyons, 1980; Nussbaum, 2001) the judgments with which emotions are identified.[24] These replies are *ad hoc*, however, because no convincing explanation is given for why emotion judgments are conceptually or causally connected with action desires by virtue of their content. A better strategy is to explicitly add a conative dimension to judgmentalism, and propose that emotions are combinations of beliefs/judgments and desires. Versions of this belief–desire theory of emotions have been developed by both philosophers (Marks, 1982; Green, 1992) and psychologists (Reisenzein, 2012; Castelfranchi & Miceli, 2009), but the jury is still out on whether they succeed in solving the motivational problem and are overall satisfactory (Brady, 2013; Scarantino, 2014).[25]

The problems with judgmentalism, however, go deeper. An issue that has attracted significant attention is that of *rational recalcitrance*, the phenomenon instantiated when emotions are in tension with one's judgments, as when a snake-phobic subject experiences fear of a snake picture while at the same time holding the belief that the snake picture is not dangerous (D'Arms & Jacobson, 2003). In these sorts of cases, judgmentalists are forced to describe recalcitrance as the holding of contradictory beliefs, a position many consider to ascribe to emoters the wrong kind of irrationality (Helm, 2001; Döring, 2008; Benbaji, 2012; Brady, 2007; Tappolet, 2000; Faucher & Tappolet, 2007).

Another problem with judgmentalism is that, if we identify emotions with evaluative judgments, we cannot explain how emotions sometimes precede and cause such judgments (Brady, 2013). For example, we may first feel ashamed at being seen in public with a lover who is half our age, and then form the evaluative judgment that our behavior constitutes a failure to live up to an ego ideal. But if shame were the judgment that our behavior constitutes a failure to live up to an ego ideal, it could not causally contribute to the formation of such a judgment, because nothing can cause itself.

Finally, judgmentalism has been charged with the inability to account for the emotions of infants and animals, because nonlinguistic creatures cannot make judgments on the standard understanding of judgments, and with the inability to account for the special phenomenology of emotions, because making judgments seems to lack the distinctive subjective quality of emotions, most significantly their "hotness" and their "bodily" dimension (see, e.g., Leighton, 1985; Deigh, 1994; Tappolet, 2000; Scarantino, 2010; Deonna & Teroni, 2012; Reisenzein, 2012, for further discussion of the flaws of judgmentalism).

Recent philosophy of emotions has been largely focused on replacing judgments with other evaluative constructs capable of solving judgmentalism's flaws while preserving its two main assets: the ability to provide solutions to the problems of intentionality and differentiation. The two evaluative constructs most often proposed as replacements for judgments are *evaluative feelings* (e.g., Whiting, 2011; Kriegel, 2014; Helm, 2001; Greenspan, 1988; Goldie, 2000; Salmela, 2002; Deonna & Teroni, 2012) and *evaluative perceptions* (e.g., De Sousa, 1987; Tappolet, 2000; Johnston, 2001; Roberts, 2003; Zagzebski, 2003; Prinz, 2004b; Döring, 2007; Elgin, 2008; Charland, 1995). The qualifier "evaluative" is meant to emphasize that these notions differ from the notions of feeling and perception we have considered so far in that they are constitutively linked to evaluative properties.

Popular proposals include the idea that emotions are intentional feelings of import organized around commitments (Helm, 2001), perceptions of value (Tappolet, 2000), embodied appraisals (Prinz, 2004b), feelings of comfort or discomfort directed toward thoughts (Greenspan, 1988), combinations of bodily feelings and feelings towards (Goldie, 2000), affective perceptions (Döring, 2007), concern-based construals (Roberts, 2003), and evaluative attitudes consisting of feelings of one's body being ready to act (Deonna & Teroni, 2012).

These proposals are all clear improvements over judgmentalism, but it is up for debate which of them, if any, provides a viable account of emotions. Given the current state of the debate, a viable account would need to at least explain the differentiation and intentionality of emotions, solve the motivational problem, provide a plausible account of the phenomenal side of emotions, account for emotional recalcitrance, and explain why infants and animals can have emotions. Opinions differ as to whether any evaluative theory succeeds in satisfying all these desiderata (e.g., Deonna & Teroni, 2012; Salmela, 2011; Dokic & Lemaire, 2013; Brady, 2013; Scarantino, 2014).

An important distinction within modern evaluative theories concerns the way they account for the relation between formal objects and evaluations. According to what I call the *direct strategy*, formal objects are descriptions of what is directly perceived or felt by the emoter. For example, Goldie (2002) thinks that "emotions involve two kinds of feeling," one contingent and the other essential. The contingent feeling is a *bodily feeling*, "the feeling from the inside of the condition of one's body as being a certain way or as undergoing certain changes" (p. 235). The essential feeling, which Goldie calls the *feeling toward*, is "the feeling one has towards the object of one's emotion" (p. 235). On this view, to fear an object is to feel one's body in turmoil (bodily feeling) and to directly feel the dangerousness of the object (feeling toward).

According to the *indirect strategy*, formal objects describe the conditions of appropriateness of perceptions/feelings rather than what is directly perceived or felt. An example of such a strategy is offered by Prinz's theory of emotions as "valent embodied appraisals." On Prinz's neo-Jamesian view, fear is a combination of an *embodied appraisal* consisting of "a racing heart and . . . other physiological changes" (2004b, p. 69) with the function of being elicited by dangers, and a negative *valence marker* that says "less of this."[26] As I mentioned earlier, in a teleosemantic theory of representation, mental states represent what they have the function of indicating (Prinz, 2004b; Dretske, 1988). So Prinz proposes that perceiving a racing heart represents danger because it has the function of indicating it. On this view, the agent directly perceives bodily changes (the nominal content) and indirectly perceives the core relational theme (the real content) by virtue of what the bodily changes represent.

Another example of indirect strategy is offered by Deonna and Teroni's (2012) attitudinal theory, according to which emotions are felt bodily attitudes of action readiness. On this view, fear is the feeling of one's body being poised "to act in a way that will contribute to the neutralization of what provokes the fear" (p. 80), an attitudinal feeling that is only correct in case what provokes the fear is dangerous. In this case, formal objects constitute the conditions of correctness of feelings of action readiness.

Contemporary Developments II: Sentimental Values and the Situated Affectivity Movement

I want to briefly discuss two further areas of growing debate in contemporary philosophy of emotions. The first concerns the relation between emotions and values (see Roeser & Todd, 2014; Deonna & Teroni, 2012, 2015; D'Arms & Jacobson, 2000, forthcoming). So far we have asked whether emotions are evaluations that a certain formal object or value is instantiated. For example, we have asked whether fear is the evaluation that something is dangerous. But there is another question philosophers of emotions ask, namely, whether values themselves are to be understood in terms of the emotions they elicit. For example, should we understand dangerousness in terms of fear responses, or is dangerousness a property we can make sense of independently of fear?

The two questions are not independent of one another. At a minimum, one's theory of how values are apprehended through emotions and one's theory of how values are constituted should be compatible. For example, if one thinks that emotions are required to shed light on values, emotions themselves should not be defined in terms that presuppose those very values, on pain of circularity. Several positions on the connection between emotion concepts and value concepts are available in the contemporary debate, which has focused primarily on so-called *sentimental values*, exemplified by things like the funny, the disgusting, the shameful, and the enviable.

The three main competitors are *realism*, *dispositionalism*, and *neo-sentimentalism* (Tappolet, 2000; Rabinowicz & Rønnow-Rasmussen, 2004; Jacobson, 2011; Deonna & Teroni, 2012). *Realism* is the thesis that we can make sense of what it is for some *X* to have a certain sentimental value by relying on response-independent properties *X* has. For example, suppose someone were to propose that the disgusting is whatever is contaminating, or that the funny is whatever is incongruous (Jacobson, 2011). On this view, sentimental values would be objective properties like mass, charge, and spin—namely, properties instantiated independently of any actual or potential response to the property bearer.

A challenge for *realism* is to explain away the intuition shared by many that things would continue to be contaminating or incongruous, but would stop being disgusting or funny unless there were creatures around capable of being disgusted or amused by them. A possibility would be to abandon the claim that emotional responses are irrelevant to establishing values, but stick to the view that we can make sense of the disgusting and the funny in terms of descriptive properties alone. For example, one could propose that the disgusting corresponds to whatever descriptive properties the disgust mechanism is designed to track or that the funny corresponds to whatever descriptive properties the amusement mechanism is designed to track.

This proposal faces another challenge, namely, making sense of the fact that ascriptions of sentimental values are "normatively loaded," in the sense that they "carry a claim to interpersonal authority in virtue of their putative correctness and are the subjects of significant and trenchant disagreement" (Knapp, 2003, p. 270). For example, when we state that a certain behavior is disgusting, we seem to be implying that other people should find it disgusting too, and we would engage in reasoned debate with anyone who considered the behavior not to be disgusting at all. The central point is that neither claims to interpersonal authority nor disagreements stop once all the descriptive properties of the behavior have been agreed upon. This calls into question the possibility of reducing sentimental values to descriptive properties, suggesting the presence of an inescapable evaluative dimension to sentimental values.

Dispositionalists and *neo-sentimentalists* agree that we cannot make sense of the disgusting or the funny in merely descriptive terms, but offer different recipes for connecting sentimental values with emotional responses. *Dispositionalists* propose that we can make sense of what it is for some *X* to have a certain sentimental value in terms of the emotional responses *X* is disposed to elicit. One challenge is to get clear on the nature of the relevant dispositions: What are their triggers, manifestations, and bearers? Suppose we propose that the disgusting and the funny are, respectively, what would elicit disgust and amusement in ordinary people in standard circumstances. This proposal also faces the challenge of making sense of normatively loaded ascriptions. It seems that by calling a certain behavior disgusting, people are not simply reporting on the fact that ordinary people in standard circumstances are typically disgusted by it, but that disgust is the right emotional response to it.

This is the intuition that drives *neo-sentimentalism*, according to which the only way to make sense of what it is for some *X* to have a sentimental value is to appeal to the emotional response it is *appropriate* to have toward *X*.[27] On this view, to be disgusting or funny is to be the *fitting target* of disgust and amusement, respectively. This view holds, along with *realism*, that something can be disgusting or funny even if ordinary people in standard circumstances would not be disgusted or amused by it. It follows *dispositionalism*, on the other hand, in holding that we cannot understand sentimental values except by way of the emotional responses they elicit, although it crucially adds that such responses can be mistaken.

Neo-sentimentalism seems to offer a more straightforward account of normatively loaded discourse than competing accounts, in the sense that if ascribing a sentimental value is endorsing an emotional response, it becomes clear why such ascriptions have a claim to interpersonal authority and are objects of disagreements when endorsements clash. But it faces the difficult challenge of distinguishing the right from the wrong types of appropriateness. For example, it is certainly the case that a joke may be funny even if it is morally inappropriate, from which it follows that the funny cannot be what elicits a morally appropriate response. The problem is that it has turned out to be exceedingly difficult to explain what kind of appropriateness is the *right kind* without presupposing the very sentimental values that the account is supposed to shed light on.

The second area of growing debate in contemporary philosophy of emotions is connected to *situated approaches* in the philosophy of cognitive science, also called "four-E" approaches to emphasize that their proponents see cognition as "embodied," "embedded," "enactive," and "extended" (see Robbins & Aydede, 2009; Shapiro, 2014, for an overview of the field). Recently, this literature has started paying attention to the emotions (see, e.g., Griffiths & Scarantino, 2009; Maiese, 2011; Colombetti, 2014; Colombetti & Thompson, 2008). Proponents of four-E approaches generally do not offer complete theories of emotions, but try to emphasize the intimate connection between emotions and bodily and environmental processes.

A recent extensive treatment of emotions and affectivity from this perspective is Colombetti (2014). Drawing in particular on the "enactive" approach developed by Varela, Thompson, and Rosch (1991) and Thompson (2007), Colombetti argues that the mind is pervasively affective and not neatly divided into cognition and emotion. Colombetti also draws upon dynamical systems theory to reconceptualize emotional episodes and moods as self-organizing patterns of the whole organism (see also Freeman, 2000; Lewis, 2000, 2005; Thompson, 2007).

Central to several proposals within this tradition is an emphasis on emotion and affectivity as complex *experiential* phenomena, which connects four-E approaches to the philosophical tradition of phenomenology. For example, both Ratcliffe (2008) and Colombetti (2014) draw on classic phenomenological treatment of the "lived body" found in Edmund Husserl, Maurice Merleau-Ponty, and others, to argue that emotions can involve bodily feelings while retaining their intentional relatedness to the world (see also Slaby, 2008; Hutto, 2012; Gallagher & Zahavi, 2012).

As for the relation between emotion and the world, theorists who see emotions as "embedded" or "situated" have pointed out that affective phenomena are deeply environmentally supported. Recurrent reference can be found in this literature to the metaphor of "scaffolding" (Griffiths & Scarantino, 2009; Colombetti & Krueger, 2015), which is meant to emphasize that structures in the environment (both material and social) are necessary to enable affective phenomena to develop in the specific ways they do.

More radical approaches propose that the physical machinery that realizes affective states may include not just neural and bodily processes but also parts of the environment. Emotions and other affective states, it has been suggested, can sometimes become "extended" into the world. This approach applies the hypothesis of "extended cognition" to the domain of affectivity. In a classic example, the mind of Otto, a patient afflicted by Alzheimer's disease, is said to be extended outside his brain to include the notebook entries he uses to remember facts, because Otto relates to such notebook entries in a way that is relevantly similar to how a normal person relates to his or her intracranial memories (Clark & Chalmers, 1998). In various papers, Krueger (2013a, 2013b, 2014) has argued, drawing largely on developmental psychology (especially the development of caregiver–infant interactions), that emotions can be "extended" over several agents and accordingly be "jointly owned." Stephan, Walter, and Wilutzky (2014) have proposed that physiology, expressions, and appraisals can be "extended," whereas Colombetti and Roberts (2015) argue for the "extension" of dispositional affective states (such as dispositional emotions and temperaments), and Roberts (2015) proposes that even emotional feelings can be "extended."

Contemporary Developments III: Three Flavors of Appraisal Theory and Their Challenges

The second main approach within the *evaluative tradition* is the *causal approach*. The notion of appraisal, present in the work of a great many emotion theorists starting with Aristotle, became the object of scientific investigation with the work of psychologists Magda Arnold (1960) and Richard Lazarus (Speisman, Lazarus, Mordkoff, & Davison, 1964; Lazarus, 1966, 1991, 2001).[28] Arnold argues that psychological emotion research since James has mainly focused on clarifying the causal relation between bodily changes and the experience of emotion. What only a few theories have dealt with, she states, is "the problem of how cold perception can cause either the felt emotion or the bodily upset" (1960, p. 93). Call this the *problem of causation*.

Arnold's (1960, p. 171) solution to this problem is her suggestion that "to arouse an emotion, the object must be appraised as affecting me in some way, affecting me personally as an individual with my particular experience and my particular aims." She coins the term "appraisal" to designate this process, emphasizing that her "analysis goes back to Aristotle and Thomas Aquinas" (Arnold, 1960, p. 193). Arnold also adds "that the only approach that promises a solution of the problem of how perception arouses emotion is a careful phenomenological analysis," (p. 170), of the kind offered by Sartre, among others. As Sartre put it, the phenomenological approach investigates "psychic events . . . insofar as they are significations and not insofar as they are not pure facts" deprived of an interpretation of what they signify for us (Sartre & Frechtman, 1948, p. 19).

Apart from introducing the term "appraisal," Arnold develops appraisal theory in several important respects. First, she argues that the appraisal process is usually "direct, immediate, nonreflective, nonintellectual, automatic, 'instinctive,' 'intuitive'" (1960, p. 175). This understanding of appraisal was implicitly appealed to by Lazarus (1984) in an influential debate with Zajonc (1984) on whether affective reactions necessarily require cognitions. Lazarus argues that they do, and Zajonc denies it. It became clear during the debate, however, that the two parties understood cognition in different ways: Lazarus labeled as "cognitive" even simple and "nonintellectual" forms of information processing, whereas Zajonc reserved the label of "cognition" for the more sophisticated varieties of information processing.

This led Leventhal and Scherer (1987, p. 16), in an attempt to "steer the emotion-cognition controversy away from potentially sterile semantic arguments about what is a cognition," to introduce the idea that appraisals/cognitions can occur at different levels of information processing. In the latest iteration of the theory, four such levels are distinguished (Scherer, 2009): (1) a neural circuit level, which comprises genetically determined pattern-matching mechanisms, (2) the schematic level, which comprises memory traces from prior learning experiences, (3) an associative level involving cortical association areas, and (4) a conceptual level involving propositional knowledge.

Second, Arnold (1960) begins to unveil the internal structure of the appraisal process, suggesting that appraisals are made along three dimensions: eliciting circumstances can be evaluated as good or bad, present or absent, and easy to attain or avoid. For example, according to Arnold, the cognitive cause of fear can be described as the appraisal of an event as bad, absent but possible in the future, and hard to avoid; whereas the cause of joy can be described as the appraisal of an event as good, present, and easy to maintain.

This transition from a *molar account* of appraisal, in which the appraisals of different emotions are considered unitary mental states, to a *molecular account* of appraisal, in which the appraisals are broken down into components that can be independently studied, is a key insight of psychological appraisal theories of emotion (the molecular–molar distinction was introduced by Smith and Lazarus, 1990). These theories replace the "one-sentence" philosophical analyses of evaluations in terms of formal objects with a detailed structural account that tries to shed light on their internal composition or attributes on a limited number of appraisal dimensions.

It soon became clear that the three dimensions of appraisal proposed by Arnold (1960) are not sufficient, and also not optimally chosen, for explaining the differentiation of emotions. To overcome this limitation of Arnold's theory, additional or alternative appraisal dimensions have been subsequently proposed by a number of psychologists (e.g., Smith & Ellsworth, 1985; Frijda, 1986; Lazarus, 1991; Roseman, 1996; Scherer, 2001; Ellsworth & Scherer, 2003; Roseman & Smith, 2001; Oatley & Johnson-Laird, 1987).

Lazarus (1991, 2001) proposes to distinguish between *primary appraisal*, whose function is to determine whether and how any of the subject's goals are affected by an event, and *secondary appraisal*, whose function is to determine how best to cope with the event once it has been classified as furthering or thwarting the subject's goals. More specifically, primary appraisal comprises three component processes: (1) the appraisal of *goal relevance*, (2) the appraisal of *goal congruence or incongruence*, and (3) the appraisal of *type of ego involvement*. Secondary appraisal also comprises three components: (1) the appraisal of *blame or credit*, (2) the appraisal of *coping potential*, and (3) the appraisal of *future expectancy*. On this view, guilt is caused by the appraisal of an event as goal relevant, goal incongruent, involving a moral transgression, and one for which the self is to blame (coping potential and future expectancy appraisals are left open).

Other appraisal theorists have endowed the appraisal process with even more structure. For example, Scherer (2001) distinguishes between no fewer than 16 dimensions of appraisal, called stimulus evaluation checks (SECs), which can be grouped into four classes representing "the major types or classes of information with respect to an object or event that an organism requires in order to prepare an adequate reaction" (p. 94): appraisals of relevance, appraisals of consequences, appraisals of coping potential, and appraisals of normative significance.

Agnes Moors (2014) has drawn a helpful distinction between two "flavors" of appraisal theory. Flavor 1 appraisal theories assume that the "molecular" appraisals of an event on the different appraisal dimensions are integrated into a "molar" appraisal, which is the immediate cause of emotions such as anger, fear, disgust, and so on. Lazarus (2001, p. 64) has suggested, for example, that "we should combine the partial meanings [of molecular appraisals] into a terse, integrated gestalt or whole [the molar appraisal], which is what characterizes the . . . cause of the emotion."

Flavor 2 appraisal theories, on the other hand, assume that the molecular appraisals can cause individual emotion components (e.g., the action tendency to flee), or even parts of these components (the direction of fleeing), without a prior "synthesis" into a molar appraisal. Theories of this kind often do not even try to specify the patterns of appraisal that cause anger, fear, and so on, and assume that the appraisal process can have a wide range of combinations of appraisal outputs, only some of which will lead to familiar, discrete emotion categories.

Scherer's (2009, p. 1314) *component process model* theory is an example of a flavor 2 theory, because it assumes that "emotion differentiation is the result of the net effect of all subsystem changes brought about by the outcome profile of the SEC sequence," namely, the sequence of SECs along the 16 dimensions mentioned earlier. For example, once a stimulus has been appraised as novel and goal relevant, causal effects of this (partial) appraisal can already be detected on various organismic subsystems (e.g., orienting responses, heart rate deceleration, vasomotor contraction, skin conductance responses). Depending on the further appraisals made, these effects may or may not culminate in the emergence of a familiar, discrete emotion.

Another example of flavor 2 theory is Cunningham, Dunfield, and Stillman's (2013) *iterative processing model*, a theory that combines themes from appraisal theory and psychological constructionism and seeks to ground the recurrent nature of appraisals in the heterarchical organization of the brain (see also Barrett, Ochsner, & Gross, 2007). What distinguishes this proposal from most other appraisal theories is that it draws on connectionist approaches developed in computational cognitive neuroscience (e.g., O'Reilly, Munakata, Frank, & Hazy, 2012) to model how discrepancies between expectations and experiences of the internal or external world give rise to dynamic reprocessing of information through iterative cycles that eventually lead to changes in affect and discrete emotions.

To capture all self-described psychological appraisal theories, we need to add a third "flavor" of appraisal theory to this taxonomy. Flavor 3 theories are appraisal models that, unlike flavor 1 and 2 models, deny a causal role to appraisals (e.g., Clore & Ortony, 2013; Ellsworth, 2006, 2013). Flavor 3 appraisal theories understand appraisals as being entailed by emotions, in the sense that having an emotion of a given kind (e.g., fear) necessarily requires appraising the eliciting stimulus in a particular way.

An example of flavor 3 theory is Ortony, Clore, and Collins's (1988) "OCC model." Originally, this model was proposed as a causal appraisal theory, since its goal was to "explain how people's perceptions of the world—their construals—cause them to experience emotion" (p. 12). More recently, however, (some of) the authors have reinterpreted the model differently, and it now falls squarely into the flavor 3 camp. Clore and Ortony (2013, p. 339) state that they "do not treat appraisal as a process occurring in real time that *causes* emotions." Their proposed notion of appraisal "focuses solely on structure [and] specifies the features of the prototypical situations represented by each kind of emotion." In other words, having an emotion is now understood as representing the world in a certain way, where this representation does not precede the occurrence of the emotion and consequently does not cause it.

There is an analogy between this way of thinking of emotions and philosophical judgmentalism. Instead of identifying, say, guilt, with the judgment that one has transgressed a moral imperative, as philosophical cognitivists would have it, flavor 3 appraisal theorists identify guilt with the appraisal that one's behavior is goal relevant, goal incongruent, involves a moral transgression, and the self is to blame for it. Similarly, instead of identifying fear with the judgment that danger is at hand, flavor 3 appraisal theorists identify fear with the appraisal that the stimulus is goal relevant and goal incongruent (i.e., a "bad outcome").

Crucially, the connection between emotions and appraisal outputs is presumed to be conceptual rather than empirical, just like the connection between emotions and formal objects (see the section "Contemporary Developments I: Evaluative Theories in Philosophy and Their Challenges"). This point is made explicitly by Clore and Ortony (2013, p. 339), who write that "just as no empirical research will ever disprove that bachelors are unmarried, evidence . . . cannot show that fear involves an anticipation of bad outcomes." It cannot show it in the sense that it need not show it: fear *must* involve the anticipation of bad outcomes in the same sense in which being a bachelor *must* involve being unmarried. No amount of empirical investigation is required to draw this conclusion, which is available simply by reflecting on the conceptual entailments of the terms involved.

Flavor 3 appraisal theory does not solve the problem of causation raised by Arnold (1960), because it does not tell us how the emotions come about (see Moors, 2013, for more on this point). Furthermore, the interpretation proposed by Clore and Ortony (2013) raises a worry for appraisal theory writ large. The worry is that some of the theories that claim to be flavor 1 and flavor 2 appraisal theories may rely only on evidence that allows them to establish "flavor 3" claims, namely, conceptual connections between emotions and appraisals rather than contingent causal relations.

This challenge has been raised by various researchers over the years (Oatley, 1992; Parkinson

& Manstead, 1992; Parkinson, 1997; Russell, 1987; Frijda, 1993). For example, Parkinson (1997, p. 65) argues that "much of the self-report evidence that is used to defend an empirical relationship between appraisal and emotion actually provides more direct support for a conceptual relationship because the implemented indices of emotion depend on people's everyday interpretations of the vocabulary of affect." Appraisal theorists of flavors 1 and 2 have replied that the empirical evidence for the causal version of appraisal theory relies on evidence that goes well beyond self-reports, as it includes patterns of brain activity, autonomic system changes, and facial/vocal expressions (Scherer, 2009).

Another challenge for flavor 1 and flavor 2 appraisal theories is to find a proper place for appraisal into the emotion as a whole. Specifically, causal appraisal theorists must decide whether the appraisal is also a part of the emotion or (just) its cause. Some causal appraisal theories assume that the appraisal is not part of the emotion. For example, Arnold writes that "we can now define emotion as the felt tendency toward anything intuitively appraised as good (beneficial), or away from anything intuitively appraised as bad (harmful) . . . accompanied by a pattern of physiological changes organized toward approach or withdrawal. The patterns differ for different emotions [emphasis removed]" (Arnold 1960, p. 182).

The claim that the patterns differ for different emotions implies that for Arnold (1960) appraisals are not indispensable for differentiating among emotions. On the other hand, the option of using appraisals to differentiate among emotions remains available, because emotions are defined by Arnold as felt action tendencies *caused* by emotion-specific appraisals (see also Gordon, 1987; Reisenzein, 2012). Proposals that rely on appraisals to differentiate among emotions without considering them to be parts of emotions have a long and reputable history in philosophy (see Lyons, 1980).

Other appraisal theorists, however, explicitly take appraisals to be part of the emotions (e.g., Lazarus, 1991; Scherer, 2005). For example, according to Scherer's component process model of emotions, "emotion is defined as an episode of interrelated, synchronized changes in the states of all or most of the five organismic subsystems in response to the evaluation of an external or internal stimulus event as relevant to major concerns of the organism" (p. 697). Hence, an emotion is instantiated if any three of the following five components are engaged in synchronized changes: an appraisal component, an autonomic physiology component, an action tendency component, a motor expression component, and a subjective feeling component.

A consequence of this definition is that an emotion may have an appraisal as a proper part. But this is at first blush incompatible with the claim that appraisal causes emotion, because nothing can cause itself. Various solutions have been offered for this problem (cf. Moors, 2013). The solution proposed by Moors and Scherer (2013) is that when appraisal theorists who regard appraisal as a part of the emotion state that appraisal causes emotion, this is mere *façon de parler*. What theorists like Scherer and Lazarus really mean is that appraisal causes all components of emotion other than itself—namely, autonomic changes, action tendencies, motor expressions, and subjective feelings.

It seems fair to say that the *evaluative tradition* has succeeded in at least two important respects. First, most theorists now accept that theories of emotions should account for the intentionality of emotions. A sign of this newly found realization is that contemporary feeling theories (e.g., Goldie, 2000; Prinz, 2004b) and contemporary motivational theories (e.g., Scarantino, 2014) in philosophy all offer tentative accounts of the intentionality of emotions. Second, most theorists now accept that a subject's appraisal of the eliciting situation is a major determinant of the differences among different emotions. This insight is now shared by psychological theories of emotions of all stripes, including basic emotion theory, social constructionism, and psychological constructionism. Whether the *evaluative tradition*, in both its constitutive and causal approaches, can successfully tackle its outstanding challenges remains to be seen.

Methodological Coda

At the end of this survey of emotion theories across centuries and disciplines, we may ask whether there has been significant progress in emotion theory since Ancient Greece. There seem to be both good news and bad news on this front. The good news is that there is now much greater consensus regarding the characteristics of emotions that need to be explained.

The majority of emotion theorists currently agree that (1) emotion episodes involve, at least in prototypical cases, a set of expressive, behavioral, physiological, and phenomenological features diagnostic of emotions; (2) each diagnostic feature has a range of variability; (3) evolutionary explanations can be given for at least some emotions and/or their components; (4) most aspects of emotions are affected by sociocultural factors; (5) the physical seat of emotions is the brain; (6) emotions motivate actions in distinctive ways; (7) emotions are generally object-directed; (8) emotions have a cognitive basis, consisting of other mental states they presuppose (e.g. memories, perceptions, etc.); (9) emotions can be appropriate or inappropriate with respect to their objects; (10) there are different forms of appropriateness for emotions (e.g., epistemic, moral, prudential); (11) appraisals can help differentiate emotions; (12) appraisals range from primitive to sophisticated forms of information processing; (13) at least some emotions are present in infants and animals; (14) emotions can be in tension with our reflective judgments; and (15) emotions play a functional role in a variety of domains (e.g., rational deliberation, morality, aesthetics).

Although much of this may not sound especially surprising at this stage of the game, we should keep in mind that all of these ideas have at some point in the history of emotion theory been either denied or neglected.

The bad news is that we are apparently not much closer to reaching consensus on what emotions are than we were in Ancient Greece. As soon as we try to define the emotions, or even just to transition from the generalities I have listed to the pesky details (Do emotions cause the diagnostic components, or do they emerge from them? What, exactly, can be evolutionarily explained with respect to emotions?), the consensus among today's emotion researchers abruptly ends, and competing research programs start engaging in fierce fighting. The emotion community continues to be divided on the nature of emotions, on the terminology suitable for describing them, and on the experimental techniques to study them.

Why is there still so much disagreement on what emotions are after centuries of concerted efforts? One possible explanation is that emotion theorists have not been sufficiently ingenious or lucky in the exploration of their subject matter. On this view, what they need is more time, and perhaps the insights of a Darwin or a Newton. After all, the body of common knowledge about emotions has increased over time, which gives hope that, at some point, a universal theory of emotions will emerge and command general assent.

An alternative possibility brought up at various times in the history of emotion theory by affective scientists (Duffy, 1934, 1941; Barrett, 2006; Kagan, 2007, 2010; Mandler, 1975; Russell, 2003; Zachar, 2006) and philosophers alike (Rorty, 1980; Griffiths, 1997; Scarantino, 2012b, 2012c) is that emotions simply are not all of one kind. A philosophical way to make this point is to say that the folk categories designated by English terms such as "emotion," "anger," "fear," "happiness," "sadness," "shame," and "guilt" do not designate natural kinds. A natural kind is (roughly) a category whose members are sufficiently alike to allow for extrapolation from properties of category samples to properties of the category as a whole. Emotions, it is claimed, are too heterogeneous to fit this definition.[29]

Most of the theories examined in this chapter presuppose that folk emotion categories designate natural kinds. Their central theses are presented as claims of the form "emotions are *K*" or "fear is *K*," where *K* stands for a kind of psychological structure. This formulation presupposes *universalism*, namely, the idea that a single account of emotions (or at least a single account of fear, anger, shame, etc.) can fit all cases (Scarantino, 2012c). As described, the three historically most influential ways of filling in the blank have replaced *K* with *feelings*, *motivations*, and *evaluations*, respectively. The debate on the nature of emotions has generally focused on whether any of these replacements can satisfy all scientific or philosophical constraints on, and purposes of, a theory of emotions. The result has been the fragmented family tree I have outlined in this chapter, in which no theory seems to be fully satisfactory on all dimensions of assessment.

However, if emotions are not all of one kind, *universalism* is simply the wrong methodological presupposition, and the project of filling in the blank in claims of the form "emotions are *K*" or "fear is *K*" becomes doomed to failure, even if Darwin or Newton were to take a shot at it. Fortunately, *universalism* is not the only game in town. Two methodological alternatives seem especially promising, because they have led to major progress in other areas of research. The first is what we may call *componentialism*, the view that we should search for the fundamental building blocks of natural phenomena.

An example of a successful componential strategy can be found in the search for the nature of matter, which started with pre-Socratic suggestions that all matter is ultimately constituted by a single basic element (e.g., Thales proposed water, Anaximenes air, and Heraclitus fire) or a handful of elements (e.g., Empedocles suggested four: air, fire, water, and earth), and ended with the discovery of the chemical elements in the 18th century. Chemical elements are defined as substances that cannot be further decomposed into simpler substances using common chemical processes and can combine to form an infinite number of compounds.

A similar strategy has been proposed by psychological constructionists in the affective realm. These emotion theorists believe that the emotion categories of folk psychology are too heterogeneous for purposes of scientific investigation and aim to discover "elemental—but still psychological—building blocks" (Russell, 2003, p. 146) out of which emotion episodes are constructed. The heterogeneity of folk emotion categories does not preclude the success of this strategy, because even if all things we call emotions, angers, fears, and so on cannot be captured by a common definition (or theory), their *components* may still have scientifically relevant dimensions of similarity.

The second methodological strategy I call *pluralism*. Unlike psychological constructionists, pluralists think that discrete emotion categories are still a proper object of scientific investigation, as long as we accept that they have to be heavily revised (e.g., split into subcategories) in order to do scientific or philosophical work. The core assumption of *pluralism* is indeed the belief that there is a plurality of distinct natural kinds comprised within the same folk categories.

An example of this approach can be seen in research on memory. Memory scientists started from the assumption that the folk psychological category of "memory" designates a unique information-retention mechanism, but eventually came to realize that memory needs to be "divided into multiple forms or systems-collections of processes that operate on different kinds of information and according to different rules" (Schacter, 2004, p. 644). Today, it is commonly accepted that multiple memory systems exist (e.g., short-term memory, long-term memory, procedural memory), are activated by different tasks, and differ on a number of important theoretical dimensions (e.g., duration, storage modality, capacity, neural underpinnings).

Pluralists suggest the time has come for emotion theory to undergo a similar transformation—that is, to take seriously the idea of multiple emotion systems, and possibly even multiple anger systems, multiple fear systems, multiple disgust systems, and so on (Scarantino, 2012a, 2012b, 2012c; LeDoux, 2012). Just as the fact that the folk psychological category of "memory" is not a natural kind is compatible with the existence of a plurality of more specific natural kinds of memory (e.g., short-term memory, long-term memory, procedural memory), so the fact that the folk psychological categories of "emotion," "anger," "fear," and so on are too heterogeneous to designate natural kinds is compatible with the existence of natural kinds of emotion, natural kinds of anger, natural kinds of fear, and so forth.

A possible moral of this chapter is that *universalist* theories of emotions are inadequate, although they each account for a portion of the empirical data and therefore tell us something valuable about what *some* emotions are. The inference to the best explanation for why, despite centuries of efforts, we have failed to unveil a *universalist* theory of emotions that accounts for all the empirical data on what we call emotion, fear, or anger in English while achieving all our other theoretical purposes is that there is not such theory to be found. Whether a *componential* or a *pluralist* strategy will bear more fruits in the long run remains to be seen. But as both strategies start from the shared assumption that folk emotion categories are too heterogeneous for the theoretical purposes of philosophers and affective scientists, they promise to deliver the sort of progress that has eluded universalist theories so far.

Acknowledgments

I have received excellent feedback on portions of this chapter from several colleagues and friends, including Julien Deonna and Fabrice Teroni (on the evaluative tradition in philosophy), Agnes Moors (on appraisal theory), Giovanna Colombetti (on situated approaches), Tim O'Keefe (on Aristotle and the Stoics), Jessica Berry and Eric Wilson (on early modern theories of emotions). I have also received feedback on the full chapter from Rainer Reisenzein, who made countless outstanding suggestions on various points of analysis (down to the sentence-structure level!). Eddy Nahmias, who also read the whole draft, gave me valuable advice on how to structure the chapter, and urged me to include charts and explain philosophical terms in more scientist-friendly terms. All these critical insights, delivered with great generosity and often soon after I had asked for them, have been enormously helpful. I am *very* grateful for them. All mistakes that remain in the chapter are, of course, my responsibility. I also wish to thank the Alexander von Humboldt Foundation for funding in the Spring 2015 semester during my stay at the University of Osnabrueck in Germany.

Notes

1. Aristotle's list, as several other lists I introduce in this chapter, contains some items that in contemporary taxonomies would clearly qualify as emotions (e.g., fear), other items that would clearly not qualify (e.g., emulation), and some borderline cases (e.g., calmness). I do not discuss the origin and import of these discrepancies in what follows, but they suggest that the overlap between the contemporary emotion category and the other affective categories I consider (e.g., passion, sentiment, affect) is only partial.
2. Aristotle does not explicitly associate all passions with either pain or pleasure. For example, he does not explain whether friendliness, kindness, confidence in the face of danger, contempt, and hatred involve either pleasure or pain. This is either an oversight on Aristotle's part or evidence that feelings of pain and pleasure are not strictly necessary for an Aristotelian passion to be instantiated.
3. The solitary exception is constituted by philosophy students, who indicate instead cognitive changes as being more important attributes than feelings.
4. Descartes also offers a description of the concomitant movements of the animal spirits that function as proximal causes of such passions.
5. Hume accepts that the passions can be unreasonable, but he thinks they are so only derivatively, namely by virtue of the judgments that accompany them (what we now call the *cognitive basis* of emotions; see the section "The Rise of the Evaluative Tradition"). For example, it is for Hume unreasonable to fear a person on the false assumption that he or she exists, or to buy a gift for someone we hate on the false assumption that he or she will suffer as a result. The mistake here, Hume thinks, does not lie with the emotion, but with our judgments about what exists or about what is a good means to an end.
6. This view contrasts with Descartes' analysis, according to which emotions represent the goodness or badness of things, and do so (most of the time) in an exaggerated way (James, 1997). But note that not everyone agrees that Cartesian passions are representational (see e.g., Greenberg, 2007, for a dissenting opinion).
7. Since James's theory is very similar to Carl Lange's (1885/1922) theory, independently developed at the same time, it is common to refer to the James–Lange theory of emotions. I will disregard Lange's contribution in what follows.
8. James's mature account, as Ellsworth (1994) first emphasized, also comprises an evaluative dimension, captured by the idea that the perceptions of the exciting fact that directly cause bodily changes are evaluations of the stimulus situation (see also Reisenzein, Meyer, & Schutzwohl, 1995). This aspect was added by James only in 1894, in response to critiques his theory had received from, for instance, Worcester (1893) and Irons (1894). These writers had argued that the same stimulus (e.g., a bear) can elicit different emotions in different subjects. James acknowledged that objects can be evaluated in different ways, and consequently lead to different emotions: "The same bear may truly enough excite us to either fight or flight, according as he suggests an overpowering 'idea' of his killing us, or one of our killing him" (James, 1894, p. 518).
9. In a footnote, James himself hinted at the possibility that some emotions may correspond to neural changes that have no counterpart in real bodily changes: "it is of course possible that the cortical centres normally percipient of . . . organic sensations due to real bodily change, should become *primarily* excited in brain-disease, and give rise to an hallucination of the changes being there. . . . Trance, ecstasy, &c., offer analogous examples—not to speak of ordinary dreaming" (James, 1884, note 4; see Prinz, 2004b; Reisenzein & Stephan, 2014, for further discussion).
10. Deigh (2001) has suggested that this passage does not offer conclusive support to the interpretation that Freud did not believe in the existence of unconscious emotions. On Deigh's view, appreciating that for Freud emotions can literally be unconscious is "essential [for] understanding Freud as having . . . broken completely with the Cartesian conception of the mind" (p. 1250).
11. The converse does not hold for James, as there are emotions not generated by instincts. James (1890) writes, "emotional reactions are often excited by objects with which we have no practical dealings. A ludicrous object, for example, or a beautiful object are not necessarily objects to which we do anything; we simply laugh, or stand in admiration, as the case may be." As a result, James concludes that "the class of emotional, is thus rather larger than that of instinctive, impulses, commonly so called" (p. 442).
12. Skepticism about the usefulness of the notion of emotional expressions is at the heart of Fridlund's (1994) *behavioral ecology view* of facial displays, which focuses on how facial changes convey social motives, and rejects the assumption that automatically expressing emotions to recipients is in the evolutionary interest of emoters. The view that facial expressions are largely audience-dependent has since gained wide ascendancy in the literature on emotional expressions (see Russell, Bachorowski, & Fernández-Dols, 2003, for a review).

13. Ryle (1949/2009) acknowledges that emotion terms may also refer to *feelings* that "wax and wane in a few seconds" (p. 85), but he describes them somewhat disparagingly as "thrills, twinges, pangs, throbs, wrenches, itches, prickings, chills, glows, loads, qualms, hankerings, curdlings, sinkings, tensions, gnawings and shocks" (p. 70).
14. We must distinguish this case from the case of action readiness discussed by Dewey (1894, 1895). A person can be proud in the Rylean dispositional sense even while he or she is sleeping, by virtue of what would happen were he or she to wake up, and were other circumstances to be fulfilled. But a person cannot be angry in the Deweyan dispositional sense while sleeping, because being angry in such sense requires the actual activation of aggressive behavioral options.
15. Several basic emotion theorists also assume that basic emotions are associated with distinctive hardwired neural circuits (e.g., Izard, 2011; Levenson, 2011). The debate on the existence of such circuits is unresolved (see, e.g., Panksepp, 2000; Panksepp & Biven, 2012; LeDoux, 1996; LeDoux & Phelps, 2008; Lindquist, Wager, Kober, Bliss-Moreau, & Barrett, 2012; Barrett & Satpute, 2013).
16. We should note the existence of a minority view within basic emotion theory that is *impulsivist* rather than *reflexivist*, in that it assumes that, except in rare cases, basic emotions lead to impulses to behavior rather than reflex-like behaviors (e.g., Levenson, 2011; Scarantino, 2014, 2015; see also Roseman, 2011).
17. Several social constructionists focus on the interpersonal social functions played by emotions while remaining agnostic on what emotions are at the intrapersonal level. But since they generally tend to emphasize the active side of emotions and the fact that emotions do not just happen to emoters but are means to fulfill ends, it seems fitting to include them as *sui generis* members of the *motivational tradition*.
18. Since the class of Stoic passions is not coextensive with our class of emotions, the claim that we should strive for *apatheia* is not equivalent to the claim that we should strive for freedom from all emotions. In fact, the Stoics explicitly admit some emotions as legitimate. The *good emotions* are labeled by the Stoics as *eupatheiai*, and three varieties of them are distinguished: joy (*khara*), will (*boulesis*), and caution (*eulabeia*).
19. Brentano (1874/1995) emphasizes a peculiar feature of the intentionality relation, namely that the object toward which a mental state is directed need not exist. This feature has led a number of philosophers to doubt that the intentionality relation can be explained in physical terms, because one of its relata need not exist in the physical world. Others have suggested instead that the intentionality relation can be naturalized despite this peculiarity (see, e.g., Mendelovici & Bourget, 2014, for further discussion).
20. As it turns out, Kenny (1963) was right on the assumption that there are conceptual entailments between emotions and formal objects, but wrong on the assumption that one must believe that a stimulus is bad in order to fear it, due to the phenomenon of rational recalcitrance (D'Arms & Jacobson, 2003). As I discuss later in the chapter, philosophers are now identifying emotions with mental representations other than beliefs to account for recalcitrance.
21. For an exploration of the complex connections between the three job descriptions for formal objects, see De Sousa (1987) and Teroni (2007). For skepticism about the usefulness of the notion of formal object, see Deigh (1994).
22. Although formal objects are generally instantiated by material objects, there are exceptions to this rule. In so-called *objectless emotions*, no material objects are seemingly present. For example, in objectless anxiety the world at large appears to be dangerous, without anything in particular appearing to be dangerous. Cases of this sort can be handled in several ways. Objectless emotions can be handed out to a theory of moods, or they can be considered to be emotions with an especially broad material object (e.g., the world at large), or they can be considered to be emotions without material objects. The discussion of these possible solutions and others lies outside the scope of this chapter.
23. See De Sousa (2002) and Salmela (2006) on the topic of emotional truth.
24. Some have also suggested that emotions provide reasons to act without motivating to act (see, e.g., Tappolet, 2010).
25. Reisenzein (2012) has recently distinguished among three main versions of the belief and desire theory in psychology and philosophy: the *causal view*, according to which beliefs and desires are causal preconditions of emotions but not constituent parts of them; the *part–whole view*, according to which beliefs and desires are parts of emotions; and the *fusion view*, according to which emotions result from the fusion between beliefs and desires.
26. Another notable neo-Jamesian account of emotions is Robinson (1995, 2005).
27. Two important formulations of the view can be found in D'Arms and Jacobson's *Rational Sentimentalism* (see D'Arms & Jacobson, 2000) and in Rabinowicz and Rønnow-Rasmussen's *Fitting Attitude Theory* (see Rabinowicz & Rønnow-Rasmussen, 2004).
28. As Scherer (2001, p. 28) puts it, all appraisal theories that have appeared in the last 40 years are

"based, at least in part, on the pioneering efforts of Arnold and Lazarus."

29. There is a rich debate in philosophy concerning whether emotions are natural kinds (see, e.g., Nussbaum, 2001; Ben-Ze'ev, 2000; Charland, 2002; Prinz, 2004a; Griffiths, 2004a; Scarantino, 2009, 2012c; Clark, 2013).

CHAPTER 2

The History of Emotions

Ute Frevert

The claim that emotions have a history might come as a surprise to those scholars who think of emotions predominantly as biological, chemical, neuronal, or cognitive phenomena. Those focused on such phenomena may assume that all feelings are innate and universal and can be encountered in any human being at any place and time. In recent years, historians have started to question this assumption. Alongside anthropologists and scholars of literature and art, they have identified a great variety of emotional concepts and expressions in different societies at different times. They have shed light on how language and culture set particular frames for experiencing emotions. Additionally, they have highlighted the fact that by tabooing certain emotions, societies render them invisible and, ultimately, obsolete. Conversely, emotions that are deemed positive and valued highly may become firsthand experiences for an increasing number of people.

This chapter introduces the reader to various aspects of how to deal with emotions in a historical perspective. It first provides an overview of the shifts that the concept of emotions underwent over time and in different regions of the world. It then examines how specific emotions have been defined, judged, and handled in different societies, offering a glimpse of the methodological problems faced by historians of emotions. Third and finally, it tackles the question of when and why historians became interested in the subject and what kind of stories they intend to tell.

What Are Emotions, Historically Speaking?

The term "emotion" is relatively recent. When English-speaking authors started using it after the mid-19th century, they parted from a semantic field that had been cultivated since antiquity. This field had been diverse in content as well as in regional scope, and it had included numerous words describing various bodily and mental states. In Sanskrit and Bengali, terms for emotions and thoughts, mind and heart were most frequently not differentiated. *Bhava*, for example, covered a wide range of emotional experiences, with connotations of perception, thought, and movement. Similarly, terms for cognition often implied feelings (McDaniel, 1995). In accordance to a perception of the world as fluid, the *rasa* theory, which was developed between 200 B.C.E. and 200 C.E., was based on the ayurvedic concept of the body as both physical and subtle. A *rasa*, which can be translated as juice or flavor, was thought to emerge in the subtle body as the outcome of a catalytic process. Aesthetic forms such as drama, dance, and poetry activated certain *bhava* (e.g., love, courage, disgust, anger, and pity) and transformed them into a purely aesthetic and transcendental *rasa*. Experiencing *rasa* thus served as "a preparation for, a sensibility to, and a cultivation of the emotional taste for divinity and supreme self-realization" (Lynch, 1990, p. 18; Pollock, 2012). Medieval devotional movements and social reformers later reinterpreted *rasa* as a mode of religious experience or *bhakti* (Reddy, 2012, pp. 223–289).

In China, Confucian philosophy was similarly uninterested in drawing a clear line of distinction between inner/outer, body/mind, and subjective/objective (Hansen, 1995). Living a harmonious life of *li* (ritual) and *jen* (goodness) entailed a set of social practices related to other people and one's ancestors. Emotions were thus "established, evaluated, and expressed in how we live" (Bockover, 1995, p. 174). They were not only thought to be motivationally indispensable, but considered to be important in themselves. A person who lacked the passions for the good clearly suffered from a deficiency in character. Since emotions were believed to be heavenly endowed, they were recognized as highly significant features of ethical life (Wang, 2008), although not quite as prominent as in Europe (Santangelo, 2003, 2007; Santangelo & Guida, 2006; Santangelo & Middendorf, 2006).

In the Western tradition, Greek philosophers used the term "pathos" when they examined emotional states such as pleasure and pain, fear and daring, and rage and hope. According to Plato, the human soul knew powerful *pathê* that energized the body and enabled it to expect pleasant or unpleasant feelings from a given object. Aristotle agreed with his teacher and stressed, as Plato had done, that human beings were to be educated from a very young age to feel pleasure and pain when appropriate (i.e., in relation to virtuous acts). Conceiving of the soul as the seat of passions, powers, and habits, he considered passions (e.g., "appetite, anger, fear, confidence, envy, joy, love, hatred, longing, emulation, pity") to be the primary movers of men. As such, they were virtue neutral. It was up to each person's powers and readiness to allow those passions to be felt, as much as it needed certain habits or virtues ("excellences") to deal with them in a praiseworthy and rightful manner (Aristotle, 1984, pp. 1744–1747).

An eminent philosopher and long-term tutor of Alexander the Great, Aristotle was not only concerned about individual ethics: Writing in the 4th-century B.C.E., he cared deeply about the political community and how it was governed. Public life in the *polis* depended on educated citizens who were not only able to lead a good life and engage in self-government but also well versed in the art of persuasive reasoning and discourse. In his *Treatise on Rhetoric*, he focused on how an orator's speech "stirs (their) emotions" and puts the audience "into a certain frame of mind." Pathos, like anger, pity, or fear, and their opposites, was thought to transform one's condition to an extent that judgment was affected (Aristotle, 1984, pp. 2155–2156; Gross, 2006. pp. 1–20).

Civic audiences in Ancient Greece, however, were not moved only by emotional persuasion: They also learned about pathos at the theater where they enjoyed plays, comedies, and tragedies alike. Here Aristotle strongly diverged from Plato's negative viewpoint. While Plato had cast a very critical eye on artistic mimesis since it allegedly drove people to indulge in orgies of passion, his student suggested that catharsis was a mechanism that generated the virtuous control of *pathê*. *Éleos* (sorrow, pity, compassion) and *phóbos* (fear, terror, scare) were not only evoked but brought into equilibrium. After experiencing those *pathê*, the audience was supposed to leave the theater in a purified and elevated state of mind, body, and soul (Aristotle, 1984, p. 2320).

Aristotle's writings on *pathê* offered philosophers a first glimpse of what might be called an ancient Western "theory of the emotions" (Cooper, 1996). Others have commented on how *pathê* figured in his moral psychology (Striker, 1996) and how he used them for "rational persuasion" (Nussbaum, 1996). For scholars of literature, his concept of poetic catharsis is particularly significant, especially since it had inspired early modern and modern theories and practices of theater (Belfiore, 1992; Munteanu, 2012). Yet historians have been reluctant to attribute excessive importance to a single author. Even though Aristotle is considered one of the giants on whose shoulders later generations of philosophers, theologians, and scientists could stand, it is far from clear to what extent his ideas and concepts provide adequate descriptions of what and how people in classical Greece actually felt (Chaniotis, 2012; Chaniotis & Ducrey, 2013). We return to this caveat in the section "What Kind of Emotions Matter When and for Whom?"

Aristotle was succeeded by another school of philosophical thought. The *Stoa* conceived of *pathê* as propositions and judgments that moved the soul in a certain way and direction. Whereas joy and pleasure elevated the soul, pain forced it to shrink and tighten. Fear caused it to recoil, while desire let it strive. Stoic philosophy was well aware that such *pathê* played an important role in people's lives, and they were not generally against them. Nevertheless, they urged their contemporaries to distinguish between good and bad *pathê*: indulge in joy but keep away from lust; be prudent instead of fearful; fight desire in favor of a sensible will. According to the Stoics, *pathê* should not be radically suppressed; instead they had to be well comprehended and processed. Wise men had to liberate themselves from the impulses of *pathê* in order to achieve *apatheia*, complete impassivity and peace of mind (Graver, 2007).

Stoic philosophy overall bore a great impact on Roman thought and literature. In his study on rage, Emperor Nero's teacher Seneca warned against the bad outcomes of an *adfectus* that reduced man's freedom of action and reasoning. He also advised his student to treat his future subjects with mild clemency rather than with haughty arrogance, and praised a conduct of life that sought serenity and harmony by tempering down passions and affections. As far as this last point was concerned, his teachings proved relatively ineffective as they did not prevent Nero from becoming one of the most voluptuous and violent statesmen in Ancient Rome (Braund & Gill, 1997; Sorabji, 2000).

What Seneca translated as *adfectus* from the Greek pathos and what Cicero called *perturbationes*, became of major concern for early Christian thinkers. As much as they criticized the notion of desire and associated it with carnal sin, they did not altogether condemn *passiones* and *affectiones*. The Stoic ideal of *apatheia* was not what human beings should pursue. Although *passiones* were thought to be signs of man's fallen state (and had thus been absent in paradise), they were considered God given. According to St. Augustine of Hippo, Christians had a right to *affectiones* of fear and desire, and grief and joy as long as their love of God was fairly ordered. But the human soul, as the seat of reason composed of intellect, will, and morality, could also become sinful and disordered and give root to evil passions such as jealousy, anger, envy, and licentiousness. This was seen as a willful process, depending on *voluntates* that turned away from God and focused on earthly desires (Dixon, 2003, pp. 29–35; Knuuttila, 2004).

Building on St. Augustine's writings but also taking into account Aristotle's work (that had been reintroduced to Europe, after long centuries of negligence or highly selective reception through Arabic translations) the work of the Franciscan monk Thomas Aquinas emerged during the 13th century as an impressive synthesis of former knowledge about affections and passions. Like St. Augustine, he chose *passiones* as a collective term defining them as active sensual appetites accompanied by a bodily transformation. Since *passiones* belonged to the sensitive part of the soul (*anima*), they occurred naturally and were neither good nor bad. Will did not have an original stake here, but was essential in order to mold, regulate, and channel the *passiones*. If reason held them in proper order, they were considered virtuous; if not, they led to sin (Dixon, 2003; Miner, 2009; Lombardo, 2011; Rosenwein, 2006).

Writing in Latin, Christian authors such as Augustine and Aquinas framed basic concepts of how to think about what people felt. Those concepts continued to be used by Europeans until the 18th century. When in the 17th century René Descartes took a fresh look at what he called *les passions de l'âme* (the passions of the soul), he claimed that they originated from so-called animal spirits (i.e., movements of the soul that reacted to outer impressions and, through the nerves, caused bodily organs to stir). Passions—defined as *des perceptions ou des sentiments ou des émotions*—thus had a somewhat exterior status in that they incited and predisposed the soul to desire certain things and keep away from others. By assuming a dynamic connection among the soul (located in the center of the brain), its spirits (fine matter of blood), and the body agitated by that matter, Descartes conceived of passions largely as "passive perceptions of bodily motions" (James, 1997, p. 94).

During the Age of Enlightenment, those bodily motions received increasing attention by medical doctors and scientists. While medieval thinkers considering passions as movements of the will had neglected the body and its physiology, French *médecins-philosophes* discovered the body as the seat of sensations and ennobled it as a mechanism of functional perfection (Vila, 1998; Williams, 1994). At the same time, the concept of the soul was widened so as to encompass passions and affections as a separate and independent faculty. While Christian thought believed the soul to comprise knowing/understanding and willing, 18th-century continental philosophy added a third faculty: feeling. According to Immanuel Kant, *Gefühl* was composed of affects and passions distinguished both temporally and morally. While affects were regarded as short-term eruptions of strong and immediate desires, passions appeared as long-term states of feeling that left room for evaluation and judgment. What mattered most, however, was that feelings were granted a proper foundational status and attributed independent causal power (Newmark, 2008).

This resonated well in an age of sensibility that had elevated feelings to the status of crucial tokens of humanity (Barker-Benfield, 1992). In 1765, the

French *encyclopédistes* held *la sensibilité* to be the mother of humanity. Without feelings, men would act like machines bereft of joy and sorrow, pleasure and pain. Although certain feelings might be more harmful than others, they all contributed to rendering human life exciting and worthwhile. Even passions that entirely consumed a person's heart and mind could eventually promote both his or her own happiness and the well-being of society at large (Frevert, Scheer, Schmidt, Eitler, Hitzer, et al., 2014, pp. 12–31).

Despite the fact that contemporaries still distinguished between various kinds of feelings and used different words for different states, such as "appetite," "sensation," "sentiment," "desire," "affect," and "passion," the 19th century gradually saw the vocabulary of feeling become more homogeneous. This was due to the triumph of science and its attempts to neatly classify and objectify empirical phenomena. In the Anglo-Saxon world, "emotion" turned out to be the overarching category, not without shedding most of the former vocabulary's diversity and subtleties (Dixon, 2003). When the American physiologist and philosopher William James posed the question "What is an emotion?" in 1884, he answered it by stressing the prevalent importance of the body. In his view, emotions were but perceptions of physiological disturbances. Those disturbances or changes occurred mainly on an involuntary and instinctive basis; they were processed through the sense organs that sent impulses to the brain, which then sent currents running down to muscles and viscera, and back again. Once those currents returned to the cortex, they were then perceived as emotions (i.e., they were felt rather than apprehended; Calhoun & Solomon, 1984, pp. 127–141).

In this sense, emotions were regarded as "a set of morally disengaged, bodily, non-cognitive and involuntary feelings" (Dixon, 2003, p. 3). And even though most 20th-century psychologists did not fully agree with all aspects of James's definition, they largely accepted the dichotomy between cognition and emotion. This was the price they paid for secularizing emotions and emancipating them from the Christian discourse on sinful vice and godly virtue. As much as this served the purpose of liberating them from moral judgment, it helped to establish a new distinction between cognitive reasoning and emotional feeling. Demoralization went hand in hand with somatization, and somatization signified universalization (Frevert, Scheer, et al., 2014). The notion that the body was an unchanging biological entity independent of culture implied that its movements and functions pertained to all human beings. Emotions thus acquired a universal character, as argued by Charles Darwin in 1872 and confirmed by Paul Ekman in 1998 (Darwin, 1998).

What was lost during this process of somatization and universalization was the idea that feelings comprised a wide range of different states, sensations, and perceptions. They not only varied in terms of temporality and intensity; they also differed in the way the body was affected or was thought to play a major or minor role. Furthermore, pre- and early modern concepts of passions and affections had emphasized social diversity. A person's feelings were supposed to depend on age, gender, social class, and ethnicity. Social contexts and religious beliefs were considered important framings of what could actually be experienced as passion, desire, appetite, or sentiment. The same held true for climatic conditions and physical habits as they were enshrined in certain professions and ways of life (Honegger, 1991). Unlike the climate, those habits could be altered *ad libitum* and were thus open to social intervention and education. In their wake, passions, affects, and sensations could change too.

Experimental psychology, as it developed and boomed from the late 19th century onward, tended to forget about the plasticity of emotions. Even when scientists acknowledged the "great varieties of human personalities and societies" and attributed them to the "innate plasticity of the affect mechanism, which permits the investment of any type of affect in any type of activity or object" (Tomkins, 1968, p. 219), they were far more interested in the mechanism itself than in its variability. Drawing heavily on evolutionary biology, mainstream psychologists disregarded differences in time and space and discarded both earlier concepts and non-Western traditions. There were but a few critics who questioned the hegemonic epistemology and alluded to "the possibility that the very objects of psychological discourse, and not just opinions about them, have changed radically in the course of history" (Danziger, 1990, p. 336).

As the short recapitulation of those opinions has shown, this possibility seems quite real. As much as reflections on, and perceptions of, the human body and soul have changed significantly throughout the last 2,000 or 3,000 years, so have concepts of feelings, passions, and affects. From the present standpoint this cannot be dismissed as false or "unscientific." Developmental psychologist Jerome Kagan (2007) recently reminded his colleagues that former emotion knowledge tended to be far more "robust" than what current experimental science had discovered (p. 1). Furthermore, this knowledge constructed its own reality by genuinely shaping what human beings could and would experience as emotional states and acts. If people, as the Confucian tradition held, did not distinguish between inner feelings and outer expressions, they were likely to take those expressions at face value. Conversely, modern West Europeans who grew up with a strong sense of the inner self might conceive of emotions as hidden states unreadable to anyone beyond the feeling person.

The claim that cultural diversity can shape concepts and experiences of "emotions" poses critical questions to the new discipline of affective neuroscience. Self-evidently, the discipline has little to say about the history of emotions since experimental analysis depends on living objects. But it might and should be open to a more nuanced and culturally informed inquiry into people's neuronal setup. If the brain is both biologically and culturally defined and possesses a high degree of plasticity, as neuroscience keeps reiterating, cultural traces might be identifiable on neuroimaging. Seeking help from anthropologists who have done extensive surveys on the social and cultural mapping of emotions in different parts of the world (Plamper, 2015), neuroscientists could develop new insights into how those mappings are reflected in the way that body and brain cells communicate.

What Kind of Emotions Matter When and for Whom?

Since the topic of emotions was first tackled in a systematic and explorative way, experts have come up with a wide range of different enumerations and taxonomies. Many present-day psychologists adhere to the concept of six or eight basic emotions that seem to be universally recognizable in people's facial expressions. The *rasa* theory applied in Indian drama, music, and theater knows eight to nine emotions that are rather distinctively expressed in facial gestures and less easily identifiable by non-Indian audiences. Descartes stressed the existence of six "primitive" passions of the soul (wonder, love, hatred, desire, joy, and sadness) from which all others derived their origin, while Spinoza recognized only three "primary emotions": pleasure, pain, and desire (Calhoun & Solomon, 1984, pp. 66–70, 79–85).

The manner in which emotions were classified and grouped together depended largely on the way in which they were explained and judged upon, as well as on the social practices and institutions to which they pertained. As a result, emotions were by no means distinct, stable, and finite entities. Whether and how they were experienced depended on their relative status in a given society. This status in turn was derived from the weight and impact of institutions that gave emotions meaning and credit. What love was and how it felt, for example, cannot be understood without knowing about the institution of marriage vis-à-vis nonmarital relations. What men felt when they invoked notions of pride and honor needs to be studied by examining, among others, institutions such as the military and their social ramifications. In a similar vein, pious emotions and practices of religious enthusiasm have to be contextualized as part of an emotional topography that reflects the relative importance of (organized) religion. Such investigations demand more than an interest in the history of philosophy or science: They need to be based on a thorough knowledge of social, economic, cultural, and political history in order to maintain a grasp of the complex compositions, meanings, and practices of emotions. To proceed on a comparative scale that includes different societies in time and space poses even more difficulties, and is still far beyond the means and linguistic abilities of most historians. Having said this, the following paragraphs focus on a small number of emotions that have already attracted a certain degree of historical attention and can thus be discussed with reference to their diachronic and synchronic plasticity.

Acedia/Melancholy/Depression

There is much talk concerning depression as the number one emotional disturbance in contemporary Western societies, with non-Western ones following at a fast pace. At the same time, conscious efforts are made to distinguish depression from other emotional states such as burnout, generally attributed to rising levels of stress and increased demands for overefficiency, self-optimization, and self-maximization in postmodern cultures. Yet there is no clear-cut definition of depression, either as an emotional state or as a biochemical description of a person's lack of self-confidence and initiative. Since the term entered the psychological lexicon in 1905, it has had a breathtaking and self-defining career. Over the years and decades, it has been recognized as a mental illness that affects up to one in five people at some point in their lifetime, at least in Western countries. Its symptoms include loss of interest or pleasure, sadness or barely any emotion, feelings of fatigue, guilt, helplessness, anxiety, and fear, often for little or no reason. The direct cause is nowadays attributed to neurobiological disorders with the level of neurotransmitters being either too high or too low (Lawlor, 2012).

Reading through the list of symptoms, one feels reminded of early modern descriptions concerning the state of melancholy. Melancholy used to be a favorite condition of mind and soul widely discussed by theologians, philosophers, and medical doctors. In antiquity it was thought to be caused by an excess of black bile, and was accompanied by sadness, low levels of enthusiasm, and no inclination to become actively involved. The German name was *Schwermut*, meaning that the *Gemüt* (which might be translated as soul) carried a heavy (*schwer*) load. Melancholy could express itself both through physical and mental symptoms, and was viewed as an internal state with ambiguity regarding its characteristics. In a famous engraving by Albrecht Dürer titled *Melencolia I*, dating from 1514, the female allegory was portrayed in a pensive mood. Instead of being overcome by anxiety, weakness, and inertia, she seemed to be immersed in a state of expectation, which in the 16th century was associated with creativity and ingenuity. During the early 17th century a cult of melancholy emerged in Britain; similar movements could be witnessed in late 18th-century Germany and during Romanticism (Clair, 2005; Radden, 2000; Schings, 1977).

While melancholy was thus supposed to be in close relation to an elevated state of self-reflection, *acedia* was not. In ancient Greek, acedia meant a kind of listlessness, of not caring or not being concerned with one's position or condition in the world. An English translation would be "sloth." In antiquity and during the Middle Ages, acedia was particularly noted as a problem among monks and other ascetics who led a solitary life. While religious passions ranked foremost in Christian, especially monastic life (Boquet, 2005; Nagy, 2000; Nagy & Boquet, 2009), "the sorrow of the world," in Thomas Aquinas's definition, was in sharp contrast to the kind of "spiritual joy" resulting from a person's close union with God. Acedia was thus perceived as a demonic intervention that could strike at any time, causing tedium or boredom. An overall laziness or refusal to work, a temptation that frequently befell the monastic at rest, was closely associated with tedium. Another characteristic of acedia was the lack of the desire to read or pray (Crislip, 2005; Irvine, 1999).

On the surface acedia, melancholy, and depression seem to share a number of characteristics. Yet there are also clear differences. First, the symptoms are not alike. Premodern sources talk about acedia's corporeal signs that range from mere sleepiness to general sickness or debility, alongside several more specific ailments: fever, pain in the limbs, and weakness in the knees. Second, and even more important, the interpretation of those signs was quite peculiar and would not fit into today's mental map. According to ancient beliefs the bodily signs did not just signal a certain state of mind: Instead, they demonstrated the presence of a demon, some external influence that invaded the body and transformed it for the worse. If the soul did not have the strength and willpower to cast off those influences and protect the body, one would fall prey to demonic illness. Somatic signs of the demon's activities thus meant that the spirit was too weak to fight and allowed the presence of sin and vice. Acedia ultimately placed guilt on the afflicted individual: his or her dedication to God was simply not strong enough. Consequently, acedia was considered a mortal sin, an affront to both God and the religious community.

This clearly affected the way in which people experienced and felt about it. For a 13th-century monk or nun, committing a mortal sin practically equaled a death sentence and was accompanied by profound soul-searching and painful feelings of personal guilt. By contrast, a 17th-century writer who felt his heart to be heavy had a completely different self-perception, which shaped his being affected by melancholy. Similarly, a person on antidepressants in the 21st century is equally far away from concepts of mortal sin and ideas about creative inspiration and apprehension. Knowing about neurotransmitters and synapses allows for an approach that differs from pondering over temperaments and fluids, demons, and sinning against God and community.

The general argument here is that the way in which a feeling state is labeled, framed, and contextualized deeply influences the way in which it is felt. Relating similar symptoms to diverse systems of reference (magic, religion, arts and sciences, neurobiology) affects the value attributed to them. This in turn has repercussions on the appraisal and experience of those states. What people feel and how they feel it is thus highly dependent on complex "emotional scripts" (Kaster, 2005) provided by social institutions. As these institutions undergo historical changes, their scripts and related emotional practices change too. Historians have only just started to investigate those changes—for instance, anger (Harris, 2001; Rosenwein, 1998; Stearns & Stearns, 1986) and fear (Bourke, 2005; Laffan & Weiss, 2012; Plamper & Lazier, 2012).

Pity and Compassion

An integral part of Aristotle's concept of tragedy and catharsis, pity might seem to be an "ancient" or "classical" emotion. But is the *éleos* that a 5th-century B.C.E. Athenian felt, identical or similar to the pity that a 20th-century Englishwoman might have experienced when watching a dramatic performance on stage (Wiles, 1997, p. 6)? Obviously, this question cannot be answered empirically. Historians, however, have cast serious doubt on the longevity of a general sense of pity by contextualizing literary and archaeological sources. As David Konstan (2001) writes, even in Greek and Roman antiquity, pity was not "a simple or uniform concept" but a complex emotion with numerous aspects. Moreover, it "underwent fundamental changes" over the course of a millennium (p. 1f). Pity was involved in the ancient practice of appealing to the judge or jury—something that is virtually unheard of in current judicial practice but was strongly endorsed by classical handbooks of rhetoric. Defendants asking for pity had to plead innocent, since pity depended on merit. Only those suffering from an undeserved misfortune could expect pity, which is why defendants in ancient systems of justice tended to affirm their innocence instead of expressing remorse or requesting pardon and forgiveness. Pity also relied on the distance between a suffering person and those who observed the suffering. While moral philosophers during the 18th century stressed that pity was a sentiment of sympathy toward a fellow human being, Aristotle claimed that "people pity just those things happening to others that they fear [may happen] to themselves" (pp. 73, 128–136). Furthermore, ancient pity was structurally connected to power: Only those who were in a position to show pity (and grant clemency) could afford it. In this vein, it was usually the fate of elders or women to beg for pity, and it was the powerful who either pitied or not.

Not each and every kind of suffering warranted pity. No one was supposed to feel pity for captured, tortured, and killed enemies. Neither slaves nor Christian martyrs deserved pity in ancient times. Later on, religious communities that preached the gospel of brotherly love and love of neighbor found no difficulty in denying it to those who did not belong and believe. This attitude only started to change during the 18th century. Playwrights reviving the Aristotelian concept of catharsis discovered pity as the most natural and most moral human faculty that should be cultivated by theater, literature, and music (Schings, 1988). Philosophers who sought a moral foundation for modern civil society praised pity and sympathy as counterforces of self-love and egoism. Novelists were eager to devise plots and stories that would elicit the readers' pity, inspiring them to become sensitive and sensible citizens. At the same time, hundreds of thousands of European and North American men and women campaigned for the abolition of slavery and the liberation of slaves. Spurred by an "imagined empathy" (Hunt, 2007, p. 32) and using a language of love for those "brothers" and "sisters" whose freedom and human dignity were trampled upon, they engaged in an unprecedented—and ultimately successful—struggle against the slave trade and the institution of slavery (Frevert, 2011, pp. 153–175).

Pity and compassion thus traveled across the Atlantic in both directions, connecting people from different regions, nations, and religions. This was enabled by a growing awareness of the world's integrative economy that delivered the products of slave labor (e.g., Caribbean sugar) to British tearooms. The spread and extension of compassion thus followed the increasing globalization of trade. Instead of being reserved for family members, close friends, neighbors, and fellow citizens, it began to encompass those whom one had never met and would never meet but whose fate could be imagined and felt as an all-human disaster. Geographical and social distance, however, had to be bridged by narratives. The media revolutions of the 19th and 20th centuries (with newspapers, radio, TV, Internet) generously provided those stories and, most important, added visual proofs of human suffering. "Distant suffering," as sociologist Luc Boltanski (1999) called it, thus became a prime object of global compassion yielding billions of dollars in human aid and donations (Wilson & Brown, 2009).

Tracing the history of pity/compassion as an ever more powerful and encompassing feeling thus cannot but acknowledge the deep impact of modern sensibilities that clearly departed from older and far more restricted notions of benevolence, charity, and neighborly love. Those sensibilities, however, were charged with cultural and political meaning. As much as they had to be taught, learned, and cultivated, they became part of a social capital that distinguished the haves from the have-nots. Colonial policies offer a glimpse as to how the social capital of compassion could be turned into a political asset. Emotional terms were often employed in order to justify the European urge to colonize non-European peoples: It was compassion for the misery suffered by Africans or Asians that rendered necessary the European presence among them (Rai, 2002). Even postcolonial humanitarianism frequently used this language of superiority, thereby stabilizing the close link between compassion and power and between suffering and powerlessness.

A global history of pity/compassion—which does not yet exist—would thus have to be aware of the structural asymmetry between those who pity and those who are pitied. Departing from the hitherto usual focus on new sensibilities toward suffering as they emerged and expanded during the 19th century, history should proceed further, concentrating on the men and women who were at the receiving end: How did they feel about the compassion they attracted, and how did they deal with it? Did gender make a difference? Could religion build bridges, or did it serve as a further obstacle? And what about those for whom this worldwide compassion affair was altogether irrelevant? We know a lot about European and North American humanitarian policies—state and nonstate—but we know far less about other parts of the world, other regional elites. Did they and do they share Western sensibilities and related practices, or did they and do they differ, and in what ways?

A Short Note on Methodology

Regarding emotions as practices is of the utmost importance to any history of emotions that aims to move beyond philosophical ideas about definitions and lists of emotions and their differentiation from allegedly nonemotional cognitive procedures. By this there is no intention of dismissing those ideas as mere thought material. In one way or another, they were indeed able to influence people's opinions, judgments, and behavior. The ancient Indian theory of *rasa*, for example, has had a long-lasting influence on Indian music, theater, and poetry, and even contemporary Bollywood movies. Aristotle's notions of pity as developed in his writings on aesthetics made a huge impact on 18th- and 19th-century European theater, as mentioned earlier. Similarly, his elaborations on emotional rhetoric continued to inspire modern orators and demagogues. In a similar vein, early Buddhist theories on empathy and compassion are still popular today and have been brought into a mutually fruitful dialogue with Western psychology (Dalai Lama & Ekman, 2008).

All these examples highlight a crucial point: The history of emotions is not so much a history of words and concepts, but of practices (Scheer, 2012). Words and concepts are interesting only to the extent that they inform, guide, and frame emotional practices, be it in art, prayer, and meditation, or in the diverse kinds of economic, political, and social communication. It is those practices that give emotion words their historically precise meaning. Without them, emotion words like "love," "hatred," "joy," "anger," "envy," "shame," and so on might claim an ahistorical presence thus confirming the conviction of many contemporary psychologists that emotions or affects are timeless as well as spaceless.

But how can historians discover and analyze emotional practices? Can they ever do without words? Do not words—printed on gravestones or monuments, written down in diaries and letters, transcribed in parliamentary minutes and legal documents—have to guide our search for practices? The answers are clear: Evidently, historians cannot conduct their research without relying on written sources, and so their work has to start with emotion words. As the literary critic Jean Starobinski (1966) commented: "For the historian, an emotion exists only beyond the point at which it attains a linguistic status. No facet of an emotion can be traced before it is named, before it is designated and expressed" (p. 81). This is correct. But what about Starobinski's next sentence: "It is not, then, the emotion itself which comes before us; only that part which has passed into a given form of expression can be of interest to the historian" (p. 81)?

There are two objections to this claim: First, what does the author mean by "the emotion itself"? He seems to imply that there is something beyond the expression, a kind of inner essence hidden and possibly unknown to the self. Such a distinction between a preconscious state of feeling and its defining expression is, however, highly dubious. On the one hand, it tends to overestimate the degree of consciousness that accompanies the expression of a feeling; on the other hand, it underestimates the constructive impact of that process. Expressing an emotion is a creative act: It bestows meaning on what is felt by labeling it and integrating it into a shared lexicon of understanding. To give an example: A person might feel a vague unease. But only after finding it a name (anger, shame, disgust etc.), is the person able to communicate it to him- or herself and others. Identifying the feeling means defining it, relating it to a cause, and acting on it. All this has a huge transformative effect on the initial feeling state by instantly giving it power and direction. Therefore, it seems futile as well as unnecessary to draw a clear line between "the emotion itself" and its expression. Such distinction tends to be counterfactual in that it overestimates the emotion at the expense of the expression. Instead, we should consider the expression as emotion *tout court* and not reduce it to the external part of something much greater that unfortunately does not "come before us" so that historians can never reach it.

A second objection to Starobinski (1966) concerns his implicit assumption that the "given form of expression" is always words. As argued earlier, words surely matter when it comes to labeling and thus defining an emotion. They set limits to what can be felt; at the same time, they offer opportunities to connect this feeling with other ones that are semantically related. But linguistic evidence does not reveal the whole story. The language of the body through mimics and gestures also contributes to that story, and so do spatial arrangements and material objects. Words are spoken in a particular context, and it is this very context that gives them meaning and communicative power. They are part of complex social practices, and even they themselves can be defined as practices. As the philosopher J. L. Austin (1962) famously explained in his theory of speech acts, we can "do things with words." To say "I love you" does not only define my feelings, but also makes suggestions about my current and future desires and related behavior. It might be an act of confession meant to initiate a chain of further communication. Or it might give confirmation to a relationship that has already been established but undergoes a period of doubt and crisis. In any event, it functions, in Austin's terms, as a "performative utterance"—or, in historian William Reddy's (2001) terms—as an "emotive," moving far beyond mere description and statement.

Furthermore, the word "love" implies promises and invites expectations of future practices that are firmly rooted in specific cultures and depend on historical circumstances. This is what renders emotional practices so important. If historians only focused on emotion words, as suggested by Starobinski (1966), they would miss the point. Emotion words lack a fixed meaning or status. They rather derive their meaning from the practices that they form part of. Those practices usually take place under particular social, cultural, political, or economic conditions that set limits to how emotion words can be understood and interpreted by those who speak, listen, and act. When present-day teenagers in the United States finish their phone calls to friends or family with the ubiquitous phrase "I love you," they say and mean different things than when they say it to the one they are attracted to. In other cultures, teenagers sometimes alter the phrase slightly in order to make space for different feelings labeled by the same word.

That love among friends might be different from love among lovers is not a new discovery. Since the late 18th century, when contemporaries praised both forms of love as the ultimate proof of upper- and middle-class sensibility, there have been numerous attempts to define each kind on its own terms. Although those emotional bonds have a lot in common, they were and still are linked to altogether different practices and aims. This shows once more that emotion words are not sufficient for historical research. Although the word "love" (or its equivalent in other languages) has been in use for a long time, we should not assume a stable, unchanging meaning (Orsini, 2006). The love that a medieval knight felt for his beloved was, presumably, quite different from the love that a 20th-century Indian stockbroker and his wife experienced for each other after their marriage had been arranged by their respective families. Since love was framed by different expectations and cultural scripts, it was similarly performed and acted upon through different practices and habits.

Shame and Humiliation

With regard to emotional practices, shame and shaming offer a highly instructive example. Shame is generally regarded as a social or moral emotion that is instigated by the awareness of having violated a social norm or moral law. In modern Western societies, shame tends to be private and individualized: A person feels ashamed once he or she realizes that he or she has done something of which others (whom the person cares about) would strongly disapprove if they knew about it. Shame can also occur when one fails to conform to one's own moral guidelines. One might even feel ashamed for someone else's embarrassing behavior.

Although shame depends on cognitive procedures—a moral law or social norm has to be known and remembered before it becomes violated—it is accompanied by certain physical signs that seem to be remarkably universal: People who are ashamed usually blush, and they lower their head and eyes. Describing their emotional state, they talk about wanting to disappear from the face of the earth. This again testifies to shame being a social emotion that involves others as witnesses, commentators, and guardians of moral/social standards.

But shame is not an automatic response to a certain kind of behavior. It is learned from early childhood, taught by adults, institutions, and the media. Parents demand children to feel ashamed if they have misbehaved. Teachers at school do the same and use shame sanctions as a way of punishing a student's deviance. Children's books published in increasing numbers from the 19th century onward describe how their young heroes experience shameful situations and suffer the consequences. Advice manuals and self-help literature inform adolescents and adults about how to avoid shaming others and how to react when they witness such behavior (Frevert, Eitler, et al., 2014). More recently, films and videos posted on the Internet provide ample evidence of shaming acts and their meaning for those who participate in them.

Shame thus is a feeling that needs education and cultivation. Before one can experience it, one has to learn the rules and their importance. Those rules are by no means universally valid. Societies differ greatly as to what they consider shameful behavior (in most Western societies spitting in public, or in India blowing one's nose in public—and not vice versa!). But they also differ internally, for instance, by setting different rules for men and women. Until the latter part of the 20th century, most European and North American girls grew up with a sense of bodily shame that their brothers never had to share. Girls were taught that it was shameful to expose certain body parts, and, later in their lives, to engage in premarital sex. An illegitimate child brought shame over the mother and the family (including the child); it often led to the "fallen woman" being cast out and having to move away. According to the official mantra, women's shamefulness served as a cornerstone of moral decency and social stability. Shameless women were women without honor and deserved public contempt.

This sheds light on deliberate acts of shaming, such as disdainful looks, derogative comments, and exclusion from "good society" that was reserved for women with children born out of wedlock. But shaming practices usually start much earlier. When mothers or fathers tell a child to be ashamed ("Shame on you") in a reproachful and authoritative voice, they can trigger a chain of reactions that eventually results in the very feeling to occur. For generations, school teachers developed elaborate practices of shaming those students whom they thought guilty of unruly behavior: They had them wear a donkey's hat, or, more mildly, had them stand in a corner of the classroom with their back to the other students. Exposing pupils in such a humiliating manner and making them the object of public attention and, possibly, *Schadenfreude*, was considered a more effective punishment than giving students a simple flogging or forcing them to stay behind after school.

Such shaming practices have only recently become obsolete. Under the battle cry "shame is over" (Meulenbelt, 1980; Millet, 1975), the second wave of feminism successfully fronted the shame verdict issued against women who had transgressed the strictly prescribed gender roles. Pedagogues warned that placing children and adolescents in a shameful position and making them the target of collective ridicule was not only counterproductive, but also reduced their sense of self-esteem and impinged upon human dignity. More often than not, those practices produced the opposite of what was intended: instead of feeling shame about what he or she had done, the shamed person harbored resentment against those who had inflicted shame on him or her, and openly rebelled against what the person perceived as humiliating.

However, criticism of shaming as a pedagogical tool was not universally accepted. As a recent BBC documentary showed, shaming practices continue to be used in Chinese elementary schools. In one incident, a little boy who had not taken good care of his eraser was reprimanded by his teacher in front of his classmates. As a shame sanction, he was made to wear a torn sweater. At the end of the day, he was allowed to take it off, and in turn promised to never be negligent about the eraser again. So the class welcomed him back, and the whole process was celebrated as a successful move to morally correct and reintegrate a trespasser (Chinese School, 2008).

The Chinese teacher obviously did not consider her sanctions as humiliating for the little boy. Rather, she intended to shame him in front of his peers in order to enforce the standard model of a good student's behavior: Take care of your study tools and chores, and be a competent and reliable member of the school community. Singling him out and ostracizing him for a day (while wearing the torn sweater) was supposed to make him feel lost and lonely, which was then succeeded by the heartwarming experience of returning to the community. The lesson for the boy was that he should feel ashamed about his misdemeanor, and that he should never repeat it or else he would suffer shameful exclusion.

Such tactics would no longer be endorsed in the Western hemisphere, where shaming has lost currency, both in schools and in the wider public. As explained earlier, shaming is generally held to be a violation of human dignity and the duty of respect. In highly individualistic societies that put personal autonomy first and community values second, public shaming seems no longer acceptable. Instead, it is judged as an act of humiliation, of degrading a person below the level of dignity that every human being deserves by right.

Europe's past cultural landscape, however, had been entirely different. For many centuries, public shaming had been a staple in local jurisdiction. Each town had stocks or a pillory where petty criminals were held for a few hours or even days. Placed in the marketplace or on crossroads, pillories were often elevated on a platform so that the gathered crowd would be able to watch the offender. The idea behind this was to publicly shame someone who had brought shame upon him- or herself by failing to comply with social norms and laws and thus insulting the community to which he or she belonged. The offender had to endure public contempt and ridicule, being exposed to the townsfolk in a demeaning, helpless, and uncomfortable position, without, though, being excluded from the community permanently. Meant to deter others from committing a similar transgression, the pillory served as a short-term punishment, which, unlike branding, did not leave any visible marks. Even if people remembered the incident, it did not match the exclusionary effect of the scarlet letter "A" (for adultery) in Nathaniel Hawthorne's 1850 novel (Nash & Kilday, 2010).

Shame sanctions thus particularly suited a society that spelled "community" with a capital "C" and placed individuals under its command. The more people emancipated themselves from that command claiming personal autonomy and independence, the more shame receded from the public interest. The new language of human rights and dignity that started to be spoken from the 18th century and, with ever greater force, after World War II, identified shaming as a practice of top-down humiliation. By linking humiliation to power and hierarchy, it was judged as incompatible with democratic practices and civic equality. Humiliation was the predicament of slaves at the hands of their masters who treated them in a disdainful manner. Humiliation was employed when state anti-Semitism as practiced by the National Socialist regime forced Jews to wear the yellow star or clean public toilets with their toothbrushes. Humiliation was involved in instances when the quest for equal and respectful treatment was denied. In this vein, women talk of the humiliating experience of being raped, and homosexuals have long stories to tell about humiliating homophobic slurs and assaults.

Humiliation is therefore closely associated with the concepts of human rights and individual dignity—concepts that were basically nonexistent in premodern societies and are still not popular in countries such as today's China. Shaming, by contrast, draws on the concept of a community or group whose norms and values have to be reinstated once a member of that group or community has violated them by offending his or her peers. Even though both practices might occasionally appear similar, sharing certain traits (e.g., ridicule), they follow a different logic and are structured by a different language. Consequently, they produce different emotions: Feeling humiliated is not the same as feeling (a)shamed. Feeling humiliated (as a slave, Jew, woman, homosexual, etc.) has different roots and calls for other actions compared with feeling shame (about one's own or someone else's offense).

Historicizing Emotions: A Political and Cultural History

Despite some initial attempts (Miller, 1993; Williams, 1993), the history of shame and humiliation has not been written yet—except, of course, for Norbert Elias's (2000) seminal study of *The Civilizing Process*. First published in the late 1930s, Elias's book presented a narrative of European history that deliberately linked sociogenetic and psychogenetic developments. He argued that state building in early modern Europe went hand in hand with installing stricter norms of self-control. Since the state monopolized physical violence, citizen subjects could form societies engaging in peaceful competition. Faced with increasing social differentiation and rising levels of interdependence, those societies were keen on coordinating and fine-tuning human behavior. In its wake, people's affective apparatus gradually changed so as to incorporate more restrained modes of conduct and interaction. Instead of giving in to spontaneous desires and strong affects, human beings learned to hold back, think twice, and reflect on the consequences of their actions. This is what Elias called "rationalization" and attributed it to the European nobility whose members transformed themselves from fierce warriors and knights into polite and polished courtiers from the 16th century onward.

During that transformation, shame thresholds were exponentially raised. Manners (concerning for instance, spitting, defecating, and cursing in public) that had been considered normal and acceptable in earlier times were now turned into something utterly despicable and shameful. As the fear of losing face, reputation, and honor in front of one's peers gained prominence, shame became a central regulator of human drives and appetites. It helped to internalize social demands by translating them into individual or psychic constraints. At the same time, the early modern period saw the boundaries of shame and embarrassment expanding, encompassing evermore modes of behavior and extending to evermore social strata (Elias, 2000).

Writing in the 1930s, Elias's intention was not to cast an overly positive and optimistic light on what he identified as a Europe-based process of civilization and rationalization. Although he criticized psychoanalysis for its lack of historical and social understanding, he still borrowed from Freud's language of "drives" and "superego." Behind the ever increasing thresholds of shame, he argued, lay the ubiquity of fear: man's fear of social degradation, of someone else's superiority, of his own vulnerability and defenselessness. Those fears were kept in check by the state and its stable monopoly of violence that allowed for the pacification of social interaction and communication. But, as Elias added, this particular arrangement was open to change, and the hitherto productive tension between fear and shame could be reversed in its wake. He remarked, toward the end of his book,

> At present, we are so accustomed to the existence of these more stable monopolies of force and the greater predictability of violence resulting from them, that we scarcely see their importance for the structure of our conduct and our personality. We scarcely realize how quickly what we call our "reason," this relatively farsighted and differentiated steering of our conduct, with its high degree of affect-control, would crumble or collapse if the anxiety-inducing tensions within and around us changed. (2000, p. 441)

Keeping in mind that Elias, who was born into a German–Jewish family, left his home country in 1933, wrote *The Civilizing Process* in British exile and published it in Switzerland in 1939, the year of Germany's attack on Poland and the beginning of World War II, those final sentences still seem to lack political acumen. Although the author had by then witnessed numerous instances of state-induced loss of affect control in German politics and society, he could obviously not imagine that "reason" would collapse altogether, giving way to an upsurge of anxieties and the breakdown of public decency. The narrative of progressive civilization and rationalization was too powerful and had too much to offer for it to be questioned and challenged. It took Elias another 20 years to acknowledge that civilization could and had indeed collapsed or regressed under the Nazi regime (1996, pp. 299–402).

The narrative of rationalization had not been invented by Elias. It can be traced back at least to Max Weber, who had published his complex analyses of modernity some 30 years earlier. Weber saw modern societies becoming increasingly rational and thus predictable. As members of market classes, people became accustomed to acting instrumentally, carefully relating means and ends. Instead of following culturally defined habits and moral duties, they organized their behavior so as to follow their own economic, political, or social interests. In order to achieve those goals, they learned to control their passions, hold back their immediate impulses, and channel their energy into promising fields of action. Rationalization thus was accompanied by an increasing level of self-reflection and self-evaluation that, at the same time, included awareness of other people's interests, strategies, and conduct. It was aided by institutionalizing rules and norms that rendered individual behavior uniform, regular, continuous, and, thus, transparent and predictable to others. According to Weber (1968), a major force and proponent of rationalization was capitalism, which by 1900 had pervaded all parts of modern life, with the exception, perhaps, of erotic life and art (pp. 340–483).

Although Weber, just like Elias some decades later, was not uncritical toward capitalist rationalization, he had a sound grasp of its overall advantages. Those advantages had already been spelled out by early modern authors who, in Albert Hirschman's words, sang capitalism's praise long "before its triumph." In their view, capitalism, *le doux commerce*, would eventually tame the wilder passions and turn them into far less disturbing interests that could be jointly realized in mutual harmony and peaceful cooperation. The calculating spirit of capitalism, as Weber, Joseph Schumpeter, and John Maynard Keynes perceived it later, did not lend itself to passionately heroic adventures or other tyrannical pursuits of self-aggrandizement (Hirschman, 1977).

Notwithstanding the fact that capitalism could be—and indeed was—conducive to no less violent pursuits of colonial exploitation and, as recent crises revealed, destructively short-term maximization of private profit, it seems noteworthy that even those intellectuals who had a clear and critical grasp of its pitfalls and dangers still praised its rationalization potential. They considered this a major achievement and contrasted it to a picture of precapitalist and prerational societies that was painted in very dark colors. The exuberant passions that medievalist Johan Huizinga (1919/1996) saw reigning in the late Middle Ages were frowned upon by the heirs of the Enlightenment heralding accountable bureaucratic rule and rational science. They despised both the risibility that had allegedly characterized the 14th and 15th centuries, as well as the grim hatred and the unrestrained violence that ensued.

The French historian Lucien Febvre shared this profound distrust of passions and emotions. As an expert on the 16th century, he was deeply troubled by what he observed in his own times: an overabundance of what he called "primitive feelings." Among his contemporaries, he witnessed "revivals of the cult of blood, red blood," of the "cult of Mother Earth" and the healing sun, a quest for "cruelty at the expense of love." He found emotions dominating over reason and hailing "animal behavior," and he warned that those emotions might soon turn the world into a "stinking pit of corpses" (Febvre, 1973, p. 26). Without presenting a stringent narrative of emotional development, as Elias did in 1939, Febvre obviously shared the general misgivings about excessive passions trumping reason and, in his view, erupting in bloody violence and the destruction of civilized society. This is why, in 1938, he strongly urged researchers to tackle emotions as a subject of historical inquiry. His first lectures in liberated Paris thus dealt, for obvious political reasons, with the topic of *honneur et patrie*, honor and fatherland—which both Vichy France and Charles de Gaulle's Free France had used as highly emotional catchphrases and mobilizing slogans during World War II (Febvre, 1996).

When Febvre turned his attention to the history of emotions—or sensibilities, as he preferred to call them—he did so with a sharp sense of cultural and political despair. His generation had witnessed what they perceived as the downfall of European civilization and the return of barbaric feelings and practices, a lack of reliable processes of continuous rationalization and refinement, and no progress toward greater freedom, equality, and solidarity. Rational insights and mutual respect could easily be brushed aside by "irrational" claims that drew on allegedly archaic drives and desires. Studying those in their precise historical settings and contexts, avoiding assumptions about unilinear and general trends, was meant as a project of radical self-enlightenment and disillusionment.

It is precisely this cautious attitude toward generalization and linearity that continues to prevail among scholars who have followed Febvre's lead. They include the historians of the Annales school, who focused on the history of mentalities and herewith increasingly included senses, sentiments, and sensibilities (Corbin, 1995; Flandrin, 1979). In his five-volume study of the "bourgeois experience from Victoria to Freud," American cultural historian Peter Gay (1984–1998) likewise focused on the "education of the senses." Covering the long 19th century and drawing on a wide range of primary sources from European and North American societies, he scrutinized sexual desire as much as the tender passions of love, the cultivation of hatred, aesthetic tastes, and the various attempts to discover the secret life of the self. While Gay was more interested in the emotional experience of individuals than in normative prescriptions and regulations, Carol and Peter Stearns embarked on an equally ambitious project of unraveling "emotionologies" (i.e., "the attitudes or standards that a society, or a definable group within a society, maintains toward basic emotions and their appropriate expression"; Stearns & Stearns, 1985, p. 813). Firmly placed in social and gender history, this approach materialized in multiple volumes of American emotional standards as they evolved during the modern period, ranging from jealousy to fear and anger, from parents' anxiety about child rearing to coolness as a distinct 20th-century emotional style (Stearns, 1989, 1994, 1999, 2004, 2006).

Interestingly, both Gay's and Stearns's projects largely remained individual enterprises that did not trigger a wider and broader disciplinary interest (with a few exceptions: Matt 2003, 2011; Matt & Stearns, 2013). At best, they were considered more or less useful additions to social and cultural history that flourished in consecutive order from the 1970s onward. It took the profound irritation of postcolonial theorizing and the radical suggestion of cultural relativism to have a new generation of historians take an interest in the history of emotions. Reading anthropological studies that, rightly or wrongly, asserted the nonconformity of emotional concepts and practices with those familiar from the Western tradition, historians felt encouraged to look at historical sources of emotions in a decidedly nonessentialist way. At the same time, the burgeoning field of neuroscience, assisted by newly available techniques of neuroimaging, suggested a novel take on emotions: Rather than confirming the older European tradition of strictly distinguishing between rational elaborations and irrational or emotional feeling, studies delineated the close connection and interaction between both processes. Held against the long devaluation of emotions to the benefit of reason, such findings served to "ennoble" emotions, investing them with strong cognitive meaning, and vice versa.

In order to make sense of the recent interest in the history of emotions, however, it is not enough to draw attention to developments in science and humanities proper. Historiography does not only receive incentives from various scientific fields; it is also influenced by, and takes account of, experiences that are part and parcel of historians' own contemporary culture. It seems that this culture entertains an intense love affair with emotions. Starting with the therapeutic wave of the 1970s and the vastly increased interest in the self, emotions have taken center stage, in self-help literature as well as in the numerous therapeutic cures of body and mind. They were discovered and highly valued by new social movements that used them as mobilizing forces, but also sought to emancipate them from "repressive" forces such as religion, social mores, or, *tout court*, rationalizing capitalism. This went hand in hand with the perception of emotions as basic, authentic, and non-negotiable. It did not take long for consumer societies and advertising industries to utilize this perception as a unique selling point. Products sold better if they were coated in positive emotions.

This is what cultural sociologist Eva Illouz (1997, 2007) called "emotional capitalism." Her studies have focused on how emotions like romantic love became commercialized and connected to a wide range of objects and goods. Trust can serve as another case in point: As much as trust talk has become ubiquitous in contemporary Western societies, more and more companies and businesses use it in order to market their services and appeal to customers' emotions (Frevert, 2014). Emotions have thus been pushed into the center of economic and political attention, with evermore penetrating efforts to read and understand the affective lives of citizen consumers.

While many sciences—from affective neuroscience and computing to behavioral economics—enthusiastically contribute to, and participate in, this surge of interest in emotions, historians are facing a different challenge. What they have to offer is critical distance and contextualization. Instead of focusing on short-term and fractioned phenomena, they situate them in a wider and broader context that includes cultural as well as social, economic, and political processes. They can thus provide a far more nuanced and complex perspective of contemporary developments by reading them against the background of preceding events, trends, and constellations. Theirs is both a genealogical and a critical endeavor: unearthing and unveiling the way in which people have thought, felt, expressed, and experienced emotions in history, while, at the same time, keeping in mind and emphasizing that emotions are themselves products of history, undergoing shifts both in content and shape. Those changes are not always easy to detect, and they do not proceed in a linear direction, neither within a given country or region, nor on a global scale.

CHAPTER 3

The Sociology of Emotion

Kathryn J. Lively and Emi A. Weed

Since its introduction nearly 40 years ago, sociological interest in the study of emotion has flourished. Today, it is no longer necessary to defend the role of emotion in social life. Indeed, emotions and their consequent processes are recognized as relevant and crucial, to many—if not all—aspects of society. In addition to drawing on numerous theoretical perspectives (see Stets & Turner, 2008; Stets, 2005, for recent reviews), sociological scholarship on emotion includes a variety of substantive topics. Nearly all this scholarship begins with a shared question: How do historically and culturally specific norms influence the experience and expression of emotion, and to what degree are emotions structured by one's position within groups, organizations, and social hierarchies?

Building on this common foundation, sociologists of emotion have turned their attention to a wide range of subjects, including the socialization of emotion in both children and adults; processes of intra- and interpersonal emotion management; emotional deviance; how emotion is sold for a wage and the consequences thereof; the role that emotion plays in the creation and maintenance of individual and group identities, small groups, and stratification hierarchies; the relationships among emotion, stress, and mental health; and the role emotion plays in the creation of social movements and social change. This chapter is not meant to be a comprehensive review of the field—such a task would be impossible. Instead, we present a sampling of the types of research that arise from a sociological perspective on emotion as well as opportunities for future research.

We begin by introducing sociological definitions of emotion as well as two broad theoretical paradigms used by sociologists studying emotion: the cultural perspective and the structural perspective. We then address a number of relatively well-studied substantive areas, before introducing new lines of inquiry in the field. In particular, we identify two areas where we see the greatest opportunities for interdisciplinary growth in the field of emotion: emotion regulation (Grandey, Diefendorff, & Rupp, 2013; Grandey, 2000) and affect control theory (Heise, 2006; Lively & Heise, 2014; Rogers, Schröder, & von Scheve, 2014).

Sociological Definitions of Emotion

Sociological definitions of emotion usually assume that emotions are inherently social. Hochschild (1983), for example, likens emotions to senses that signal what is personally relevant about surrounding social events. Similarly, Thoits (1984) posits a four-factor model of emotion, which suggests that emotional experience comprises four factors: physiology, cognition, emotional expressions, and emotion words. According to Thoits's model, the four factors of emotion—physiology, cognition, expression, and labeling—are interdependent, and most sociologists assume that a change in one may lead to a change in the others (Francis, 1997; Pollak & Thoits, 1989; Thoits, 1995).

Although recognizing the utility of Thoits's four-factor model, Lively and Heise (2014) have recently defined emotion as "responses to events that are linked with corporeal manifestations" (p. 68). Their streamlined conceptualization recognizes the possibility of "ineffable emotions," or emotions that are marked by particular physiological experiences and facial expressions, but are often not yet recognized or labeled as emotions, per se, and are detectable in both computer simulations and photographs, as well as lived experience.

Cultural and Structural Perspectives on Emotion

Sociological analyses presuppose that human behavior and interaction are constrained by individuals' locations in social structures, which are themselves influenced by culture (Stets & Turner, 2008). Most sociologists tend to view structure as one's position within a social network or as a set of status positions that grant access to various levels of prestige or other resources (Lawler & Thye, 1999; Ridgeway, 2011), whereas culture most often refers to a set of symbols and meaning that people create or use to regulate their behaviors, interactions, and emotions (Heise, 2006; Stets & Turner, 2008; Swidler, 1986).

From this perspective, individuals are seen as occupying roles (e.g., mother, teacher, surgeon) within sets of positions (e.g., an organization, an institution, a social structure) that are regulated by rights and obligations between role partners and systems of cultural symbols (e.g., words, expressions, norms). In keeping with this view of human behavior, the sociological approach to emotion also assumes that the emotional arousal, cognitive appraisals, expressions, and language that compose emotional experience are constrained by both culture and structure.

Although most sociological studies of emotion contain elements of both culture and structure, much of the existing empirical scholarship tends to privilege one over the other (Clark, 1997; Kemper, 1978; Simon & Nath, 2004), which can lead to complementary, if not incomplete, results (Lively & Powell, 2006).

The Cultural Perspective

The idea that emotions are socially patterned in large part by feeling rules—that is, culturally and historically variable norms defining what should be felt and expressed in various situations—was first introduced by Arlie Hochschild in 1975. Today it is well established that cultures differ in which emotional experiences are encouraged or discouraged (Wei, 2014; Smith & Francis, 2005). This leads to important differences in behavioral dispositions and expectations, which are historically specific (Lofland, 1985; Stearns & Stearns, 1989).

Candace Clark's (1997) seminal work on sympathy in everyday life exemplifies the cultural perspective. In this piece, she compares the emotion culture regarding sympathy in the United States to that of the Ik, a tribal community known for their marked lack of sympathy. With their tendency to laugh when older group members fall down or to simply watch when an unattended child walks toward an open fire, the Ik provide a stark contrast to most Western cultures, whose members tend to be sympathetic toward the elderly, children, and those whose misfortunes seem largely beyond their control.

Clark's (1997) corresponding analysis of the U.S. emotion culture, by contrast, details a sympathy economy governed by an elaborate set of rules, under which individuals are automatically granted certain amounts of sympathy (or "sympathy margins") as a function of their age, gender, social class, and so on. As individuals move through daily life, they draw upon and invest in sympathy "accounts" (much like a bank account) by asking for sympathy and providing it to others. Using a range of methodologies, including content analysis, vignette studies, observation, and interviews, Clark identifies four sympathy rules to which individuals are expected to adhere in order to avoid becoming overdrawn. These include not making undue claims to sympathy, not asking for too much sympathy, asking for some sympathy, and reciprocating once sympathy has been received (see also Charmaz, 1980; Lofland, 1985).

In addition to providing cross-cultural comparisons, the cultural perspective takes into account how feelings, and expectations regarding them, change over time (Stearns & Stearns, 1989; Stearns & Lewis, 1998). This perspective also reveals how emotion norms vary by actors' social status characteristics (Harlow, 2003; Lively & Heise, 2014; Pierce, 1995; Wingfield, 2010), their social and historical circumstances (Cancian & Gordon, 1988; Cancian, 1987; Hochschild, 1979; Lofland, 1985), and their participation in localized subcultures (Heise, 2007; Hunt, 2008; Ritchie & Barker, 2006; Smith-Lovin & Douglas, 1992).

As illustrated above, cultural approaches to the sociological study of emotion tend to focus on rules and cultural expectations that emerge over time and govern emotional experience and expression. Still, scholars who identify more with this paradigm do not ignore social structure entirely, as evidenced by their attention to how the emotional norms that guide emotional experience and expression are influenced by structural considerations, such as gender (Cancian, 1987; Hochschild, 1979; Pierce, 1995), race (Durr & Wingfield, 2011; Harlow, 2003), relative status (Clark, 1997), social role identities (Lively & Heise, 2014), access to tangible and intangible resources (Lofland, 1985), and, as we see below, occupational position (Hochschild, 1983; Lively, 2000; Sutton, 1991).

The Structural Perspective

In addition to the effects of culture, emotional experience and expression are likewise shaped by social structure. As noted previously, social structures can refer to status characteristics, one's position in a group or dyad, or one's membership in organizations.

Unlike the cultural perspective, which focuses on the more socially constructed aspects of emotion and the degree to which emotions are subject to acts of management, the structural perspective tends to focus more on the emotions that individuals experience as a result of their perceived, if not actual, structural conditions. An exemplar of this approach, Kemper's (1978) social interactional theory posits that most emotions can be determined by two fundamental dimensions governing social interactions: power and status (see also Kemper & Collins, 1990).

According to social interactional theory, when individuals experience the levels of status or power they expect during the course of a social interaction, they are predicted to feel content or happy. Experiences of excesses or deficits along these dimensions, however, produce certain distressful emotions depending on whether one attributes the cause to one's self or others. For instance, if an individual loses status as a result of his or her own incompetence, embarrassment is expected. However, if he or she loses status as a result of another's actions, anger is the expected response.

Consistent with the structural perspective, sociological stress researchers have argued that individuals who occupy disadvantaged positions within the larger social structure may also experience more negative emotions than those individuals who occupy more privileged positions (Simon & Nath, 2004; Simon, 2007; Simon & Lively, 2010). For instance, Simon and Lively (2010) suggest that women's higher levels of self-reported distress—a problem that has puzzled mental health scholars for decades—is likely a function of their structural position relative to men, which causes them to experience more intense and enduring anger (see also Collins, 2004). Notably, Ross and Mirowsky (2003) attribute the increased *positive* affect reported by the elderly to structural changes in living conditions, including elders' involvement with smaller networks, few mandatory roles, and the absence of children in the home (see also Evenson & Simon, 2005).

While stress research tends to be concerned with broader systems of seemingly enduring inequality, unlike the most interaction-based theories of emotion cited above (Kemper, 1978), both approaches generally assume that emotions arise more or less automatically as a result of structural arrangements. Thus, from the structural perspective, emotion is less something to be shaped, but is instead a rational response that signals an individual's standing within the context of a face-to-face interaction or acts as a sign of the perceived social and structural conditions in which he or she is embedded (see Hochschild & Machung, 1989; Hochschild, 1983).

Taking each of these perspectives as a backdrop, we now turn our attention to a number of substantive areas of interest within the sociology of emotion. We begin with the process of childhood socialization before turning our attention to the emotional lives and experiences of adults, organizations, and societies at large.

Emotional Socialization

Emotional socialization refers to the processes through which members of a society learn the expectations, rules, practices, and consequences of emotional experience and its display (Johnson, 1992). Young children are taught about emotions both explicitly and implicitly, most often by parents and teachers. For example, Pollak and Thoits (1989) found that children attending a therapeutic day care center for those with emotional difficulties were taught explicitly how to link emotion words ("sad" or "angry") to physiological experiences (an upset stomach) and events (being dropped off at school). The goal, rather than to teach students to manage their emotions in appropriate ways, was to get children to understand the causes of their emotions, to express them properly, and to understand their consequences. Notably, Leavitt (1994) documented analogous messages, as well as lessons involving emotion management, in her study of day care settings geared toward more general custodial care.

Although adults tend to be the primary agents of emotional socialization for young children (Johnson, 1992), by adolescence, teens are active in their own and others' socialization processes (Corsaro, 2005). Simon, Eder, and Evans (1992), for example, found that adolescent girls created new, and sometimes contradictory, norms about romance, while also mirroring norms from the dominant culture. Although the girls policed one another via gossip, name-calling, and, in some cases, shunning, some—especially those with high social status—successfully resisted these norms through the strategic use of humor (see also Thorne, 1993).

Emotional socialization, like other forms of socialization, occurs throughout the life course. Indeed, studies of black students attending predominantly white colleges (Jackson, 2012), medical students (Smith & Kleinman, 1989), and mortuary science students (Cahill, 1999) all reveal the hidden and sometimes not-so-hidden curriculum of emotion in higher education. Additionally, studies of occupations ranging from low-end service workers to high-end professionals document the processes of emotional selection, socialization, and—in the case of less professional or prestigious jobs—monitoring (see Lively, 2006, for a complete review of this literature).

Emotion Management

One of the most studied phenomena within the sociology of emotion is the act of emotion work, or as it is more widely known, emotion management (see Lively & Weed, 2014, for a recent review). Emotion management, generally speaking, refers to the strategies that individuals use to bring their feelings in line with existing emotion norms (Hochschild, 1979). Techniques used to manage emotions include surface acting, to mask or enhance the expression of emotion, and deep acting, wherein the actual emotion is changed (Hochschild, 1983).

Although Hochschild (1983) focused primarily on the cognitive strategies that flight attendants used in order to manage their negative feelings regarding unpleasant and unruly passengers, later studies revealed that each of the four factors of emotion identified by Thoits (1984) are potential points where emotion management can occur. Specifically, individuals can manage their emotions not only by reframing the meaning of a situation (i.e., reenvisioning a problematic passenger as a frightened child, or oneself as a gracious hostess, in order to cultivate positive emotions), but also by changing their emotional expression (Thoits, 1995), the labels they use to describe their feelings (Ritchie & Barker, 2006), and their physiological state (Simon & Nath, 2004).

Intrapersonal Emotion Management

One distinction that sociologists studying emotion make is the difference between intrapersonal and interpersonal emotion management. Whereas intrapersonal emotion management refers to the attempts that individuals make in order to bring their own emotions in line with existing feeling norms, and which may have an indirect effect on others, interpersonal emotion management refers to individuals' attempts to directly affect the emotions of others.

Here, empirical studies illustrate how emotion management specialists (e.g., therapists; Francis, 1997), psychodrama leaders (Thoits, 1995), and social movement activists (Britt & Heise, 2000) use interpersonal emotion strategies to manage the emotions of others directly. Such strategies tend to target one or more of the four factors in Thoits's model of emotion. For example, the therapists in Thoits's study of a psychodrama group helped participants relabel past traumas by inviting participants to take another's perspective or to exaggerate their emotional expression, all the while manipulating the elements of the physical space using lights or music. These interventions, when taken together, typically resulted in participants experiencing more positive emotions and an improved sense of well-being.

Notably, many interpersonal emotion management strategies involve moving subjects through numerous emotions, leading some scholars to conclude that making several moves between emotions that are experientially near, or similar in terms of one or more dimensions of affective meaning, is easier than making one big leap between two relatively distant or dissimilar emotions (Lively & Heise, 2004; Lively, 2008, 2013). Indeed, political leaders often move their constituents out of distress (a relatively weak and inactive emotion) and into pride (an emotion marked by higher levels of potency and activation) by first invoking fear and anger (Wasielewski, 1985; see also Britt & Heise, 2000).

Whereas most of these studies illustrate how therapists and group leaders target emotions directly, Francis's (1997) analysis of two support groups for individuals who had lost a spouse (either through divorce or death) highlights the relationship between emotion and identity (see also Britt & Heise, 2000). In much the same way that Hochschild's (1983) flight attendants were encouraged to see themselves as gracious hostesses and their belligerent passengers as frightened children, Francis illustrated how group leaders encourage their members to reframe themselves and their former or deceased spouses in ways that would allow them to experience more positive, powerful, and active emotions (Heise, 2007).

Finally, interpersonal emotion management also occurs in dyads and among peers. Staske (1996, 1998, 1999), for example, documents the collaborative emotion management that occurs among friends and lovers during intimate talk. Similarly, Lively (2000) illustrates how coworkers routinely engage in reciprocal emotion management in backstage areas, out of the earshot of troublesome employers or clients. Hochschild and Machung's (1989) account of dual-earner couples further reveals how husbands and wives cocreate family myths in order to manage individual and shared emotions. Notably, Lively's and Hochschild's analyses both reveal how interpersonal management, either through reciprocal exchanges of support over time or as collaborative "myths," has the capacity to manage individual or group feelings and to obscure or alleviate the negative effects of ongoing inequities (see also Jackson, 2012).

Emotional Labor

Another distinction made by sociologists is that between emotion management and emotional labor (Hochschild, 1983). Emotional labor, simply put, is the commercial exploitation of emotion management. Hochschild's flight attendants were paid to be nice regardless of insults, and paradoxically asked to be genuine in order to bring about ease and loyalty in passengers. Bill collectors, on the other hand, were taught to be angry, mean, and impatient in order to bring about fear and compliance in debtors (see also Sutton, 1991). Unlike emotion management, which typically occurs in individuals' private lives (such as trying to feel happy when one has adopted the role of bride) and has a "use value," emotional labor is sold for a wage and typically benefits the corporation by whom the actor is employed or the customers, clients, or patients on behalf of whom the actor is engaged (Hochschild, 1983).

Since its introduction, scholarly studies on emotional labor have multiplied. Although at first limited to middle- or low-end service workers (Hochschild, 1983), the literature on emotional labor now elucidates the experiences of employees all along the occupational continuum, from fast-food workers (Leidner, 1993), waitresses (Paules, 1991), home health care aids (Stacey, 2011), and exotic dancers (Barton, 2007) to registered nurses (Bolton, 2001), attorneys (Pierce, 1995), professors (Bellas, 1999; Harlow, 2003), and other professionals (Wingfield, 2010;.see also Erickson & Ritter, 2001; Sloan, 2004, 2007.) As part of the recent focus on emotional labor at the upper end of the occupational hierarchy, emotional labor is now seen as contributing not only to the passenger, client, and patient experience (Hochschild, 1983) but also to the workers' experience of themselves as being professional (Lively, 2001; Siemsen, 2004).

Because most service encounters and most workplace settings are hierarchical, studying emotional labor provides scholars with one way to better understand how the effects of culture and social structure intersect. Generally speaking, individuals at the lower end of the hierarchies within formal organizations have lower-status shields and, thus, less emotional leeway than those at the top (Hochschild, 1983). Not only are displaced negative emotions more likely to flow down status hierarchies (from those with higher status to those with lower status), those at the bottom are also expected, if not required, to transform those negative expressions into something substantially more positive (Hochschild, 1983).

In her study of attorneys and paralegals, for example, Pierce (1995) found that paralegals were expected to manage their own feelings of frustration, irritation, and being overwhelmed that arose from their troublesome encounters with adversarial litigators, and also transform the attorneys' combative and, on occasion, insecure feelings into feelings of confidence and powerfulness. Because most litigators in Pierce's study were male and most of the paralegals were female, these organizational expectations regarding emotional labor matched the cultural expectations that men are more aggressive and women are more nurturing (Simon & Nath, 2004; see also Ridgeway, Li, Erickson, Backor, & Tinkler, 2009). As a result of the confluence of these cultural and structural expectations, many female attorneys (and to a lesser degree male paralegals) were faced with a double bind when it came to expressing powerful and or negative emotions in the workplace.

Although Hochschild (1983), herself, did not discuss race explicitly in her discussion of status shields, racial and ethnic minorities face different emotional expectations and have different emotional experiences compared with their white counterparts. These differences are structurally similar to—though culturally distinct from—those between men and women. In the United States, African American professors employed in predominantly white colleges and universities, for example, routinely face challenges to their knowledge base, as well as their authority (if not their ability) to assess students' work, often resulting in feelings of frustration and irritation, which, in turn, require additional emotion management above and beyond that of their white colleagues (Harlow, 2003). Black professionals, especially males, also feel pressure to avoid expressing anger in order to avoid cultural stereotypes, such as being just another "angry black man," a prohibition not experienced by their white colleagues, who routinely express minor frustrations, irritations, and even anger (see also Wingfield, 2010). Perhaps somewhat surprisingly, black female professionals seem to be more likely than their male counterparts to embrace cultural stereotypes surrounding black women and anger—and their white colleagues' subsequent fear and discomfort—in order to express themselves outside of the norms governing predominantly white social spaces (Durr & Wingfield, 2011).

Consequences of Emotion Labor

In addition to the plethora of studies documenting emotion management and emotional labor in the workplace, scholars have also attempted to understand its consequences. While some have documented the social consequences—that is, the reification of social status hierarchies (Lively, 2000) or other systems of inequality (Harlow, 2003; Pierce, 1995; Wingfield, 2010)—the bulk of scholarship assessing the consequences of emotional labor has focused on Hochschild's intuitive, but largely anecdotal, claims that emotional labor has deleterious effects on the individual (Hochschild, 1983). Based on a range of methodologies, including ethnography and survey methods, these inquiries have produced mixed results regarding her initial concerns about the cost of emotional labor to individual well-being (see Wharton & Erickson, 1995; see also Lively, 2006; Wharton, 2009, for recent reviews of this literature).

Controlling for a variety of individual and job-related characteristics, Wharton (1993), reported that workers in jobs requiring emotional labor were no more likely than other workers to experience job-related burnout (see also Wharton & Erickson, 1995). Instead, burnout was better explained by more general job characteristics (e.g., autonomy and number of hours worked) than by emotional labor. Moreover, workers who performed emotional labor were significantly more satisfied with their jobs than those who did not (Wharton, 1993).

Similarly, Erickson and Wharton (1997) examined the relationship between inauthentic feelings and emotional labor by comparing the experiences of workers who engaged in emotional labor and those who did not. Distinguishing among client–contact, the amount of time spent working with people on the job, and the degree to which "handling people well" is an important aspect of the job, they found that the latter was the only dimension of emotional labor positively related to feelings of inauthenticity (see also Wharton, 1999).

Finally, Erickson and Ritter (2001) teased apart the more potentially damaging dimensions of emotional labor and the degree to which these differed for women and men. Controlling for different types of emotional experiences and different forms of emotional labor, they found that managing feelings of agitation (e.g., hiding feelings of anger) is the only form of emotional labor related to feelings of burnout and inauthenticity. Furthermore, they found that the severity of one's feelings of inauthenticity corresponds with one's level of agitation, and that the negative effects were similar for both women and men (see also Sloan, 2007).

Emotional Deviance

Sociologists are also interested in the ways in which individuals—and their emotions—deviate from cultural and structural expectations. Although questions of emotional deviance originally grew out of an attempt to better understand the relationship between emotion and mental health (Thoits, 1985), the concept has, in recent years, been applied to individuals who are not viewed as mentally ill, per se, but who are simply unwilling or unable to adhere to traditional emotional scripts.

Drawing on Becker's (1963) labeling theory of deviance in order to better understand individuals' increasing willingness to seek professional help for emotional problems, Thoits (1985) suggests that individuals who are unable to bring their emotions in line with existing feeling norms, may be labeled—by both self and others—as emotionally deviant. With this background in place, Thoits takes a role perspective, and argues that discrepant (or deviant) feelings may arise from having multiple roles, role transitions, and unrealistic role demands. In accordance with this view, individuals who self-label as emotionally deviant are increasingly likely to seek professional help today, in large part because of the deinstitutionalization of mental health care and the corresponding destigmatization of seeking professional help for emotional problems. In this regard, Thoits's analysis draws attention to the more micro processes of coping behaviors and social support, as well as the more macro structural and cultural processes associated with structural and cultural change.

Since its introduction in the late 1980s, the concept of emotional deviance has been applied to numerous populations, though most often to mothers (Lois, 2013; Taylor, 1996). Notably, these recent studies suggest that individuals do not always simply accept the label of being "emotionally deviant," and may instead resist it (see Simon et al., 1992). Such resistance can occur in face-to-face interactions or in small groups (Lois, 2013), as well as within the contexts of institutions (e.g., families) and social movement organizations (Taylor, 1996).

Most of the scholarship on emotion management, emotional labor, and emotional deviance has relied disproportionately on qualitative methods, including in-depth interviews and ethnography (but see Lively & Powell, 2006). The exceptions are largely a handful of studies detailing the consequences of emotional labor in the workplace. This reliance on qualitative methods is partly due to a strong affiliation with the cultural perspective on emotions. In the next section, we shift our attention to more structural considerations, and a number of midrange social psychological theories, all of which have been expanded to address emotion more centrally, most often as an outcome of social interaction. In keeping with the structural perspective, this body of work is more likely to rely on experimental and survey methods to investigate the relationships among social structure, perception, and emotion.

Identity, Emotion, and Social Structure

According to sociologists, our sense of self, or our identity, is connected to social structures and institutions (MacKinnon & Heise, 2010; Stryker & Serpe, 1982, 1994; see also Burke, 1991). This is in part because identities are embedded in social roles. Obviously, the roles that we see as available to us are guided, in large part, by culture, and emotions influence role performance (e.g., confidence may propel us forward, whereas fear may cause us to choke). Emotions also arise from role performances (e.g., pride when things go well or shame when they do not), and may shape future performances.

The emotional aspects of identity work are, in effect, commitments to role performances. When actors conform to the emotional and behavioral expectations of social roles, they are managing their sense of self, as well as reifying the institutions, the organizations, and the cultures in which these roles are embedded. For example, when doctors enact the emotional and behavioral expectations of a physician, they reify the institution of medicine. They also perpetuate the relative status positions of physicians, patients, and other health care providers, as well as the common cultural understandings of what it means to be a physician.

Affect Control Theory

According to *affect control theory*, individuals create events that confirm their fundamental affective sentiments regarding themselves, others, and settings (Heise, 2007). Fundamental sentiments capture *evaluation* (how good or bad something is), *potency* (how powerful or weak something is), and *activation* (how lively or quiescent something is); these dimensions of affective meaning have been documented across numerous cultures and, within a single culture, represent shared meaning regarding identities, behaviors, settings, attributes, and emotion (Heise, 2007).

When individuals find themselves in transient situations that disconfirm their fundamental sentiments, they feel a form of affective dissonance, typically referred to as deflection, which is experienced as discrete emotion. The actual emotion that is experienced is a function of the direction and the magnitude of the disconfirmation. For example, someone whose fundamental sentiments regarding him- or herself are disconfirmed in a positive way, is likely to experience joy, surprise, or pride. On the other hand, someone whose fundamental sentiments regarding his or her identity are disconfirmed in a negative way is more likely to experience embarrassment, shame, or guilt. Drawing on a cybernetic model, affect control theory predicts that when transient sentiments contradict fundamental sentiments, individuals are motivated to alter their behavior in order to minimize deflection and reduce the likelihood of reidentification of self, other, or both.

Much of the theoretical work within the sociology of emotion has been based on qualitative methods, such as ethnography and in-depth interviews. In contrast, affect control theory incorporates a unique computer program, Interact, that uses mathematical models to make probabilistic predictions regarding behaviors, emotions, and labeling, many of which have been replicated using ethnography, survey data, and experiments (Francis, 1997; Lively & Powell, 2006; Robinson, Smith-Lovin, & Tsoudis, 1994). This more quantitative approach to identity and affect illustrates clearly that emotion and emotion norms are not entirely emergent, as many early sociological accounts seemed to suggest, but rather inextricably linked to culturally shared affective sentiments regarding social role identities, social settings, behaviors, and attributes. In fact, Lively and Heise (2014) argue that the static emotion norms cited by many cultural sociologists, such as feeling sad at a funeral or feeling joyous at a wedding, are simply the characteristic emotions of a mourner or a bride, respectively, whose fundamental identities have been confirmed perfectly. Notably, when you model the interaction between two mourners at a funeral, their emotions, while starting with sad, will rapidly become more pleasant and active, which may shed insight as to why it is not that uncommon to find people smiling and laughing at a funeral or acting boisterously at a wake.

Although affect control theory was initially developed as a theory of identity, where emotions were essentially a signal of the degree to which one's identity was being confirmed or disconfirmed during the course of daily interaction, emotions have become increasingly more central (Smith-Lovin & Heise, 1988). Lively and Heise (2014) recently summarized the contributions of affect control theory to the sociological literature on emotion and have suggested a number of new applications for the theory, including how the emotional experiences and expressions seem to have differential consequences for those with positively and negatively valued identities. Additionally, Rogers et al. (2014) has nominated affect control theory as a long-overdue launching point for cross-disciplinary collaboration on emotion because of its empirically grounded conceptualization of social mechanisms operating at multiple levels—including individual interactions, groups, and culture—and its mathematical specification of the actual processes that link social and individual aspects of emotion (a point to which we return below).

Identity Theory

Identity theory, as articulated by Burke (1991) and Stets (2005), also illustrates the emotional effects of disconfirming individual identities. Unlike affect control theory, which calculates deflection using culturally shared affective meanings of social roles, behaviors, and settings, identity theory is focused primarily on the correspondence between individuals' self-conceptions and others' reactions to their identity performances. For example, several early studies in this tradition examine intimate relationships, where spouses were asked to compare their own individual self-conceptions with the specific reflected appraisals of their partners (Burke & Harrod, 2005; Cast & Cantwell, 2007). When there was a discrepancy between their partner's reflected appraisals and their own self-conceptions, distress ensued, even in cases where they were viewed more positively than they anticipated. Notably, Burke and Harrod's (2005) analysis of identity processes among intimate couples takes temporal components into consideration as well. Their findings reveal that individuals within committed relationships are more content when their partner's evaluations of them match their own, compared with individuals at the beginning stages of relationships, who would rather their partners see them as slightly better than they see themselves.

Since its introduction, identity theory has been applied not only to relationship satisfaction, but also to individuals' attempts to engage in purposeful self-change. In her study of weight loss, for example, Granberg (2006) found that individuals were more satisfied with, and more committed to, their weight-loss endeavors when the reactions of those around them—both real and imagined—were consistent with their own conceptions and expectations. Recently, Stets and Carter (2011) have extended identity theory to the discussion of moral identities and emotions. Their results reveal that the disconfirmation of moral identities also results in negative feelings.

Emotion and Justice, Equity, Expectation States, and Exchange

Other social psychological theories—including justice theory (Hegtvedt & Parris, 2014), equity theory (Walster et al., 1978), expectation states theory (Ridgeway, 2006), and exchange theory (Lawler & Thye, 1999; Lawler, 2001)—also detail the co-constitutive relationship between emotion and social structure. Importantly, equity theory, justice theory, and exchange theory all rely on the assumption that it is the perception of equity, fairness, or net gains over the course of a single, or ongoing, interaction that affects emotions, not the actual, obdurate conditions in which the individual is embedded.

Justice Theory

Justice theory generally considers two processes: procedural and distributive justice, and has grown to include the study of emotion (Guillermina, 2006; Hegtvedt & Parris, 2014). Whereas procedural justice is focused on the means by which outcomes are distributed, distributive justice is more concerned with the actual allocation of outcomes, often taking into account such issues as need, equity, and equality (Hegtvedt, 2006). Generally speaking, people are happy when they feel that procedural decisions are just and the outcomes fair. By contrast, when people believe the procedures to be unfair and the outcomes unjust, they experience negative emotions. This is true whether the individual is a target of the procedure, a recipient of the outcome, or simply a third-party perceiver of the process. However, even when individuals receive less than they expected, if they believe that the procedure governing the decision is fair (Hegtvedt & Killian, 1999), or that the decision maker is legitimate (Clay-Warner, 2006), their negative feelings are somewhat alleviated.

At first justice theory focused primarily on distributive justice or fair outcomes, such as pay; recent work has focused more on procedural justice and fair methods of distribution (Hegtvedt, 2006). Although most people assume that fair procedures will lead to fair outcomes, this is not always the case. As a result, justice research today is often situated at the intersection of procedural and distributive justice. Organizational justice combines these categories and adds one of its own: interactional justice. Interactional justice refers to the way individuals are treated in the decision-making process (Greenberg, 1990). For example, an organization that treats its employees with respect and keeps them abreast of the decisions being made within the company would be viewed as more interactionally just. Studies in organizational justice also draw particular attention to the individual consequences of organizational practice by elucidating the effects of status characteristics and investigating how individuals feel about the organization to which they belong (e.g., satisfied, disappointed, uncommitted) as well as their role in that organization (Clay-Warner, Hegtvedt, & Roman, 2005; Foschi, 2000).

Equity Theory

Consistent with the justice framework, *equity theory* predicts that individuals are likely to experience negative emotion when they perceive an inequity in their interactions with others, and are motivated to maintain equity in their relationships. Notably, equity does not mean that partners contribute or benefit equally, but rather that partners have an equal ratio of contributions to benefits, subject to individual perception. Originally, the theory predicted that individuals would experience generalized distress, whether they under- or overbenefited (Adams, 1965). However, later scholars specified that anger was more likely in the former case, whereas shame was more likely experienced in the latter (Walster, Berscheid, & Walster, 1975).

Most of the early scholarship on equity and discrete everyday emotion utilized experiments using college student samples and were limited to undifferentiated emotions such as generalized distress (Adams, 1965). Later survey-based studies of married and cohabiting adults, however, found that a broad range of emotions—including positive ones—are affected by perceptions of inequity within the context of long-term romantic relationships (Lively, Powell, Geist, & Steelman, 2008). They also found that emotional responses were affected by perceptions of under- and overbenefiting, as well as by biological sex (Lively, Steelman, & Powell, 2010)

Expectation States Theory

Expectation states theory, with its focus on status hierarchies, provides predictions for socioemotional behavior, particularly within task-oriented groups, such as those commonly found in the workplace. Recent studies of small groups—either based on experiments or computer simulations—illustrate how status hierarchies structure emotion (Heise, 2013; Ridgeway, 2006). Research has shown that low-status individuals are expected to constrain their negative emotions when interacting with high-status individuals in ways that high-status individuals are not (Ridgeway & Johnson, 1990). Further, people have a general understanding of certain emotions as being more or less acceptable for low- or high-status individuals (Tiedens, Ellsworth, & Mesquita, 2000). Correspondingly, when people interact with a group, they are able to use these types of emotion cues to ascertain the relative status of different group members (Tiedens et al., 2000). For instance, in a group of undifferentiated actors, the one who expresses the most anger is often viewed as having the highest status.

Importantly, these predictions are problematized with the consideration of status characteristics, such as gender or race (Ridgeway, 2006; see also Wingfield, 2010; Pierce, 1995). So, it would be normal for a high-status businessman to feel and express more anger if his idea is rejected than his lower-status colleagues; however, it is less normal or permissible for a businesswoman to feel and express anger in the same way. Instead, she is expected to feel guilty or depressed. This example, like the one of the male and female attorneys, cited earlier, illustrates how cultural understandings regarding gender have the ability to undermine institutional power when it comes to the experience and expression of emotion. In his study of juror participation, Heise (2013) argues that any marked identity—that is, any social role identity that is marked by the gender category of female or by race—is automatically viewed as less powerful than those identities that are not marked, therefore signifying maleness and whiteness.

Exchange Theory

Finally, *exchange theory* has also been expanded to include the role of emotions in exchange interactions (see Stets, 2005, for a short review). Exchange theory is a framework for a number of more specific theories—for example, the theory of social commitments (Lawler, Thye, & Yoon, 2009), relational cohesion theory (Lawler & Yoon, 1996), and the affect theory of social exchange (Lawler, 2001). Exchange theory, at its most basic, suggests that individuals who perceive equity in their social arrangements, who see these arrangements as inherently just, and who believe that their contributions are successful, are happier with their outcomes, experience more group cohesion, and are more affectively committed to participating in ongoing exchanges. Conversely, individuals who feel that their costs outstrip their rewards, their contributions are not valued, or the exchange is not successful are likely to exit the exchange—whether within the context of a friendship, a marriage, a job, or a small task-focused group.

Taken together, these perspectives—be they rooted in identity or affective processes, justice, equity, or social exchange—reveal that emotions are shaped by existing social and structural arrangements. They also illustrate emotions' ability to contribute to and disrupt the very conditions that gave rise to them initially, an insight seen most clearly in the scholarship on emotion and social change.

Emotions and Social Change

Whereas the bulk of sociological analysis of emotion has focused on the ways in which emotion is shaped by culture and social structure, emotions have always been recognized as an important part of social movements and, thus, social change (Goodwin, Jasper, & Polletta, 2001). That said, prior to the 1970s, emotions were often viewed pejoratively by movement scholars, who perceived them as something that transformed protestors into angry, irrational mobs (Jasper, 2014). Then, from the 1970s to the 1990s, scholars routinely overlooked the emotions of protesters, mainly out of fear that documenting strong emotions (e.g., pride or righteous anger) would paint the protestors as irrational—as opposed to rational—actors. As such, it was not until the 1990s, bolstered by the rise of cognitive-appraisal theories and the influence of a cultural paradigm sympathetic to protestors' points of view, that emotion began to reappear as a normal part of political action (see Jasper, 2014).

Since making emotions more central, social movement scholars have identified several emotional dynamics that help explain social and political protest. These include acts of motivation (Collins, 2001; van Stekelenburg & Klandermans, 2013), group solidarity (McGarry & Jasper, 2014; van Zomeren, Spears, Fischer, & Leach, 2004), the impact of morality on political action (Jasper & Poulsen, 1995; Jasper, 1997; see also Gould, 2009; Nepstad & Smith, 2001; Risley, 2011; Warren, 2010; Young, 2001) and the gendered division of labor—which tends to assign emotional labor and other devalued emotional tasks to women—in social movement organizations (Taylor, 1996).

In addition to the role that emotions play in social movements, scholars have also turned their attention to the role that emotion management, particularly interpersonal emotion management, plays in motivating social movement participation. Identity-based social movements, for example, face a unique challenge in motivating potential constituents to participate in collective action (Britt & Heise, 2000). Because identity-based movements often involve overcoming stigma, and thus shame, constituents who fear further stigmatization may wish to limit their involvement. As such, inspiring individuals to take action can be difficult. According to Britt and Heise (2000), movement activists use identity-based emotion management strategies that maneuver constituents through fear and anger in order to get them from an affective space largely characterized by shame into one of pride. When potential constituents feel pride (a relatively positive, powerful, and active emotion), they are more likely to participate in positive, powerful, and active behaviors, such as social protest, marching, and chanting (see also Taylor, 1996).

Gould's (2009) analysis of the rise, success, and eventual decline of ACT UP organizations during the beginning of the U.S. AIDS epidemic documents the role of both emotion and emotion management in creating and sustaining social change. According to Gould, the gay and lesbian community actively encouraged members to feel and express anger toward the federal government following a Supreme Court decision that upheld a state ruling deeming homosexual sodomy in the privacy of one's own home illegal. The successful transformation of the groups' collective shock and grief, which had arisen during the early years of the AIDS epidemic into anger and rage after the Supreme Court decision, resulted in the proliferation of ACT UP organizations across the country, and this led to both short-term upheaval and long-term social change. Gould's analysis suggests that in order for emotions and, subsequently, protest, to ignite, a certain emotional habitus, a template for what and how to feel, is necessary. Prior to the Supreme Court decision, the gay and lesbian community was lacking such a template that would not only allow, but also *encourage*, its constituents to feel anger and engage in sustainable protest.

Conclusions

This review drew attention to two of the guiding perspectives within this particular subfield of sociology—that is, the cultural and structural perspectives—to highlight a few of the founding and enduring questions that have come to characterize much of the work within the sociology of emotion. Sociological analysis of emotion uniquely illuminates the interdependent relationship between emotions and the cultural and structural arrangements in which they occur. Just as emotions are shaped by these arrangements, they also have the ability to reify existing structural and cultural arrangements, and to facilitate large-scale cultural and social change.

Although certainly not exhaustive, we seek in this review to outline the current state of the field as we see it and to introduce some of the emerging lines of sociological research on emotion, as scholars continue to venture into increasingly specialized organizations and subcultures (Hunt, 2013; Kolb, 2014; Lois, 2003; Newmahr, 2014; Vaccaro, Schrock, & McCabe, 2011), create evermore detailed datasets (Erickson & Ritter, 2001; Sloan, Evenson Newhouse, & Thompson, 2013), and adopt increasingly complicated and nuanced models of emotional experience, many of which are rooted deeply within identity processes (Dippong, 2013; Hoey, Schröder, & Alhothali, 2013) . To this end, we would like to conclude by drawing attention to what we hope is a trend in the general study of emotion—a trend that sociologists are involved in and, in some cases, leading.

Over the last 10 years, we have seen the introduction of broad theoretical frames large enough to invite, promote, and incorporate interdisciplinary inquiry in the study of emotion. One of the most recent examples comes from Rogers et al. (2014), who propose affect control theory (Heise, 2007) as a useful medium for cross-disciplinary collaborative studies of emotion. Their argument is grounded in the fact that affect control theory rests on an empirical base, links individual and social aspects of emotion, and describes how emotion is affected by social mechanisms operating at the interaction, relationship, and cultural levels. The authors illustrate how affect control theory's emotion model corresponds with other major theories of emotion construction at four different levels of analysis—cultural, interactional, individual, and neural—and extend an invitation to scholars in a range of disciplines to participate in their multidisciplinary vision that is already being answered (see Rogers et al., 2014; Lindquist & MacCormack, 2014; Salmela, 2014; Pornpattananangkul & Chiao, 2014; Robinson, 2014).

While the creation of interdisciplinary bridges is not unheard of, such endeavors do remain relatively rare within academia. This no doubt stems in part from the increasing specialization within social sciences, as well as the ongoing organizational specialization perpetuated in most academic settings (House, 1981; Mills, 1956). Despite such barriers, however, the interdisciplinary research that does exist has been extremely fruitful, as psychologist Grandey's decade-long study of emotion regulation in the workplace has revealed (Grandey et al., 2013; Grandey, 2000).

In a series of papers and projects, including an edited volume drawing from a range of academic disciplines, Grandey and colleagues (2013) have successfully unified many of the discipline-specific perspectives on emotion management and emotional labor in the workplace under the umbrella of emotion regulation. Such an approach embraces insights from Grandey's home discipline as well as from sociology and organizational behavior, among others. This model, like that of Rogers et al. (2014) introduced above, invites and encourages analysis of emotional labor in the workplace using a wide range of methods, from lab experiments to field observations, and provides a useful frame under which those studying emotion can engage in meaningful dialogue around commonly held interests and concerns.

Nearly 40 years have passed since sociologists turned their attention to the social and cultural influences of emotion, as well as the ways in which emotion has the ability to reify or alter existing cultural and structural frames. While these analyses bring important sociological insight to a topic that has been historically dominated by psychology, and more recently, neurology, many—if not most—have been less attuned to the intrapersonal, or even neurological, processes associated with emotionality, in much the same way that psychologists and neurologists have been less attuned to the social aspects for which sociology is best known. To the degree that these disciplinary boundaries are beginning to recede, through the introduction of multilevel, interdisciplinary frames, scholars will undoubtedly be increasingly able to develop more nuanced understandings of emotion as it occurs within, between, and outside of the individuals through which it is experienced.

CHAPTER 4

Emotions in Music, Literature, and Film

P. N. Johnson-Laird and Keith Oatley

Emotions appear to be common to all social mammals. Human emotions, however, are unique in their connection to music and literature—the arts. People can experience an emotion not because of a real event, but because they are reading a poem or a novel, watching a play or a movie, looking at a picture or a sculpture, or listening to music. People probably go out of their way to have these experiences. They spend much of their time seeking emotions, because to be bereft of them is hardly to be alive. Psychologists need to study these phenomena, because they mutually inform their understandings of both the arts and emotions.

The artistic side of the equation reduces to words, images, and music, which may be singular or combined in what the composer Richard Wagner referred to as *Gesamtkunstwerk*—a total work of art. For him it was opera; for us nowadays it is cinema. The most striking effects from a psychological standpoint, however, are that emotions can arise from music and from words.

> Oooooooooooooooooooooooo,
> dll rrrrr beeeee bö
> dll rrrrr beeeee bö fümms bö,
>   rrrrr beeeee bö fümms bö wö,
>   beeeee bö fümms bö wö tää

This is an extract from Kurt Schwitters's poem "Ursonate." You probably noticed that it is not written in German, Schwitters's native tongue. It is not in any natural language. It is a "sound poem," written in a sequence of speech sounds that don't mean anything. You can listen to Schwitters's dramatic reading of his poem at *www.costis.org/x/schwitters/ursonate.htm*. If you do, you may be slightly amused at first, but it grows tiresome. The sounds don't refer to anything, and it lacks emotional impact.

Pure music is a sequence of sounds that don't refer to anything. Yet pure music can move you. So, why the difference? One clue comes from another sort of poem, such as W. H. Auden's poem "Night Mail," which he wrote for the final minutes of a film about the express train that took the mail from London to Scotland. You can watch the movie and hear the poem on *www.youtube.com/watch?v=JPLH00tlcnM*. The images its rhyming couplets evoke—the jug gently shaking, and so forth—are so powerful that the movie's directors felt no need to accompany them with matching pictures.

Poetry stands midway between fiction and music. It communicates *propositions* that can summon up a world (i.e., a mental model), much as novels can. Propositional content often suffices to create emotions. But, poetry can also embody rhythm and meter, much as music can. Poetry may move readers even if they don't quite understand it, as, say, in the symbolist works of Valéry. Likewise, a novel such as Joyce's *Finnegans Wake* with its torrent of neologisms, is almost beyond comprehension, and yet for dedicated readers it is a source of joy; and at least one of them discerns within it a musical structure (Kitcher, 2007). Speech sounds, however, cry out for referents, and when they have none, as in "Ursonate," the result is tedium.

This chapter focuses on music, literature, and film. Since our last review (Johnson-Laird & Oatley, 2008), the field has continued to burgeon. For example, the topic of music and emotion now has its own handbook (Juslin & Sloboda, 2010). This chapter's goal is to bring readers up to date. It begins with a cognitive theory of emotions—the one that underlies our research. It addresses the mystery of how music creates emotions even though it has no propositional content. It then considers literature, drama, and film, to explain the emotional effects of narratives.

A Communicative Theory of Emotions

Mammals need to solve problems. Some problems, such as the quest for a mate or the care of offspring, arise from their social environment. Thinking, as a means to solve these problems, takes time and memory, and almost all problems that fall within the purview of logic, probability, or decision theory, are computationally intractable (Johnson-Laird, 2006). Emotions are a way around this impasse. Many situations trigger emotions that direct attention, coordinate plans, prepare appropriate behaviors, and signal to conspecifics. Emotions are communications both within and between individuals (Oatley & Johnson-Laird, 1987, 1996, 2011). Within individuals, they can combine a subjective feeling, a physiological response, and behavior. Between individuals, they can spread emotions to others.

A system of emotions is common to all social mammals. It handles innate *basic* emotions that have evolved to cope with their principal problems. To generate such emotions, very simple computations, which do not require any working memory for intermediate results, appraise the current situation and transmit signals within the brain. These signals do not require working memory for their interpretation because, unlike propositions, they do not depend on computations that construct their meanings from the meanings of their parts and the grammatical relations among these parts.

The distinction between signals that do and do not have propositional content is critical to our argument in this chapter. In humans, nonpropositional signals underlie facial expressions, tone of voice, postures, and behaviors that communicate basic emotions such as happiness, sadness, anger, and fear (see Russell, Bachorowski, & Ferndandez-Dols, 2003; Keltner, Oatley, & Jenkins, 2013). In all cultures, a smile is a signal of happiness, and weeping is a signal of sadness. These and other expressions of basic emotions are human universals, and their creation and interpretation is carried out in specialized regions of the brain (see, e.g., Panksepp, 1998, 2005; Keltner, Ekman, Gonzaga, & Beer, 2003).

An emotional signal begins with an appraisal. If a piece of music lifts your spirits, you can be aware both of your emotion and of the music as its cause. But if the music is in the background, you may not realize that your feelings are attributable to it, and you may fail to notice a change in them. Hence, contrary to Freud (1915/1971), your emotions can be unconscious. Likewise, you may not be aware of the exact features of the music responsible for your feelings or of the transition from appraisal to emotion. You cannot choose to switch an emotion on or off: you feel anger or fear without choice (Aristotle, 1984, *Nichomachean Ethics*, line 1106a3). Basic emotions arise as a result of rudimentary appraisals, and they can be experienced for no known reason (Oatley & Johnson-Laird, 1996). Psychological illnesses appear to arise from pathology in these basic emotions (Johnson-Laird, Mancini, & Gangemi, 2006).

Consider these events:

A couple's two sons stabbed them and left them to bleed to death in order to inherit their money.

You are likely to feel revulsion and to judge the sons as wicked. This scenario and many others elicit emotions prior to moral evaluations. The order of events, however, is different in other scenarios, because moral judgments can precede emotions (Bucciarelli, Khemlani, & Johnson-Laird, 2008). In either case, you are aware of the propositional content and the emotion it triggers. *Complex* emotions, as we define them, can be experienced only by means of the propositional content of the appraisals that give rise to them. Such emotions include remorse, jealousy, and sympathy. Their propositional content may vary depending on culture (Johnson-Laird & Oatley, 2000). Yet, even so, you cannot control the unconscious transition from an appraisal to an emotion.

In sum, humans have basic and complex emotions. Basic emotions depend on evolutionarily older subcortical regions of the brain, such as the limbic system. They can be experienced in the absence of propositional content. Complex emotions occur when a conscious appraisal with propositional content evokes a basic emotion (Keltner et al., 2013), and they depend on the evolutionarily newer prefrontal lobes of the brain. If these regions are damaged, individuals suffer impairments in these emotions, and cease to be able to plan their lives or to make sensible decisions (Damasio, 1994). Propositions can be mapped into, or from, language. And their creation and interpretation depend on working memory, because their structures are often recursive (Fitch, Hauser, & Chomsky, 2005), and call for people to determine the referents of expressions. The human emotional system handles both simple signals and complex messages, as internal and external communications.

Music and Emotions

Most people enjoy music; and, as far as we know, every culture makes music, often as a social activity. Its universality implies that, like basic emotions, it has an innate basis. This basis includes the fundamental properties of mammalian hearing:

- Logarithmic steps in frequency yield equal steps in perceived pitch.
- Natural sounds, which contain a fundamental frequency and overtones of higher frequencies with small amplitudes, are perceived as individual events.
- A pair of notes that have harmonic overtones and that are an octave apart sound very similar, where the higher note in an octave has a fundamental frequency twice that of the lower note, and harmonic overtones are those with frequencies that are integral multiples of the frequency of the fundamental; for example, a fundamental frequency of 20 cycles per second has integral multiples of 40, 60, 80, . . . , cycles per second. String and wind instruments produce notes with harmonic overtones.
- Overtones that are close in frequency create rapid beating, because they stimulate adjacent regions of the basilar membrane within the cochlea. The result is a roughness in sound (Helmholtz, 1877/1912).

The processing capacity of human working memory both constrains scales—the notes from which most music is constructed—to contain 7 ± 2 notes (Miller, 1956), and leads to temporal groupings of musical events, a principle that underlies meter (Longuet-Higgins & Lee, 1984).

Most Western music consists of a melody and an accompaniment, where the accompaniment consists of sets of pitches in chords. And, from around 1600 C.E. to the present day, most Western music is *tonal*, including popular songs and jazz (Johnson-Laird, 2002). Tonality, despite the claims of composers from Hindemith to Bernstein, is not innate, and it cannot be derived from the series of harmonic overtones. It depends on a division of the octave into 12 separate notes—nowadays into 12 *equal* logarithmic intervals of frequency, and the use of major and minor scales. These choices are cultural. Other cultures make other choices (e.g., Indian classical music originally divided the octave into 22 notes, and used other scales). Western musicians also prefer string and wind instruments, which produce harmonic overtones. Other musicians differ. Indonesians, for example, favor instruments made from metal, which produce notes with inharmonic overtones, and their gamelan orchestras are tuned individually to no common standard (Sethares, 2005).

Granted its innate basis, the question of whether music conferred evolutionary advantages is unresolved (see, e.g., Darwin, 1872/1965; Pinker, 1997; Miller, 2000; Huron, 2003; Patel, 2008, chap. 7). Our aim is to try to answer three more tractable questions. First, does music create emotions? Listeners can tell that a piece of music conveys happiness, but can listening to it make them happy? The evidence shows that it can. The second question is, accordingly: What emotions can music create? The third question is How does music evoke these emotions?

Music Creates Emotions

Many, if not most, listeners can grasp that different pieces of music communicate different emotions. For instance, they know that the tune of the Beatles' "Yellow Submarine" communicates happiness, whereas Thelonious Monk's theme "Round Midnight" communicates sadness. Yet they themselves may be bored or irritated by these pieces. Indeed, many people feel happy listening to sad music (Kawakami, Kiyoshi, Katahira, Kamiyama, & Okanoya, 2013). This distinction between recognizing an emotion that is communicated and feeling the emotion also occurs with literature. The demise of Little Nell in Dickens's *The Old Curiosity Shop* is a poignant moment in literature, but Oscar Wilde remarked, "One would have to have a heart of stone to read the death of Little Nell without laughing." Granted this distinction, studies of whether participants have real feelings from listening to music are essentially over once experimenters have selected the musical extracts, because at least some individuals—the experimenters themselves—are affected by the music. Since the 1890s, experiments have examined what participants report about their experiences, and they say that music creates real feelings (see e.g., Gilman, 1891, 1892; Downey, 1897; Gabrielsson & Lindström, 2001; and Eerola & Vuoskoski, 2013, for a review), and that it is a way to induce moods (Västfjäll, 2001–2002; see Juslin & Sloboda, 2010).

Of course there are skeptics. The most famous was the composer Igor Stravinsky. He wrote, "I consider that music is, by its very nature, powerless to express anything at all, whether a feeling, an attitude of mind, a psychological mood, etc." (1936, p. 91). Likewise, some philosophers argue that emotions are *about* something, but pure music is not about anything, and so it can't create emotions (see, e.g., Nussbaum, 2001; cf. Sloboda & Juslin, 2001). Such arguments are baseless according to our communicative theory, because basic emotions can be experienced without being about anything or having any propositional content. An empirical rebuttal to the skeptics is the evidence of brain activity when individuals report emotional responses to music; such activity occurs in regions of the brain that mediate emotions (e.g., Blood & Zatorre, 2001; Trainor & Schmidt, 2003). Another rebuttal comes from medicine. Music has calming effects on physiological indices of stress in premature babies (Loewy, Steward, Dassler, Telsey, & Homel, 2013), and it induces relaxation and a rise in oxytocin levels after open-heart surgery (Nilsson, 2009). In summary, individuals report that a piece of music stirs them, they tend to concur about the emotion, and it is mediated by regions known to be active concurrently with the emotion. People report that they listen to music to reinforce their current emotion or to change it, especially as a form of psychotherapy in order to relieve stress. The evidence is overwhelming: Music can create emotions in human listeners.

It does not follow that the popularity of music depends on its emotional appeal. The 19th-century Viennese critic Eduard Hanslick accepted that music evokes emotions, but he argued they were not crucial to its appreciation. He wrote, "An art aims, above all, at producing something beautiful which affects not our feelings but the organ of pure contemplation, our *imagination*" (1854/1957, p. 11). The notion that listeners respond to beauty without an emotional reaction seems at odds with aesthetic experience (Scherer, 2004). People often have a feeling of awe—a complex emotion based on fear. Beauty creates it, not just in music, but also in many other human activities from science (Farmelo, 2003) to sports (Richards, 2010). In music, it can elicit gooseflesh and other physiological reactions (Panksepp, 1995), and their correlates are evident in the brain (Trost, Ethofer, Zentner, & Vuilleumier, 2012). Later, we consider the literary evocation of aesthetic emotions.

Emotions That Pure Music Can Create

Music is a Rorschach test. It is easy to project interpretations onto it (see, e.g., Downey, 1897). Consider what three distinguished commentators wrote about the same musical moment:

> A flame of incandescent terror. (Lam, 1966, p. 161)
>
> The sky . . . blazing from horizon to horizon. (Simpson, 1970, p. 60)
>
> One of the most horrifying moments in music, as the carefully prepared cadence is frustrated, damming up energy which finally explodes in the throttling murderous rage of a rapist, incapable of attaining release. (McClary, 1987)

They are all referring to the start of the recapitulation (measure 301) in the first movement of Beethoven's Ninth Symphony. It *is* an extraordinary moment. But, no piece of pure music can refer to flame, sky, or rapists. Whatever music may convey, its meaning is not composed from the meanings of its parts, and its parts do not refer to entities, their properties, or relations among them. They do not refer at all. At best they can mimic a sound, as in Olivier Messaien's *Catalogue of Birds*, or Arthur Honegger's simulation of a steam train in *Pacific 231*. When listeners indulge in interpretation, they are exercising their imagination, perhaps creating a sequence of events—a program—for which the music offers an accompaniment. This interpretative propensity leads commentators to ascribe complex emotions to music, such as love, morality, and spirituality (e.g., Ives, 1962, p. 36). They less often describe it as conveying hatred, immorality, and the mundane.

If you hear the John Philip Sousa march "The Liberty Bell," you are unlikely to think of that iconic symbol of American liberty. Instead, you may think of *Monty Python*, because it was the show's theme music. If you play it in your mind's ear, you may hear the flatulent squelch with which it ended in *Python*. Such associations often occur in songs: the music takes on the lyric's emotions. If you listen to Schubert's "The Erl-King," and are unfamiliar with Johann Wolfgang von Goethe's poem, then you will hear that the music conveys fear. But if you understand its German lyrics, then it communicates fear of a greater intensity. Associations can intensify the emotional impact of music. But, as moviemakers know, causation can work in the opposite direction: Music can intensify, and even create, the emotion that a scene conveys (Cohen, 2001). In *Psycho*, the director Alfred Hitchcock shocked viewers: less than half way through the movie he had his leading lady, Janet Leigh, stabbed to death in the shower. Hitchcock's original idea was to have no music during the scene, just screams and the sound of the shower. When the film's composer Bernard Herrmann heard of this plan, he was furious, because he'd already written music for the scene. He persuaded Hitchcock to view the sequence with, and without, his music—high-pitched shrieks on the violins—which anyone who has seen the movie is likely to recall. Hitchcock agreed that the montage was more frightening with the music.

If one discounts associations and the propensity for propositional interpretations, what emotions does pure music prompt? The communicative theory implies that it can elicit only basic emotions, that is, those that are not necessarily *about* anything. As Hanslick (1854/1957, p. 24) wrote: "'Music] cannot reproduce the feeling of love but only the element of motion. . . ." The emotions that music elicits are, accordingly: happiness, sadness, anxiety, anger, and their cognates and mixtures. Music can create surprise, it can be exciting, it can even be shocking—as it was to the audience a century ago at the premiere of Stravinsky's "The Rite of Spring." They rioted. Surprise is a surprising emotion; it can make you happy, sad, fearful, or angry. Excitement, or arousal, may also differ in its affective tone. Meyer (1956) argued that emotions derive from musical expectations, delayed in fulfillment. The longer their resolution is postponed, the greater the emotion. This account can explain how music creates tension, but not how it evokes different emotions, such as happiness or sadness (Budd, 1985).

On the whole, evidence bears out the occurrence of basic emotions to music, but just about every logically possible view about the emotions that music elicits has a defender (see, e.g., Juslin & Västfjäll, 2008). One complication is that some music communicates little or no emotion; another complication is that not everyone experiences the same, or any, emotion to a given piece of music. A recent study, however, sampled 32 students, at random intervals during the day. If they were listening to music, they had to describe their emotions in their own words (Juslin, Liljeström, Västfjäll, Barradas, & Silva, 2008). In their reports, the six most frequent emotions were in rank order: calm–contentment, happiness–elation, interest–expectancy, nostalgia–longing, pleasure–enjoyment, sadness–melancholy. Other studies have obtained similar results using different procedures, such as a large-scale questionnaire (Juslin, Liljeström, Laukka, Västfjäll, & Lundqvist, 2011). These studies show that music–perhaps on television or in a social setting–elicited these emotions, which for the most part are basic. The one exception is nostalgia–longing; you have nostalgia for a past situation or experience, and you long for someone or something. It is feasible that some extra-musical aspect of the listeners' situations elicited this emotion. But what the communicative theory rules out is that music alone can create object-oriented emotions such as love or hate, or complex emotions such as jealousy or remorse. Evidence corroborates this account. Children ages 4 to 6 years are able to discriminate music that expresses basic emotions (Cunningham & Sterling, 1988). Adults can recognize basic emotions in music (Krumhansl, 1997; Kreutz, Ott, Teichmann, Osawa, & Vaitl, 2008). Musicians and music therapists can improvise music to convey these emotions to others (Bunt & Pavlicevic, 2001; Juslin & Timmers, 2010). But perhaps the best evidence is that a people who had never heard Western music, the Mafa in Cameroon, recognized it as happy, sad, or fearful (Fritz et al., 2009).

How Music Evokes Emotions

Granted that music that you have never heard before can stir you, music itself must contain cues that engage the unconscious appraisals creating basic emotions. The process occurs rapidly, with minimal computational power, and without working memory. One corroboration is the speed with which music conveys emotions. Individuals need less than a quarter of a second—a chord or a few notes of melody—to identify whether a musical excerpt is happy or sad (Peretz, Gagnon, & Bouchard, 1998). The question, then, is What cues in music signal emotions?

The answer, following Aristotle (*Politics*, 1984, 1340a11 et seq.), is a mimetic one. Music can signal characteristics of emotional behavior, speech, and thought (Scherer, 1986; Davies, 1994; Juslin &

Laukka, 2003, 2004; Pronin, 2013). When people are happy, they move and think quickly, and speak loudly with an intonation contour that can leap upward for emphasis. But when they are sad, they move and think slowly, and speak softly with a low intonation contour that has only small changes in pitch. Music imitates these features with its "global parameters" (i.e., settings that can vary but that tend to remain constant for some time, such as tempo, volume, pitch, timbre, the range of pitches in a melody, key, and consonance or dissonance). In tonal music, the notes in melodies and chords tend to be from a major scale or a minor scale, which have a psychological reality (Krumhansl, 1990). The C major scale contains the notes C D E F G A B—the white notes on the piano—and the C minor scale replaces the note E with E flat. Settings for the main basic emotions are roughly as follows (see, e.g., Bunt & Pavlicevic, 2001; Juslin, 2001; Johnson-Laird & Oatley, 2008):

- Happiness: medium tempo, loud, wide range of pitches in melody, major scale, consonant.
- Sadness: slow tempo, soft, low pitch, small range of pitches, minor scale, mildly dissonant.
- Anxiety: rapid tempo, moderate volume, low pitch, minor scale, dissonant.
- Anger: rapid tempo, loud, high pitch, minor scale, dissonant.

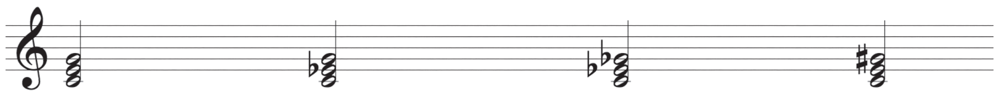
Settings of single parameters affect the ratings of emotions (Juslin & Laukka, 2004). Music in a major scale tends to elicit happiness, whereas in minor or less familiar scales it tends to elicit negative emotions (Gagnon & Peretz, 2003; Temperley & Tan, 2013; Trochidis & Bigand, 2013). The contrast between fast tempo and slow tempo has the same effect (Rigg, 1940; Fritz et al., 2009). When several parameters in music cue a particular emotion, they have an enhanced effect (Webster & Weir, 2005).

A striking phenomenon occurs when music embodies conflicting cues to emotions, such as a major key but a slow tempo. Listeners experience mixed emotions. One study investigated happiness and sadness with actual recordings (Hunter, Schellenberg, & Schimmack, 2008). And an unpublished study due to Olivia Kang exploited a computer program that created music. The program (written by J-L) builds up a matrix of transitions from one note to the next from a corpus of melodies. The transitions embodied both pitch and rhythm. With an input of a chord sequence, the program uses the matrix to generate new melodies. With matrices based on corpora of music eliciting different basic emotions, and with appropriate settings of global parameters, the resulting output is a novel piece of music expressing the relevant emotion. Kang's study confirmed the effect with music based on three corpora of melodies (happy, sad, and anxious). But when the global parameters were set to conflicting values, the listeners were less certain about what emotion the music conveyed, and their choice of terms to characterize it referred to mixed emotions.

Harmony, as the parameter settings above show, communicates emotions. Consonant chords convey positive emotions; dissonant chords convey negative emotions. But what causes consonance or dissonance? The question is one of the oldest in cognitive psychology, probably going back to Pythagoras, though he lived a century before the invention of academia, and published nothing. He is reputed to have argued that consonant musical intervals depend on simple arithmetical ratios between the fundamental frequencies. Galileo and Euler speculated about consonance in a similar way. In contrast, Helmholtz (1877/1912) argued that the roughness caused by fundamentals or overtones creates dissonance, and this view has recent defenders (e.g., Parncutt, 1989).

Figure 4.1 epitomizes the problem. It presents ratings of the dissonance of the four main "triads" in tonal music (i.e., chords of three notes). As the figure shows, roughness fails to explain why the augmented triad is the most dissonant of triads. A modern version of the Pythagorean idea uses the numerical ratio of the fundamental frequency of the lowest note in a chord to the repeating period of the complex waveform of the fundamentals of all the notes in the chord (Stolzenburg, 2010). Figure 4.1 shows these ratios, and they account for the dissonance of triads, but they cannot explain the effects of either timbre or tonal context on dissonance. An alternative theory explains these phenomena, and it combines the innate component of roughness with the cultural component of tonality (Johnson-Laird, Kang, & Leong, 2012). On this account, the augmented triad is the most dissonant because, unlike the other triads, it cannot be constructed from the notes in a major scale. It requires a minor scale. Within the two scales, roughness predicts relative dissonance.

Consonant chords in a tonal sequence convey happiness, whereas dissonant chords create sadness, anxiety, or anger, depending on other parameters, such as tempo. Roughness may explain the observation that 2-month-old infants prefer consonance to dissonance (Trainor, Tsang, & Cheung, 2002). Infants appear to be born sensitive to an



Chord	Major	Minor	Diminished	Augmented
Dissonance	1.67	2.41	3.89	5.26
Roughness	7.27	9.72	22.14	16.07
Periodicity	4.00	10.00	17.00	20.03

FIGURE 4.1. The four main triads of tonal music, their rated dissonance (Johnson-Laird, Kang, & Leong, 2012), roughness following Parncutt's algorithm (multiplied by 100), and periodicity (Stolzenburg, 2010).

emotional component of music as shown in a study of 2-day-old hearing infants of congenitally deaf parents. These neonates prefer singing intended for infants, which is more emotional than singing intended for adults (Masataka, 1999). Likewise, the hemispherical differences in the processing of music are evident even in newborn infants (Perani et al., 2010).

Musical works can have a large-scale structure, made possible by notation, which is a substitute for working memory, and which allows greater computational power in musical composition. No one, for example, is likely to be able to improvise a crab canon, such as the one in Bach's Musical Offering (BMV 1079), in which a melody is accompanied by the same melody played backward. Structure, as Hanslick (1854/1957) intimated, can be beautiful, and this beauty may elicit an aesthetic emotion (Scherer, 2004). What happens more often is that music expresses basic emotions. It does so by *mimesis*. Unconscious cognitions of minimal computational power transmute melody and harmony, and the settings of global parameters, into emotions. As another theorist remarked:

> It becomes possible for motion in music to imitate the peculiar characteristics of motive forces in space, that is, to form an image of the various impulses and forces which lie at the root of motion. And on this . . . essentially depends the power of music to picture emotion. (Helmholtz, 1877/1912, p. 370)

Emotions in Literature and Film

In this section we move from music, which has no propositional content, to forms of art that depend on such content: novels, plays, and films. For such genres, we can use the term "narrative." There is, of course, a distinct psychology of film and its related visual genres (Oatley, 2013a), but text and film versions of a story have been found to have similar emotional effects (Green et al., 2008), which suggest that cognitive processes for narratives in different genres are comparable. We therefore treat together hearing, reading, and watching narratives. For music, a principal question is whether it can elicit emotions, but it is hardly controversial that narratives can do so. The present section accordingly addresses three new questions. The first is What emotions do people want to experience from narratives? The second is How do narratives create emotions? The third is What psychological effects do these emotions have?

Emotions and the Choice of Narratives

People choose pieces of narrative fiction depending on their current emotional state, on their anticipation of the emotions that they will experience from the narrative, and on their personal goals, which are often of an emotional nature (Mar, Oatley, Djikic, & Mullin, 2011). According to a theory of mood management (Zillmann, 1988), people try to promote positive moods and to reduce negative moods, where moods are based on what we refer to as *basic* emotions, because they need not have any propositional content. But Zillmann's theory doesn't explain why people choose narratives that induce negative emotions, such as sadness in tragedy, or anxiety in suspense stories. The same problem arises in listening to music that elicits these emotions. Zillmann (1998) has countered this criticism by arguing that anxiety is acceptable in stories because it magnifies the relief that will be felt on its resolution. This argument leaves unanswered why people enjoy tragedy or sad music.

Oliver (2008) has proposed that people are interested in what she calls tender emotions, which arise from situations in which humans are vulnerable or show compassion. In an experimental test of this idea, participants watched one of three versions of an excerpt from a sad film—Mimi

Leder's *Pay It Forward*—in which the protagonist is stabbed to death as he tries to defend someone (Schramm & Wirth, 2010). One extract was the original version in which the music becomes increasingly upbeat; a second version replaced the original music with a sad piece from Beethoven's Moonlight Sonata; and a third version cut the scene of the protagonist's death, replacing it with a scene underscoring the notion of paying forward good deeds. This third version transformed viewers' sadness into enjoyment, perhaps because it encouraged them to explore deeper meanings of the film, and its underlying social implications. Emotional considerations of this kind influence what people choose to read and to watch.

How Narratives Prompt Emotion

Emotions are at the center of most narrative fiction. In a review of stories worldwide, the two most common genres are the love story and the story of an angry conflict (Hogan, 2003). The emotions that such stories prompt are of several sorts (Oatley, 1994, 2004). One sort, as in the case of music, is aesthetic. It depends on holding the work at a certain psychical distance and considering it as a cultural artifact (see Cupchik, 2002). In this way, individuals might enjoy it as innovative, as possessing a distinctive style, or as having historical significance. Emotions of the second sort are basic: People report about movies that comedies make them happy, thrillers make them anxious, and tragedies make them sad (Oliver & Bartsch, 2010). But this study also showed that movies could be thought provoking and lead to emotions of a third sort: complex emotions. They occur when, like Alice through the looking glass, you enter through a story's surface into its interior, and engage with its characters.

If you enter a narrative, you experience complex emotions such as empathy and sympathy with the characters (Miall & Kuiken, 2002; Oatley, 2002). The so-called paradox of fiction is that to feel emotions of this kind for fictional characters such as Anna Karenina or Mrs. Dalloway, who do not exist, is irrational (e.g., Radford, 1975). Walton's (1990) version of the paradox is to say that emotions elicited by narratives—for instance, in movie thrillers, are make-believe—they are only quasi-emotions. In our view, it is the paradox that is not real. If music evokes real emotions without referring to the real world, it is hardly surprising that imaginary individuals can evoke them too.

To explain how narratives have this effect, we propose three main mechanisms. The first is empathy, which is a complex emotion in which one shares and understands the same emotion as someone else, as a result of identifying with that person (Johnson-Laird & Oatley, 1989; de Vignemont & Singer, 2006). The second is sympathy, which is a complex emotion in which one can feel for people because of their predicament. The third is the triggering of remembered emotions. We discuss each of them in turn.

Empathetic Identification

Although flint tools fashioned for practical reasons have been found from several million years ago, the appearance of art objects in the archaeological record is more recent: a flute from 43,000 years ago (Huron, 2003), burial mounds from 40,000 years ago (Bowler et al., 2003), cave paintings from 31,000 years ago (Chauvet, Deschamps, & Hillaire, 1996). Mithen (1996) has proposed that these signal the appearance into human mentality of metaphor, in which one thing can also be something else: sounds can be music, someone dead can be alive again in a different world, marks on a cave wall can be a rhinoceros. Another metaphorical step can occur in narrative: you can be yourself and someone else (Oatley, 2013b). For instance, you can be yourself and also Anna Karenina (see also Miall & Kuiken, 2002). Empathy is at the heart of this process. The emotion is fundamental to everyday life, because it enables you to feel what others feel. Kaufman and Libby (2012) have shown that people who are less self-conscious, either chronically or as result of instructions, are more able to identify with a character in a short story. These authors also showed that a story in the first-person singular in comparison with one in the third person, or one that delayed the identification of the protagonist as a member of an outgroup, increased participants' spontaneous identification with the protagonist.

Narratives typically concern human intentions and their vicissitudes (Bruner, 1986). Authors offer cues that enable you to construct a kinematic mental model that simulates a world, its characters, and their interactions (Johnson-Laird, 1983; Bower & Morrow, 1990; Oatley, 1999; Mar & Oatley, 2008). A study using functional magnetic resonance imaging (fMRI) corroborated Bower and Morrow's behavioral studies: When a protagonist put down an object he was holding, the region of the reader's brain concerned with grasping and letting go of objects was active. When a story location changed, the region of the reader's brain concerned with visual analysis of a scene was active (Speer, Reynolds, Swallow, & Zacks, 2009). Hence, the simulation that you run when you read a story depends on the brain regions that underlie comparable actions and perceptions in real life (see also Mar, 2011).

When you simulate a story, you tend to identify with the story's protagonist (see also Freud, 1905–1906/1985). You put aside your own goals and plans, and run the protagonist's plans on your own planning processor, which you use to organize your own plans in daily life. When the intentions of the protagonist in the story meet vicissitudes, you experience emotions from your simulation. Although these emotions relate to those of the protagonist's situation, they are not the protagonist's emotions. They are your own. They derive from empathy: you have emotions similar to those of the character. Any emotion can be based on imagination, and so you can empathize with fictional characters. In a crucial experiment, Trabasso and Chung (2004) asked 20 viewers to watch the films *Blade Runner* and *Vertigo*. They rated their liking for the protagonist and the antagonist soon after the beginning and at the end of each film. As participants watched each of these films, the film was stopped at 12 points. At each point one group of 10 viewers rated how well or badly things were going for the protagonist and for the antagonist. The other group of 10 viewers named their own emotions and rated their intensity. When the first group thought that things were going well for the liked protagonist or badly for the disliked antagonist, the second group felt positive emotions, such as happiness, satisfaction, and relief. But, when the first group thought that things were going badly for the protagonist or well for the antagonist, the second group felt negative emotions, such as anxiety, anger, and sadness. As Trabasso and Chung pointed out, the second group's feelings were based on empathy for the protagonist and antipathy for the antagonist, who is in conflict with the protagonist, or interferes with the protagonist's goals. The triggering of empathy may be unconscious, and it occurs in many other activities, such as watching sports.

Although empathy in fiction may be familiar, it remains surprising. As Hamlet says, after seeing an actor affected by emotion as he plays the part of Hecuba: "What's Hecuba to him, or he to Hecuba?" (Shakespeare, 1623/1997). It may be that actors during rehearsal, though not necessarily during performance (Konijn, 2000), use Stanislavski's (1936) method of drawing on events in their own lives in order to feel certain emotions. In everyday life, your intentions often run into obstacles. In fiction, sometimes as a kind of trope, such obstacles are embodied in a personal antagonist, and this embodiment seems to help you to engage in the story.

Sympathy

A second kind of narrative emotion is sympathy. T. S. Eliot (1919/1953) wrote, "The only way of expressing emotion in the form of art is by finding an 'objective correlative'; in other words a set of objects, a situation, a chain of events which shall be the formula for that particular emotion" (pp. 107–108).

In psychology, a similar idea is appraisal of such situations or events (Tan, 1996, 2008; Tan & Frijda, 1999). Readers and viewers infer how events would strike a character, and then they can feel sympathy for that character. Theories of emotions in fiction as deriving from empathy or from sympathy were first put forward as alternatives, but it now seems clear that most narratives invite both sorts of emotion. Authors use them in different ways and with different effects. For instance, when Dorothea, the protagonist of George Eliot's (1871–1872/1965) *Middlemarch*, agrees to marry the aged scholar Casaubon, she is full of enthusiasm to help him with his work. You identify with her empathetically, and share some of her enthusiasm, but at the same time your heart sinks because Eliot has conveyed Casaubon's character to you in a way that goes beyond Dorothea's understanding of him. You realize, as she does not, that she has married a desiccated scholar, and so you feel sorry for her. One of the skills of great writers is to enable you to feel the emotions of a character with whom you empathize, but also to feel sympathy toward the same character.

The distinction between empathy and sympathy, as we pointed out in our last review (Johnson-Laird & Oatley, 2008), was important for Indian literary theorists a millennium ago, such as Abhinavagupta (see Ingalls, Masson, & Patwardhan, 1990). They described the emotions depicted by an actor in a play, using facial expressions, gestures, tone of voice, and the content of utterances, and the corresponding emotions—*rasas* in Sanskrit—that occur in audiences (see Keltner et al., 2013, p. 111). For example, when an actor depicts amusement or anger, the audience identifies empathetically and feels amusement or anger, and when an actor depicts something disgusting, the audience feels loathing, which puts that character into the role of antagonist. But when an actor depicts sorrow, the audience feels sympathy for that character. According to these theorists, *rasas* were literary emotions and subtly distinct from the emotions of daily life. Each well-constructed work should be based on a single *rasa*, which is the basis for a genre (e.g., a love story, a comedy, a tragedy). Within a story, other *rasas* would also occur, but in a supporting and often transient way.

Remembered Emotions

Narratives tend to evoke memories (Larsen & Seilman, 1988). An event in a simulation can prompt a memory of an emotion but the remembered event itself may remain unconscious. Earlier, we described the concept of aesthetic distance, and according to Scheff (1979), narratives enable individuals to experience emotions at a better distance than the one at which they originally experienced them. In daily life, people may cut themselves off from emotions that would be too painful: they experience them at too great a distance. Other emotions may overwhelm them: they experience them at too small a distance. Fiction, Scheff argued, enables people to relive such emotions at a more optimal distance, so that they can cope with them properly. If they find themselves in tears at Shakespeare's (1623/1997) *Romeo and Juliet*, they may be remembering and reliving their own experience of a loss, with which they had not come to terms. They can feel sad even if they do not explicitly remember that loss. They are not just reliving a remembered experience (Miall & Kuiken, 2002); the fictional context modifies the emotion and enables them to understand it and to assimilate it. The *rasa* theorists made the same point. People can recognize their own emotions as universal, and as shared with others. When they experience a new narrative, they therefore do so with a wide variety of remembered emotions, and it can evoke them in a new context.

A Western literary parallel occurs in *À la recherche du temps perdu*. In the first book of Proust's masterpiece, the narrator, Marcel, sits with his mother drinking herbal tea. He moistens a madeleine cake in the tea, and no sooner has he tasted it than he feels exquisite pleasure. He wonders what evoked it and what it means. Proust continues:

> And suddenly the memory revealed itself. The taste was that of the little piece of madeleine which on Sunday mornings at Combray (because on those mornings I did not go out before mass), when I went to say good morning to her in her bedroom, my aunt Léonie used to give me, dipping it first in her own cup of tea or tisane. The sight of the little madeleine had recalled nothing to my mind before I tasted it. (p. 48 et seq.)

Marcel's joy, as he eventually realizes, was in being able to recall the panorama of events in his childhood, but now in a way that he could begin to understand. In day-to-day life, meanings of events very often pass one by. For Proust, one of the profound kinds of significance of literary art was that it enabled readers to experience emotions and at the same time to understand their meanings.

Remembered emotions contrast with the immediate emotions that empathy and sympathy elicit in reading a literary text. The difference has been corroborated experimentally (Cupchik, Oatley, & Vorderer, 1998). The participants read four excerpts from James Joyce's *Dubliners*. Two excerpts described the emotional sequence of an event, and two were static and descriptive. In one condition, the participants were told to sympathize with the protagonist, and in another condition they were told to imagine being the protagonist. Participants reported fewer remembered emotions than immediate emotions, but the remembered emotions were more pleasant and more intense. Overall, empathy helped readers to experience immediate emotions in response to static descriptions, whereas sympathy for a protagonist elicited remembered emotions.

Certain cues in narratives prompt personal reactions as a result of empathy, sympathy, and remembered emotions. These cues—in what Oatley (2002) calls the "suggestion structure" of a narrative—include tropes such as metaphor and metonymy. Western poetics has tended to neglect the role of suggestion. In contrast, as Hogan (2003) points out, it is central in Indian poetics: The Sanskrit word is *dhvani* (Ingalls et al., 1990). Hogan offers an illustration from the final scene in Shakespeare's (1623/1997) *Hamlet*. As Hamlet dies, Horatio says:

> Now cracks a noble heart. Good night, sweet prince;
> And flights of angels sing thee to thy rest!

"Good night, sweet prince" suggests a theme of attachment and perhaps of memories of your parents saying "good night" during your childhood—a suggestion that makes the lines deeply moving.

The role of personal suggestion has been corroborated in experiments. Readers of a narrative had more emotions that were personal as compared with generic than readers of an explanatory piece of the same length, content, and ease of comprehension (Mar, Oatley, & Eng, 2003). Likewise, Nundy (1996) demonstrated a variety of responses to suggestion. Her participants read a short story by Russell Banks in which a man cruelly severs his relationship with a woman. The participants experienced strong emotions as a result, but their nature differed from one reader to another: Some were angry, others were sad, and a few were disgusted. Suggestion lies at heart of narrative.

Effects of Emotional Narratives

Just as people who learn to fly planes improve their skills in a flight simulator, so readers of fiction—simulations of the social world—can improve their social skills. Mar, Oatley, Hirsh, dela Paz, and Peterson (2006) found that the amount people had read during their lifetime correlated with empathy and with their scores on the Reading Mind in the Eyes Test (i.e., their ability to infer the mental state of persons from photographs of their eyes; Baron-Cohen, Wheelwright, Hill, Raste, & Plumb, 2001). It also correlated to a lesser extent with a test of interpersonal perception (i.e., their ability to infer what was going on in videos of people interacting). However, individuals who read more nonfiction were no better at social skills. Even when differences in ability to empathize were controlled for, those who read a lot of fiction were more socially skilled (Mar, Oatley, & Peterson, 2009). Likewise, the more stories that children listened to, and the more films they watched, the greater was their ability to infer the mental states of others in five tests (Mar, Tackett, & Moore, 2010). In contrast, no correlation occurred between the amount of television that the children watched and these measures. Fong, Mullin, and Mar (2013) compared effects on people's scores on the Reading Mind in the Eyes Test with the amount of their reading of various sorts of fiction, controlling for age, gender, and personality of the readers. They found significant positive correlations of empathy and of the Reading Mind in the Eyes Test with the amount of reading of romances and thrillers, a positive but less strong correlation with domestic fiction, and a negative correlation with science fiction. The difference, presumably, is that romances and thrillers elicit empathy with protagonists, and inferences about what other characters are up to in the story. As a result, readers get better at recognizing other people's emotions. In science fiction, these matters are usually less important than those of a different kind, such as alien invasion, robots, and space travel.

Experiments have confirmed that the relation between reading literature and empathy is a causal one. In one such study, participants read either a short story selected from a set of eight or else an essay selected from a set of eight—the literary authors of both sorts of piece were well-known (Djikic, Oatley, & Moldoveanu, 2013). People who were low in the personality trait of openness to experience, and who read a story, subsequently rated themselves higher in empathy than those who read an essay. Kidd and Castano (2013) showed that reading a fictional story, but not a factual essay, increased participants' levels of empathy and their scores on the Reading Mind in the Eyes Test (Baron-Cohen et al., 2001), and that literary stories produced bigger effects than popular stories. In a different kind of experiment, which used a specially written story, Johnson (2012) found that the more that participants were transported by the story, the more empathy they reported with its protagonist, and the more likely they were to be helpful later, in picking up some pens that the experimenter had "accidentally" dropped.

Narratives elicit emotions, which can affect personality, as measured by the Big Five personality traits of neuroticism, extraversion, openness to experience, conscientiousness, and agreeableness (Djikic, Oatley, Zoeterman, & Peterson, 2009b). In the study, half of the participants read Anton Chekhov's story *The Lady with the Dog*, and the other half of the participants read a control story that described the same characters and events but in a documentary style. Readers rated it just as interesting, though not as artistic as Chekhov's story. Before and after they read the text, the participants rated the intensity of their current emotions and a test of the Big Five personality traits. Those who read Chekhov's story showed small but reliable changes in their personality in comparison with those who read the documentary text. The amount of emotion they experienced while they read the story mediated these changes. As another analysis of these results showed, narratives may be able to circumvent psychological defenses. People who tended to suppress their emotions, and to avoid contact with others, experienced significantly more emotion in reading the original Chekhov story than in reading its documentary version (Djikic, Oatley, Zoeterman, & Peterson, 2009a).

Conclusions

The communicative theory of emotion (Oatley & Johnson-Laird, 1987) helps to solve the mystery of how works of art create emotions. Music doesn't refer to anything, but simple mimesis can elicit a small set of basic emotions: happiness, sadness, fear, and anger. It can trigger emotions quickly, and the same emotions can be triggered in different cultures. In contrast, narratives in literature or film concern characters and their plans. People put aside their own goals and plans and, following the narrative's suggestions, take on the goals and plans of the protagonist. Metaphorically, they become models of the protagonist. Narratives, even if they don't refer to real individuals, can accordingly create in people complex emotions that depend on propositional content. As we showed earlier, the emotions that music elicits are real, and so doubtless are the emotions that narratives elicit.

Consider this vignette:

"Someone must have been telling lies about Joseph K., for without having done anything wrong he was arrested one fine morning."

If you read this sentence in a newspaper, you are likely to feel a pang of sympathy for the protagonist. But, you are also likely to do so if you read it at the beginning of Franz Kafka's novel *The Trial* (in Willa & Edwin Muir's translation), or if you watch the scene in Orson Welles's film based on the novel. A picture is said to be worth a thousand words, but a sentence can be worth more than a thousand pictures. As the need for subtitles in silent movies demonstrates, words can do things that are beyond pictures. Words can convey abstractions, such as the immorality of telling lies, and words in metaphors and other tropes also transcend depiction (Glucksberg, 2001). They can elicit our empathy and sympathy with characters in fiction, and our antipathy toward them—even toward characters that could not exist—such as the talking pig Napoleon, who is an allegory of Stalin in George Orwell's *Animal Farm*. Empathy, sympathy, and remembered emotions from suggestions in narratives are the ways in which you can enter into stories. As a result, you extend your understanding of yourself and of others.

Emotions can be so excessive in intensity that they cause psychological illnesses (Johnson-Laird et al., 2006). But music can modulate emotions, and, as a result, it can play a role in restoring mental and physical health (e.g., Davis, Gfeller, & Thaut, 2008; Loewy et al., 2013). Literature too has comparable effects (e.g., Davis, 2009). And, as Pennebaker (1997) has shown, if you write for as little as 20 minutes a day for 4 days, it can improve both your mental and physical health provided that you write about emotionally significant events in your life (see Frattaroli, 2006, for a meta-analysis).

What do you learn from listening to music? Despite many claims for improved intelligence or executive ability, the evidence is not decisive. Less controversial is that you learn to enjoy and to experience aesthetic feelings for works of art. The evidence is clearer for narratives. Beyond aesthetics and matters of fact embodied in a story, such as how to harpoon a whale, you can learn how to feel toward other people, how to cope with personal relationships, and even how to understand your own emotions (Oatley, 2003). These emotions are a foundation for altruism (Batson, 2011). They prompt moral intuitions, though sensible moral judgments depend on reasoning, too (Bucciarelli et al., 2008).

We have postponed the most difficult question. There is no doubt that human beings enjoy vicarious emotions from music, narratives, and other activities. But why? Aristotle (1984, *Poetics*, 1449b28) wrote that it was for *catharsis*. Some translators take him to be referring to the purging of emotions—in the sense that you might say to someone, "Go on, have a good cry, you'll feel better for it." But another interpretation is that Aristotle was referring to the "clarification" of experiences of a pitiable and fearful kind (Nussbaum, 1986). You can reflect on your emotions, and gain insight into them, from a wider set of circumstances than you would encounter in everyday life (Oatley, 1999). Such an account makes sense for fiction, but why do you enjoy the emotions that music inspires? Aristotle (1984, *Politics*, 1341b37) refers to catharsis in a passage concerning the different "modes" of music, which correspond in part to modern scales. He writes that musicians should learn them all. One reason is for catharsis, which again he does not explain. It is enjoyable to listen to sad music; it is enjoyable to mourn the death of Hamlet. But it is not enjoyable to mourn the death of a person one loves. Perhaps, as Cova and Deonna (2014) have suggested, being moved is a distinct emotional state. But, as far as we know, no one has a good testable explanation of why sad emotions from music and narrative are enjoyable.

CHAPTER 5

Affect in Economic Decision Making

Karolina M. Lempert and Elizabeth A. Phelps

Do you make decisions with your head or your heart? Do you follow your intuition or reason through your options? Was that a "hot" emotional choice, or a "cold" calculated one? In our language and our culture, the idea that emotion runs counter to reason is ubiquitous. When a choice is deemed irrational, many people cite "emotion" as the driving force behind it.

The notion that emotion and cognition are separate and opposing forces originated with Plato, who suggested that the soul had a tripartite structure, composed of cognition, emotion, and motivation. He argued that these components were separate, that they were in competition, and that cognition was superior to the others (Scherer, 2005). This theory has exerted a monumental amount of influence on Western thinkers since, including the philosopher Immanuel Kant and the father of psychoanalysis, Sigmund Freud. Therefore, it is unsurprising that "dual-systems" models of the mind and brain have been so prevalent in psychology (see Evans, 2008, for one review), and that "cognitive" and "affective" psychology research and theory are still so divided. In behavioral economics, a similar view of emotion and cognition has also emerged. Kahneman (2011) proposed that our choices are either driven by an automatic "system 1" or a deliberative "system 2"; emotion is considered a factor that contributes to system 1. In neuroscience, it has been suggested that emotion and reason are compartmentalized in the brain (Figner, Mackinley, Wilkening, & Weber, 2009; Cohen, 2005), and one must override emotional impulses that originate in the "limbic system," in order to make rational choices.

Early theories of brain anatomy supported the dual-systems view. The limbic system concept, introduced by MacLean (1952), and inspired by work by Papez (1937), refers to a phylogenetically older system of brain regions that line the inner border of the cortex. MacLean proposed that this set of regions was devoted to basic affective responses (Lambert, 2003). Meanwhile, the neocortex was responsible for higher cognitive functions. This theory was highly influential, but basic research in neuroanatomy and structure–function relationships soon revealed that the dividing line between emotion and cognition in the brain was not so clean. For example, the hippocampus—a major hub of MacLean's limbic system—has been found to be integral to memory, a largely cognitive function. In addition, areas of the neocortex, such as the orbitofrontal cortex (OFC), have been found to be important in affective processing (Damasio, 2005). Although scientists have attempted to modify the limbic system concept to take this research into account (e.g., Cohen, 2005; Rolls, 2015), it has become clear that there is no unified system that drives emotion, and affective and cognitive processes are not clearly separable in the brain (see LeDoux, 2000, for discussion).

As appealing and parsimonious as the dual-systems view is, without a clear neural instantiation, it is difficult to conceive of how it could be accurate. The bridge between neuroscience and psychology has been critical to the advancement of psychological theory. In other domains of cognition, such as memory, perception, and attention, the neural circuitry suggests, and the research supports, a modulatory role for emotion or affect (Phelps, 2006). The connections between the amygdala and hippocampus, for example, have been shown to underlie the influence of emotion on the encoding of episodic memories. Given that the amygdala shares connectivity with the striatum and the OFC—two regions that have been consistently linked with economic decision-making and valuation—it is likely that this is one pathway (of many) by which emotion may modulate the computation of subjective value during decision making, which then influences choice. This review will focus on the behavioral evidence for a modulatory role of affect in decision making, but it is important to bear in mind that there are proposed neural circuits that can support such a role (see Phelps, Lempert, & Sokol-Hessner, 2014).

In addition to being implausible on a neural level, dual-systems models are also problematic because they encourage researchers to perpetuate the idea of a competition between systems, and to cast affect in either a "good" or "bad" light. If the view is that emotion always leads to irrational choice, the focus will be on dampening those emotions, rather than investigating the circumstances under which emotion results in successful or unsuccessful decision making. If we want to have a nuanced and detailed view of affect and decision making, we need to understand how emotions modulate our evaluation of options and affect our choices.

In this chapter, we attempt to summarize the research on the role of affect in economic decision making. We restrict our review to studies that have explicitly measured or manipulated affect. Affect is not a unitary construct, but rather, it is composed of component processes. The number and precise nature of these processes is still up for debate (Ekman & Davidson, 1994), but for the purposes of this review, we adopt the framework of Scherer (2000), with some caveats. We define an *emotion* as a discrete response to an external or internal stimulus that entails some or all of five components: (1) subjective feelings, (2) physiological response, (3) motor expression, (4) action tendency, and (5) evaluation or appraisal (Scherer, 2000, 2005). Changes in these components vary in their intensity, and they may not all be present (Barrett, 2006). During a decision, the choice options and outcomes may elicit such emotions. When emotions arise from the choice at hand, and are relevant to the choice, we refer to them as *integral* emotions (Lerner, Li, Valdesolo, & Kassam, 2015).

In addition to discrete emotional responses to stimuli, we can also experience more enduring affective states. In this chapter, we discuss three such states: *stress*, *mood*, and *affect dispositions*. Although Scherer (2000, 2005) did not, we differentiate transient emotional responses from stress. Stress may be triggered by a discrete event, but it is defined by fixed physiological and neurohormonal changes (Ulrich-Lai & Herman, 2009), and the impact of these changes leads to a longer-lasting affective state (Dickerson & Kemeny, 2004). Specifically, a stressor disrupts homeostasis (McEwen, 2007), leading to sympathetic nervous system arousal, activation of the hypothalamic–pituitary–adrenal (HPA) axis, and the release of stress hormones. Stress hormones hit their peak concentration and begin to influence activity in brain regions related to affect and choice 10 to 20 minutes poststressor, and these effects can continue for hours after exposure (Joëls, 2011). Because of this longer time scale, stress may influence choices *incidentally*—that is, a stress response related to some other previous event may affect the way decision options and outcomes are processed. A discrete integral emotion, on the other hand, will likely only influence the current choice or related choices, and will not have an impact on unrelated decisions undertaken several minutes or even hours later.

A *mood* refers to a diffuse affective state, which may or may not be triggered by a stimulus, and is primarily characterized by subjective feelings. Unlike stress, moods do not have a well-defined neurohormonal or physiological substrate. Furthermore, while stress results in a negative affective state (Dickerson & Kemeny, 2004), there is greater variation in the valence and nature of mood states. In this chapter, we discuss how mood can influence choice incidentally.

Although choices themselves may be indicative of an emotional process (because they imply preference or "liking"), we do not include studies that have inferred emotional responses based on choices alone. Similarly, we do not include studies that have inferred the involvement of emotions on the basis of finding a blood-oxygenation-level-dependent (BOLD) signal in regions associated with emotion, because there is little evidence that affective components are uniquely tied to specific BOLD patterns (Phelps et al., 2014).

Finally, we use the term "affect," as Scherer (2005) does, simply as the overarching term encompassing discrete emotions as well as more diffuse states such as moods and stress. We acknowledge that other definitions of affect exist (e.g., *core affect*; Russell & Barrett, 1999), but for simplicity, we do not consider them here.

We begin the chapter by exploring the two major means by which affect can influence choice. First, affect can incidentally alter our choices, if we are in a particular affective state, such as a certain mood or under stress at the time of choice. Our affective state can influence how we process a decision, and can lead to differences in our decision making. Second, choice options and outcomes themselves may elicit integral emotions, or emotions that modulate the computation of subjective value (Lerner et al., 2015), thereby influencing choice. Finally, we discuss some strategies for changing emotions in order to change choices.

Incidental Affect

Affect can influence decision making indirectly, through incidental affect. When we are in a baseline affective state, we may change the way that we make our choices, even if the affective state is unrelated to the decision at hand. It is possible that baseline affect changes the way that we process attributes of stimuli, leading to changes in valuation or action tendencies during decision making. In experiments that manipulate incidental affect, an affective state is triggered in the participant before a decision-making task. Below, we discuss a few of these affective states: namely, stress, mood, affective priming, and affect dispositions.

Stress

It is not uncommon to hear someone say that he or she is "stressed out." The trials and tribulations of life (e.g., job pressures, financial strain, worries about loved ones) may overwhelm us, so that we have trouble coping. We try to avoid stress not only because it may affect our health and well-being but also because it may unduly influence important decisions. In a time of crisis, we do not want to make mistakes or act impulsively; we want to be able to reason through our options and make the best choice. The study of decision making under stress is important not only because stress is ubiquitous but also because it is so relevant in the clinical domain. Stressful events often precipitate the onset of depression (Kendler, Karkowski, & Prescott, 1999), and living with a psychopathological condition may increase stress (Yehuda, 2001; Checkley, 1996). Moreover, drug addicts are more likely to relapse under stress (Sinha, 2001), and this may be due to impaired decision making under stress.

"Stress" has multiple meanings and interpretations, but for the purposes of this review, we define stress as the induction of a response that results in an increase in physiological arousal, glucocorticoid release, and ratings of negative affect. Stress hormones are known to influence a number of brain regions related to affect and decisions. Notably, they seem to impair prefrontal cortex (PFC) function and executive control (Hains & Arnsten, 2008), as well as enhance the function of the amygdala (Roozendaal, McEwen, & Chattarji, 2009; see Ulrich-Lai & Hermann 2009; Arnsten, 2009, for reviews). In addition, stress has been shown to impact dopaminergic neurons in the ventral tegmental area and the striatum (Ungless, Argilli, & Bonci, 2010). Importantly, the physiological effects of acute stress extend after the event (Dickerson & Kemeny, 2004). Because stress has been shown to influence brain systems implicated in decision making, it is not surprising that stress can impact choices.

Several techniques have been used to induce acute, mild stress that reliably results in glucocorticoid release in humans (see Dickerson & Kemeny, 2004). The two most common manipulations are the "cold-pressor task" and the Trier Social Stress Test (TSST). In the cold-pressor procedure, participants immerse their hands in near-freezing water for about 3 minutes. In the TSST, research subjects are asked to give short public performances that will be evaluated by their peers. Despite differences in the nature of the stress induced in these two procedures, they have both been found to reliably engage an acute stress response (Ishizuka, Hiller, & Beversdorf, 2007; Kirschbaum, Pirke, & Hellhammer, 1993). These acute, mild stressors have also been shown to impair performance on PFC-dependent tasks (e.g., Raio, Orederu, Palazzolo, Shurick, & Phelps, 2013).

From Goal-Directed/Model-Based to Habitual/Model-Free Behavior

How does stress affect choices? One general theme that has emerged from the literature thus far is that stress leads to more automatic processing—that is, stress may lead us to switch from goal-directed action to habitual responding. An action is said to be habitual when it is no longer sensitive to the value of its outcome. One way to test for habit behavior in the lab is through a devaluation procedure. In a typical devaluation task, subjects are trained to make responses to receive two food rewards. Then, they are fed one of the food rewards to satiety, resulting in its devaluation (i.e., it no longer tastes pleasant). Following the devaluation, subjects who maintain goal directedness stop responding for the now-devalued food. Those who display habitual behavior, however, will continue to respond to receive an outcome, although it is no longer valuable to them.

Dias-Ferreira and colleagues (2009) examined how chronic restraint stress influenced the expression of goal-directed versus habitual actions using a devaluation task in rats. They found that the animals that were not stressed made fewer responses for the devalued outcome, reflecting its updated value. In contrast, stressed rats failed to modify their responses in light of the devaluation, consistent with habitual responding. Schwabe and Wolf (2011) used an instrumental learning task and a devaluation procedure in humans to test the effects of acute stress. In contrast with nonstressed participants, those stressed prior to the devaluation failed to show any change in responding, suggesting less goal-directed action following acute stress.

Another recent study took a reinforcement learning approach to comparing "model-based" and "model-free" learning under acute stress (Otto, Raio, Chiang, Phelps, & Daw, 2013; Daw, O'Doherty, Dayan, Seymour, & Dolan, 2006). In model-free learning, an individual learns which action is beneficial through direct experience with its reinforcing consequences. In more complex environments, however, the most rewarding outcome may depend on a series of sequential contingencies between events and actions. Learning these outcomes requires a model of the environment that allows one to make a series of choices that maximize reward. This kind of learning is known as model-based learning. Functional magnetic resonance imaging (fMRI) studies (e.g., Glascher, Daw, Dayan, & O'Doherty, 2010) suggest that model-based decisions depend on interactions between striatum and lateral PFC—a region that is adversely impacted under acute stress. Therefore, Otto and colleagues predicted that stress would lead to more model-free, and less model-based, behavior. In their study, stressed and nonstressed participants performed a probabilistic learning task that yields different patterns of choices depending on whether one is using a model-free or model-based strategy. In line with their hypothesis, the authors found that stress attenuated model-based, but not model-free, contributions to choice behavior. Interestingly, stress-induced changes in choice behavior varied depending on working memory capacity, which was measured in a different task prior to the stress manipulation. Since the switch to model-free behavior is likely a result of diminished prefrontal function under stress, people with higher working memory capacity may be protected from the deleterious effects of acute stress in this task.

Insufficient Adjustment from Default Responding

In more complex decision-making tasks, it is often hard to categorize responses as habitual or goal directed. Rather, in these tasks, it has been suggested that stress leads to insufficient adjustment from "default" responding (see Starcke & Brand, 2012, for a review). In one of the first investigations of induced stress on a specific decision variable, Porcelli and Delgado (2009) sought to examine risk taking after the cold-pressor procedure. After undergoing either the stress or a control manipulation, participants were presented with a series of gambles in either the loss or gain domain (i.e., choosing between two potential losses or two potential gains). Each choice was between a small monetary amount with high probability and a larger amount with lower probability. Behavioral economics research has shown that people tend to be risk seeking in the loss domain and risk averse in the gain domain (Kahneman & Tversky, 1979). In this experiment, exposure to the stressor exaggerated this tendency; individuals who had undergone stress became more conservative in the gain domain, and more risky in the loss domain—that is, under stress, participants were more likely to turn to their "default" response.

In other decision-making domains, stress has also been shown to affect decision strategies in a way consistent with insufficient adjustment from default responses. For instance, Kassam, Koslov, and Mendes (2009) found that exposure to a threatening social evaluation stressor decreased adjustment from an arbitrary anchor in a trivia task. Participants were more likely to use irrelevant information to answer difficult questions when they were under stress, and the degree of this bias was correlated with their physiological stress response. Similarly, in studies of moral decision making, Starcke, Polzer, Wolf, and Brand (2011) found that the level of stress response correlated with the egocentricity of decisions, while Youssef et al. (2012) found that stressed participants made fewer utilitarian judgments when responding to moral dilemmas.

Stress also seems to impair strategizing in games with a social component, such as the beauty contest game (Ho, Camerer, & Weigelt, 1998). In this game, all players submit a number in the interval (0, 100) into play, and the player with the number that is closest to two-thirds of the average of all players' numbers is the winner. In order to win, therefore, a player must be able to reason through what his or her peers will pick, and choose two-thirds of this amount. The assumption is that players who select smaller numbers are strategizing more than those who select higher numbers. In a 2013 study, Leder, Häusser, and Mojzisch found that players under stress selected larger numbers (i.e., strategized less about the intentions of other people) than those who were not under stress. It is hypothesized that the findings in these decision tasks could be attributed to the known impact of stress on executive control and PFC function. However, as of yet, there is no direct neuroscience evidence of diminished PFC involvement in these tasks.

Mixed Effects on Choice Attribute Processing

In more complicated paradigms, such as risky decision making and intertemporal choice tasks, the findings on stress and decision making are mixed. This is likely because these tasks involve several decision variables, and stress may impact these variables in different ways. For example, some studies find that stress increases risk taking, but primarily in men (Lighthall, Mather, & Gorlick, 2009; Preston, Buchanan, Stansfield, & Bechara, 2007; van den Bos, Harteveld, & Stoop, 2009; Lighthall et al., 2012). Others find that the effects on risk taking depend on the domain (gain or loss; Pabst, Brand, & Wolf, 2013b) or the level of risk (von Helversen & Reiskamp, 2013), and chronic stress may lead to risk aversion (Kandasamy et al., 2014). These mixed findings may be partially explained by the fact that many risky gambling tasks confound risk sensitivity, loss aversion, ambiguity aversion, consistency, and possibly other parameters.

Another domain in which the effects of stress are mixed is intertemporal choice. Intertemporal choices are decisions between rewards available at two different points in time. In these paradigms, participants choose between monetary rewards available immediately and larger rewards available after a delay. Participants tend to prefer rewards sooner in this paradigm, sometimes even at their long-term expense, but there are individual differences in how impatient individuals are in this task. One study found that people became more impulsive under stress (Kimura et al., 2013), another found that there were no effects of stress on intertemporal choice behavior (Haushofer et al., 2013), and yet another found that these effects depended on individual differences in self-reported daily perceived stress (Lempert, Porcelli, Delgado, & Tricomi, 2012). These inconsistencies may reflect the complexity of intertemporal decision making, and further study is needed to uncover the mechanism by which stress influences these choices.

Acute stress has been shown to influence a number of basic processes that are important in decision making, including reward responsiveness (Bogdan & Pizzagalli, 2006; Berghorst, Bogdan, Frank, & Pizzagalli, 2013), executive control (Hains & Arnsten, 2008), and learning from positive and negative outcomes (Petzold, Plessow, Goschke, & Kirschbaum, 2010; Lighthall, Gorlick, Schoeke, Frank, & Mather, 2013). Most decision-making tasks likely involve several of these processes and many decision variables. Therefore, carefully isolating different aspects of decision making will be worthwhile when investigating the effects of induced stress.

Important Considerations for Future Research

There are several limitations that are important to consider when evaluating studies on stress and decision making. First, one needs to distinguish between chronic and acute stress (McEwen, 2007). While our physiological stress responses are well suited to maintaining homeostasis when stressors are brief, our stress responses may become dysregulated and cause more general problems (including mental illness) when we are under "allostatic overload" (McEwen, 2007). Chronic decision-making problems may in part be a result of morphological changes in the brain due to chronic stress (Liston, McEwen, & Casey, 2009; Joëls, 2011). Most laboratory experiments in humans can only draw conclusions about the effects of acute stress in healthy participants. However, disorders like posttraumatic stress disorder and depression, which are marked by chronic stress (Yehuda, 2001; Checkley, 1996), may provide some insight into how chronic stress effects can be distinguished from acute stress effects in humans. Animal studies are also useful in this domain, since they may involve either chronic stress or acute stress.

Another important consideration in stress research is that of individual differences. The impact of stress on cognition most likely depends on the individual's reactivity to stress, and studies have shown that there is a great deal of interindividual variability in how stressors are perceived and how stress responses are regulated (see Frankenhaeuser, 1986). Furthermore, there is evidence that trait anxiety, perceived stress, gender, and working memory capacity can modulate decision making under stress (e.g., Sandi & Richter-Levin, 2009; Lempert et al., 2012; Lighthall et al., 2012; Otto et al., 2013). Another confounding variable in this literature is stressor timing. Stress effects vary depending on the timing after the stressor when effects are recorded. Acute effects include norepinephrine release and sympathetic nervous system activity. Ten to 20 minutes later, cortisol and other stress hormones hit their peak concentration and begin to influence activity in the PFC, hippocampus, amygdala, and other brain regions. An hour after exposure to a significant stressor, there may be changes in gene expression that further affect decision making (Joëls, 2011). Some studies have begun to explore this effect of time. For example, Pabst, Brand, and Wolf (2013a) found that participants exhibited more risky behavior in a game-of-dice task when they were tested 28 minutes after the stressor, but their decision making was actually improved when they were tested directly poststressor. The complicated orchestration of responses associated with stress can result in different decision-making effects at different times poststressor.

Finally, psychosocial and physical stressors result in similar, but not identical, downstream effects, and there are different confounding variables associated with different types of stressors (e.g., social anxiety may modulate the effects of the TSST social stressor, but not of the cold-pressor stressor). Especially when studying social decision making, it is important for researchers to motivate use of a specific stress paradigm.

Mood

Unlike stress, which is associated with well-defined psychophysiological and neurohormonal changes, the mechanisms of mood are less understood. Mood is a diffuse affective state that is primarily characterized by a change in subjective feelings (Scherer, 2005). A common technique for manipulating affect in the laboratory is focused on changing the mood of the subject. This technique, called *mood induction*, attempts to induce a shift in mood through the presentation of affective stimuli, such as films, sometimes combined with more effortful techniques such as imagining personal circumstances.

Appraisal Tendencies

One influential theory in the literature on mood and decision making is the *appraisal tendency framework* (ATF) originally suggested by Lerner and Keltner (2000). The ATF assumes that specific affective states give rise to specific cognitive and motivational properties. It has been argued that emotions and moods elicit *action tendencies* that enable individuals to deal with the situation at hand (Frijda, 1986). These tendencies depend on both the arousal level and valence of the mood, and they may differ for different moods of the same valence. For example, anger may be associated with a motivation to change the situation by confronting or fighting another person, while fear may be associated with withdrawal and avoidance. Much empirical work has been done to investigate the effects of specific moods on judgments, such as risk assessment, evaluations of others, and attributions of causality (see Lerner & Tiedens, 2006, for one in-depth review). Although such judgments are potentially relevant to the type of decision making that we are discussing here, the remainder of this section focuses on studies that have directly examined value-based decision making.

In a study designed to examine the impact of mood on economic decision making, Lerner, Small, and Loewenstein (2004) presented three groups of participants with film clips. Two of the clips elicited feelings of sadness and disgust, while the third was a neutral film clip. Immediately following mood induction, participants were either given a set of highlighters and asked to set a price to sell them (sell price), or they were asked how much they would pay for the set of highlighters (buy price). This paradigm explored the "endowment effect"—a well-documented phenomenon whereby sell prices exceed buy prices, since ownership of an item imbues it with added value. In the neutral condition, the traditional endowment effect was observed: buy prices were lower than sell prices. Participants who had watched the "disgust" clip showed reduced buy and sell prices. However, those in the "sad" film clip condition showed a "reverse endowment effect"; their buy prices were higher than their sell prices. To explain this striking effect, Lerner and colleagues (2004) suggested that the value of the choice option was appraised in a manner consistent with the mood. Sadness may drive an individual to appraise his or her current situation as unfavorable, and enhance the subjective value of actions that change the circumstances. One consequence might be to increase the likelihood of ownership when not endowed with the item (i.e., a higher buy price), and also increase the likelihood of expelling the item when it is owned (i.e., a lower sell price). Similarly, disgust may elicit a tendency to expel all current items, resulting in low prices for buying and selling.

Further evidence that feelings of disgust result in a tendency to dispose of current items comes from a study of the *status quo bias*, a powerful partiality toward one's current state and possessions (Samuelson & Zeckhauser, 1988). After watching a disgusting movie clip (as in Lerner et al., 2004, above), participants were given the choice between keeping one generic box filled with office supplies and switching to a different box that contained similar office supplies (Han, Lerner, & Zeckhauser, 2012). Critically, participants were not aware of what either box contained. The subjects who had undergone the disgust mood induction were more likely to switch to the new box than were subjects in the neutral condition. This result is consistent with the idea of an "expulsion" appraisal tendency when in a state of disgust.

Lerner, Li, and Weber (2013) tested whether sadness would influence financial impatience, by offering intertemporal choices to participants either after a sad or neutral mood induction. Since sadness is associated with a desire to change one's current situation, the authors hypothesized that sad participants would favor more immediate rewards. As predicted, sad participants were more impatient than those in the neutral condition. In a similar vein, Cryder, Lerner, Gross, and Dahl (2008) found that, following a sad mood induction, participants increased their willingness to pay for goods. Sad mood also biases choice toward high-risk/high-reward options, while induced anxious mood biases choice toward low-risk/low-reward options (Raghunathan & Pham, 1999).

Positive affective states have been relatively understudied in this domain, but a recent study examined the influence of a gratitude induction on intertemporal choice. Gratitude is a positive emotion that is future oriented, since when one has been helped in the past, one is more likely to help others in the future. Indeed, gratitude has been found to increase prosocial behavior (DeSteno, Bartlett, Baumann, Williams, & Dickens, 2010). Even in the absence of social context, however, induced gratitude was potent enough to make individuals more patient during intertemporal choice, possibly by making them more future oriented in general (DeSteno, Li, Dickens, & Lerner, 2014). This study provides a good example of how incidental affect can at times help people make more optimal choices.

Social Decision Making

The influence of mood has also been examined in social decision making using the ultimatum game. In this two-player game, one of the individuals plays the role of "proposer," while the other one is the "responder." The proposer is given the opportunity to divide a sum of money between the two players as he or she sees fit. The responder can then choose to accept the proposed split or reject the offer. If the offer is rejected, both players receive nothing. Despite the associated loss of utility for both players, unfair offers are often rejected in this game. For example, if the proposer chooses to keep $80 out of $100, and offers the responder only $20, there is a 50% chance that the responder will reject the offer (Thaler, 1988). To investigate how mood might affect choices among responders in this task, Harlé and Sanfey (2007) induced sadness, amusement, or neutral mood in three groups of participants using film clips. After mood induction, participants (in the role of responders) played a series of ultimatum games with different partners. There were no behavioral differences between individuals in the amusement and neutral conditions, but players who were exposed to sad film clips rejected more unfair offers than those in the neutral condition. Even though the affective state was incidental, it altered the appraisal of the offers, and changed behavior in this task. In a related study, induced disgust also led to an increased rate of rejection of unfair offers in the ultimatum game (Moretti & di Pellegrino, 2010).

Summary

Although the ATF theory has been highly influential, it bears similarity to other theoretical frameworks that warrant mention. The "affect-as-information" model (Schwarz & Clore, 1983) proposes that affect may be incorporated into the judgment process even when it is irrelevant. Similarly, the "feeling is for doing" model (Zeelenberg, Nelissen, & Pieters, 2007) holds that affective states, such as moods, serve the adaptive function of motivating behaviors.

While these models make testable predictions for behavior, and psychological evidence of mood effects on decision making is abundant, the neural mechanisms behind decision making in different mood states have been slow to emerge. This may be because of the challenges of studying the neural basis of mood in general—after all, it is difficult to study two different moods in the same individual within the same fMRI scanning session. However, future research with clever neuroimaging designs and analyses may yield important insights into the neural mechanisms that enable moods to influence our choices.

Affective Priming

While mood induction reliably evokes changes in self-reported subjective feelings, affective states can also be manipulated without explicit awareness, through *affective priming.* In priming, subjects are subliminally presented with affective stimuli, such as happy, angry, and neutral faces. These primes presumably elicit transient emotional responses that impact subsequent choices. To date, only a few studies have investigated how affective priming influences decision making.

Winkielman, Berridge, and Wilbarger (2005) subliminally presented three groups of participants with angry, happy, and neutral faces, while they performed a gender classification task. Afterward, participants poured, consumed, rated, and indicated their willingness to pay for a drink. Those who had been exposed to happy faces poured and consumed more of the beverage. They also rated the beverage more highly and increased their willingness to pay for it, relative to participants who saw neutral faces. The subjects who were presented with angry faces showed the opposite effect. Participants were unaware of the experimental manipulation and they did not report any changes in subjective feelings during the study, making these behavioral findings even more remarkable. It was suggested that the emotional primes generated subtle emotional responses, which were sufficient to alter the appraisal of the choice options, and to change behavior.

Luo, Ainslie, and Monterosso (2012) examined the effect of affective primes on intertemporal choice, by subliminally presenting the same set of subjects with angry, fearful, and happy faces, while they performed an intertemporal choice task (i.e., a series of choices between smaller/sooner and larger/later monetary rewards). In the trials that were preceded by presentation of fearful faces, subjects tended to choose larger/later rewards. The authors suggested that perhaps participants attributed the fearful emotional response to the option that was more readily available during the time of choice.

Individual differences may also influence the extent to which affective primes influence decision making. Participants performed the aforementioned intertemporal choice study during acquisition of fMRI data. The participants who showed the greatest changes in BOLD signal in the anterior cingulate cortex (along with a few other regions) also showed the largest priming effect (Luo et al., 2012). In another study highlighting individual differences in priming effects, Augustine and Larsen (2011) showed participants either positive or negative words while they made choices in an intertemporal choice paradigm. Participants also completed questionnaires that assessed personality variables. Individuals who were high in neuroticism and who were in the negative prime condition discounted delayed rewards at a significantly higher rate than those in any other condition.

Although responses to affective primes are subtle and outside of conscious awareness, this set of studies suggests that they may still influence decisions.

Affect Dispositions

Affect dispositions are stable traits that have an affective quality (Scherer, 2005). For instance, some people may be generally more anxious or happy than others. Affect dispositions may influence choices, because they affect the way that individuals process choices and act on them. They may also impact choices because they affect an individual's proneness to certain moods or stress.

So far, only a few studies have investigated the relationship between affective trait variables and decision-making tendencies. For example, trait positivity has been shown to predict more rejection of unfair offers in the ultimatum game (Dunn, Makarova, Evans, & Clark, 2010). Anhedonia has been found to correlate negatively with temporal discounting rate—that is, individuals who are anhedonic tend to be more patient (Lempert & Pizzagalli, 2010). Individuals who are anxious are more prone to the framing effect (i.e., more risk seeking in the loss domain and more risk averse in the gain domain; Xu et al., 2013; Giorgetta et al., 2012) and they are more likely to punish others in social decision-making tasks (Grecucci et al., 2013). Higher trait anxiety may be linked to less risky decisions, perhaps because anxiety results in a more negative interpretation or appraisal of potential outcomes (see Hartley & Phelps, 2012, for a review of anxiety and decision making).

The link between affect dispositions and decision making is unsurprising, because affect dispositions have been linked to psychopathology, which has profound consequences on decision making. For example, someone with very high trait anxiety might be diagnosed with generalized anxiety disorder. Given this connection, it has recently been proposed that basic neuroeconomic research may provide an important tool for translational studies in psychiatry (Sharp, Monterosso, & Montague, 2012). Much like the other types of incidental affect mentioned above, it is unlikely that a single mechanism or process will underlie the impact of affect dispositions or psychopathology on decision processes.

Integral Emotion

A primary function of emotion is to highlight the relevance of stimuli and events in order to guide adaptive behavior (Frijda, 2007). Therefore, it would make sense that the valuation of a particular option might incorporate the emotional response associated with it. This emotional response is also known as an integral emotion, because it arises from the choice and is an integral aspect of it. For instance, if one of the choice options elicits a fear reaction, that reaction would contribute to a negative evaluation of that choice, which would lead to avoidance of that option. While it may seem obvious that the emotional response to the choice options or outcomes should influence valuation, relatively few studies have explicitly measured integral emotions during decision making. In this section, we summarize studies that have attempted to correlate integral emotional variables with decision variables.

One affective variable that may be influenced by choice attributes during decision making, and is easily measured in the laboratory, is physiological arousal. Physiological arousal responses refer to objective, transient indications of autonomic nervous system arousal in response to a stimulus. One of the most common measures of emotional arousal in the laboratory is the skin conductance response (SCR), a well-established correlate of sympathetic nervous system activity. Below, we primarily focus on studies that have used this measure in the context of decision-making tasks, although we also include studies that have utilized subjective ratings of emotional reactions or feelings.

Physiological Arousal and Choice Attribute Processing

In one of the first examinations of a physiological response during decision making, Bechara, Damasio, Tranel, and Damasio (1997) studied patients with OFC damage as they performed the Iowa Gambling Task (IGT), a paradigm that assesses risk attitudes and value updating. In this paradigm, participants choose cards from decks that either yield large rewards and occasional large losses (“risky,” overall disadvantageous decks) or decks that yield small rewards and small punishments (“safe” decks). Over the course of the task, normal control participants began to generate SCRs before selecting from the risky decks. They began to avoid those decks shortly thereafter. Meanwhile, the patients with OFC damage did not generate these anticipatory arousal responses, and they did not avoid the risky decks. To explain these results, Bechara and colleagues proposed the somatic marker hypothesis. This hypothesis suggests that the anticipatory arousal response is a bodily signal of the value of the choice and serves to steer participants away from “risky” choices. According to this hypothesis, since patients with OFC damage could not generate these anticipatory emotional responses, they also could not change their assessment of risk in the task. Several studies have since questioned the somatic marker hypothesis and the specific interpretation of these results (Fellows & Farah, 2005; Maia & McClelland, 2004; Tomb, Hauser, Deldin, & Caramazza, 2002). Nevertheless, this study remains one of the first to link emotional responses and brain systems to decision patterns.

A more recent study examined SCRs during moral decision making in patients with ventromedial prefrontal cortex (vmPFC) damage and healthy controls (Moretto, Ladavas, Mattioli, & di Pellegrino, 2010). In “personal” moral dilemmas, when participants had to choose whether or not to perform a reprehensible action for a utilitarian outcome (e.g., pushing someone to death in order to save five people), patients with vmPFC damage made significantly more utilitarian choices than healthy controls did. In addition, they did not exhibit SCR responses when choosing these options, while healthy participants did. This study suggests that the emotional response associated with certain actions may influence moral decision making, and that the vmPFC may be an important region for mediating these emotional responses. From this experiment, however, it is unclear whether emotional responses to "personal" moral dilemmas underlie decisions.

Emotional arousal has also been associated with decision tendencies in social decision making in the ultimatum game. Van't Wout, Kahn, Sanfey, and Aleman (2006) assessed SCR while participants played the ultimatum game (as responders) with either another person or a computer. SCRs were greater in response to unfair offers relative to fair offers, but this effect was only seen when participants were playing against other people (and not when they played with a computer that randomly generated offers). In addition, the magnitude of the SCR response was positively correlated with offer rejection rate. These results are consistent with the interpretation that physiological arousal reflects a valuation process in the social domain, and that this emotional response to social cues is related to economic decisions.

These studies linking arousal to risky choices and social components of decisions suggest that specific cues or attributes on some trials of a decision-making task can induce an emotional reaction, which may influence the choice when those factors (i.e., heightened risk, an unfair conspecific) are present. However, just the simple act of potentially gaining or losing money can also elicit arousal responses (e.g., Delgado, Labouliere, & Phelps, 2006; Delgado, Gillis, & Phelps, 2008). In order to assess how arousal to losses and gains is linked to choice, Sokol-Hessner and colleagues (2009) gave participants a simple gambling task in which they had to choose between a certain outcome or a gamble with a 50/50 chance of winning or losing money. In gambling tasks, two variables that are often confounded are risk sensitivity and loss aversion. Loss aversion is the tendency to weigh potential losses more than gains when considering the choice options. Someone who is very loss averse may also appear to be risk averse, even if he or she is generally risk seeking when there is no potential loss. With their task, Sokol-Hessner and colleagues (2009) were able to separately quantify loss aversion and risk sensitivity for each participant. They found that loss aversion was correlated with the SCRs to monetary losses relative to gains, such that those participants who showed greater SCR to losses relative to gains were also more loss averse. They found no relationship between arousal and risk sensitivity. In a follow-up fMRI study, Sokol-Hessner, Camerer, and Phelps (2013) found that the magnitude of the amygdala BOLD response to monetary losses relative to gains correlated with loss aversion, but this activity was unrelated to risk sensitivity. Consistent with these results, patients with amygdala damage are less loss averse overall (De Martino, Camerer, & Adolphs, 2010) and administering a beta-adrenergic blocker (propranolol), which has previously been shown to diminish the amygdala's modulation of memory (Phelps, 2006), also reduces loss aversion, but does not affect risk sensitivity (Sokol-Hessner, Lackovic, Tobe, Camerer, Leventhal, & Phelps, 2015). Given that most risky decision tasks do not independently model loss aversion and risk sensitivity, it is possible that some observed effects of emotional arousal in risky decision-making tasks (e.g., Bechara et al., 1997) are due to loss aversion, and not risk attitudes.

Changing Affect, Changing Choices

Although we often think of emotional reactions as being out of our control, it has long been recognized by affective scientists that emotions are flexible. For example, emotional responses are highly susceptible to our choice environment and our expectations about that environment. If we want to make consistently adaptive choices, we should be aware of this flexibility, and use cognitive resources to change our emotions when necessary. For instance, it would be adaptive to fear a potentially dangerous snake when walking in the woods, but a similar reaction in a zoo would be inappropriate. The flexibility of emotion, or lack of it, may underlie a range of psychiatric disorders, from addiction to posttraumatic stress disorder.

In value-based decision making, the flexibility of emotion suggests that its impact on choices may also vary. If the emotional reaction to a choice or choice options is flexible, its modulation of the value calculation should change over time. Affective neuroscientists have investigated several techniques that can be used to alter emotion (see Hartley & Phelps, 2010, for a review). The technique that we discuss here is cognitive emotion regulation.

Cognitive Emotion Regulation

The aim of cognitive emotion regulation techniques is to change emotional reactions by actively manipulating one's cognitions about the situation at hand (see Ochsner & Gross, 2005; Gross, 1998, for reviews). One common strategy is to reappraise or reinterpret the meaning of the event. Appraisal is a component in determining the emotional significance of an event (Scherer, 2000, 2005) and by reappraising an event, an individual may change its emotional significance. In typical studies of reappraisal, subjects are provided with instructions to help them reinterpret a negative event or stimulus. These studies show reduced amygdala activation with reappraisal, coupled with increased activation of regions of the PFC that are thought to inhibit the amygdala's BOLD response (Ochsner & Gross, 2005).

In addition to changing emotional reactions to aversive stimuli, similar techniques can diminish the emotional response to rewarding stimuli. For instance, Delgado et al. (2008) showed participants neutral stimuli, that, over the course of the experiment, were conditioned to be associated with monetary rewards. These rewarding stimuli began to elicit an SCR response, but a simple emotion regulation instruction decreased this emotional arousal. In addition, BOLD responses in the striatum were diminished when participants were instructed to regulate their emotional response to anticipated monetary rewards. This decreased striatal activation was coupled with increased activation of the PFC.

Emotion regulation can also change the representation of value during economic decision making. In an fMRI study by Martin and Delgado (2011), participants performed a gambling task, during which they could make either risky or safe choices. When participants effectively utilized an imagery-based emotion regulation technique, their risk taking was reduced. They also exhibited decreased striatal activation during their gambling decisions. This finding suggests that emotion regulation can lead to decreased risk-seeking behavior. Critically, however, there are individual differences in how well participants can use this strategy.

In the gambling paradigm outlined earlier, Sokol-Hessner et al. (2009) examined the impact of a perspective shift intended to prompt the reappraisal of the significance of the choice. Participants were asked to make a series of risky monetary choices. For each participant, a loss aversion parameter was derived. In one set of choices, subjects were asked to "attend" to each individual choice and its potential outcome in isolation. In the other set, they were asked to "regulate," by considering each choice as one of many choices in a larger set, or portfolio. Simply asking participants to put potential losses in perspective in this way led to a reduction of SCR to losses relative to gains. Furthermore, this change in arousal to losses between conditions was directly related to a decrease in the participants' individual loss aversion. In a follow-up fMRI study, Sokol-Hessner et al. (2013) found that implementing this regulation technique reduced amygdala activation to losses, and led to an overall increase in BOLD responses in the striatum, vmPFC, and dorsolateral PFC. These findings suggest that this novel reappraisal strategy draws on the same neural circuitry that is engaged in more typical emotion regulation tasks.

Emotion regulation strategies can also change choices in social decision-making paradigms, such as in the ultimatum game. Van't Wout, Chang, and Sanfey (2010) invited participants to play the ultimatum game as responders under three different conditions: emotional reappraisal, expressive suppression, and no regulation. In the reappraisal condition, subjects were asked to adopt a neutral, nonemotional attitude when viewing the offers. Individuals in this condition were asked to come up with reasons why their opponent would give them an unfair offer (e.g., "He really needs the money," "She is a college student just like me"). In the expressive suppression condition, participants were asked to "not let their emotions show" as they chose whether or not to accept the proposed splits of $10. Participants who cognitively reappraised the offers rejected significantly fewer unfair offers than those who suppressed their emotions or those who did not regulate their emotions at all. Furthermore, when they played the game as proposers directly afterward, participants in the reappraisal condition were more likely to propose fair offers. These findings suggest that simply suppressing the expression of emotion is not sufficient to change decision-making patterns, but reinterpreting an emotional response to the offer of an unfair split can lead to a change in decision tendencies.

Integral emotions can occasionally lead to decisions that result in an overall monetary loss (e.g., rejections in the ultimatum game, risk seeking when probabilities of reward are low, forgoing larger potential gains to avoid potential losses).

However, research on emotion regulation suggests that, to the extent to which emotion is linked to these choices, they can be changed. This line of research also provides strong support for a role of emotion in the calculation of subjective value, since cognitive strategies that change the emotional significance of a choice option can change choices.

Conclusion

In this chapter, we have tried to present a review of the research that has sought to elucidate the relationship between affect and economic decision making. From the evidence, it is clear that this relationship is complex. There are many components of affect that may each have a unique influence on different aspects of the choice process. After all, both affect and decision making are general terms that describe a collection of processes, only some of which we have explored here. Investigating affect is challenging enough by itself, since manipulating and measuring affect in the laboratory can be difficult, and there is debate about how to characterize affective variables. There are also many variables that influence economic choice, and teasing these apart is a challenge for decision science. Finally, the relationship between affect and choice is flexible—although affect does influence choice, it is possible to regulate affect to change choice.

Given the complex nature of both choice and affect, a two-system approach, in which cognition and emotion play distinct, competitive roles in decision making, seems too simplistic to capture the breadth of their interaction. The repeated reference to dual systems of affect and reason in research on decision making potentially hampers scientific advances in this area by discouraging investigations that capture the detailed and nuanced relationships between unique aspects of affect and choices. It also suggests to the public and to scientists in other disciplines that the historical notion of competing forces of emotion and reason is supported by scientific evidence. Perpetuating this idea may result in misinformed efforts to inhibit emotion in order to promote rational decision making. There have been many exciting recent advances in the field of emotion and decision making. However, if we want to have a fine-grained and detailed science of decision making, moving beyond dual-systems approaches is a necessary step.

CHAPTER 6

Computational Models of Emotion as Psychological Tools

Stacy Marsella and Jonathan Gratch

A convergence of factors over the last 50 years has led to a growing cross-disciplinary collaboration that bridges computational technologies and research into human emotion processes. On the computational side, computer systems have become more powerful and the software that runs on them both easier to use and capable of addressing a far broader range of problems. Computers have also transformed our day-to-day life. They have moved from being behind-the-scenes calculators to become central to how people socially engage with the world. Though we are often not aware of it, we interact daily with artificially intelligent systems. The last 50 years has also seen a transformation in our understanding of human emotion. Research in psychology and the neural sciences has made significant advances in detailing the functional, often adaptive role of emotion in human cognitive processes, behavior, and social interaction.

These developments have had a number of interrelated consequences. As computer systems have become more powerful and easier to use, the sciences and social sciences have turned to computer simulations as a means to model, test, and explore theories, including theories about how emotions are elicited and their impact on behavior. Research in artificial intelligence (AI) has explored whether the functional role that emotions play in humans can suggest approaches to more capable, robust AI systems. As research has argued that emotion plays a key role in human social interaction and computer systems have become actors in our world, these systems have become more socially adept at interacting with people and their emotions. This has led to research on models that infer a human user's emotional state as well as on computational systems that model the causes and mimic the expression of human emotional states, in both cases as means to facilitate human–computer interaction. Broad discussions of these various ways psychological research and computational work on emotion can benefit each other have been presented elsewhere (Blascovich et al., 2002; Cohn, 2010; Marsella & Gratch, 2014; Reisenzein et al., 2013).

This chapter takes a more specific focus on the use of computational models as a methodological tool enabling emotion research in psychology. Even this restriction leaves a broad area of discussion. The scope of computational models can differ greatly, in large measure because emotion interacts with a wide range of human mental processes and behavior. A model may seek to broadly capture the causes and consequences of emotion or selectively focus on a specific aspect.

To begin our discussion, we provide a high-level view of the use of computational models as a tool in emotion research. We then explain their use by drawing on a few illustrative examples of computational models used to explore intrapersonal and interpersonal emotion processes.

Computational Models and Emotion Research

Models implemented and simulated on a computer have become increasingly important tools in the sciences and social sciences. These computational models are especially relevant to studying the dynamic behavior of complex systems that do not admit purely analytical answers to questions about the system's behavior. Instead, simulation serves to explore the behavior and generate predictions about the real-world system.

A key benefit of computational modeling and simulation arises from a lack of complete access to the phenomena being studied (Simon, 1969). This lack of access has several manifestations. There may be gaps in the theory. There may also be gaps in the knowledge underlying the theory, such as how other mental processes influence or are influenced by emotions. There may be difficulty in manipulating parameters, ablating functionality, or evaluating dynamics *in vivo*. From the perspective of social interaction in groups, it may not be easy to conduct controlled human subject experiments into emotional phenomena such as emotional contagion in crowds. This implies conversely that the validation of computational models against human data may in fact push experimental methodology (Marsella & Gratch, 2014).

The view that computational models are also useful for research in psychology specifically is, of course, not a new idea. It is central to the stance taken in cognitive science (Simon, 1969), a view common in much of the early work in AI (Newell, 1990), and even has its own moniker: computational psychology (Sun, 2008). Computational models provide a range of potential benefits to the study of human emotion, by impacting theory construction and evaluation during the model's formulation, implementation, simulation, and integration into larger systems.

Specifically, computational models provide additional perspicuity in theory formation and evaluation—in terms of the ability to create models and artifacts that provide a concrete basis for exploring the relationship between complex phenomena, including the dynamics of emotion processes, the role of other mental processes and emotions in social interaction.

The various roles for computational models in theory formulation and evaluation can impose very different constraints on how a model is constructed and evaluated. The benefits of models and their simulation, for theory formation and testing of course hinge on the nature of this coupling between theory and model.

The goal for the model may therefore not just be accurate prediction of human behavior. Rather, the model development may provide a framework to explore virtual *in vitro* experimentation with the constructs and processes hypothesized by a theory. In that case, the model may be designed to support the manipulation of those constructs, perhaps leading to simplifications that forgo, to a degree, quantitative or qualitative accuracy with human data, preferring instead to provide explanatory power.

In actual practice, computational models of emotional processes differ greatly in what phenomena they model, mirroring the fact that emotion influences a wide range of cognitive, somatic, behavioral, and social phenomena. The scope of models can thus differ greatly: Some models focus on the cognitive or environmental factors that cause emotion (Broekens, DeGroot, & Kosters, 2008); others address the consequences of emotion on other mental processes or behavior, such as coping strategies (Bosse, Pontier, & Treur, 2010); a few even attempt to capture circular causal interactions between emotional causes and consequence (Lewis, 2005; Marsella & Gratch, 2009), arguably their most important role. Models also differ in their representational choices (e.g., simple regression models to full-blown cognitive architectures), and the specificity of the phenomena they address—for example, focusing on specific causes or consequences of emotion, such as learned responses to threat (Li, Nair, & Quirk, 2009) or the impact of emotion on attention (Itti & Baldi, 2005). There are also distinctions between models in terms of the wide range of computational and formal mechanisms used to form a model, including neural networks (Sander, Grandjean, & Scherer, 2005), symbolic systems (Gratch & Marsella, 2004), and logical formalisms (Lorini & Castelfranchi, 2007).

In the next section, we delve more deeply into these issues concerning how computational models are integrated into emotion research.

Integrating Computational Models into Emotion Research

The paths depicted in Figure 6.1 illustrate our view on the various ways theoretical, empirical, and computational activities interact to inform psychological research on emotion. Traditional

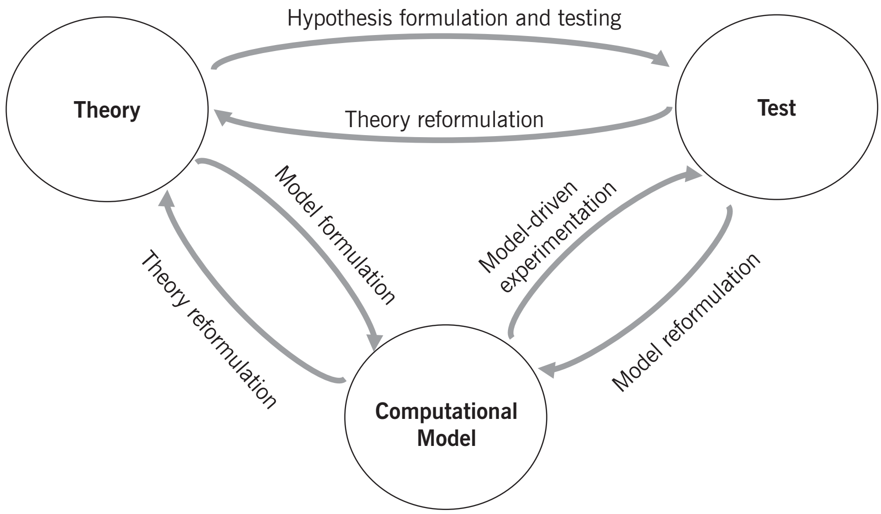

FIGURE 6.1. Points of interaction among theoretical, computational, and empirical activities surrounding the advancement of emotion research.

psychological research (i.e., research that does not involve computational modeling) is reflected in the loop at the top of this diagram. For example, classical theoretical research enters this cycle from the left: a theory is formed and hypotheses are derived and tested, confirming the theory or forcing its reformulation. Exploratory research enters this cycle from the right: data are collected and mined; a theory is formed, and then subsequently tested.

Computational models expand the range of scientific methods. The large cyclical loop in the diagram, spanning *Theory*, *Computational Model*, and *Test*, represents what we have called model-driven experimentation (Marsella & Gratch, 2014): theory is used to help formulate computational artifacts, such as a computer model of the theory or new computational approaches to creating stimuli. Constructs in the theory are essentially reified in the model. The resulting technological artifact in turn leads to empirical testing whereby those constructs are experimentally manipulated, exploiting the technology to go beyond standard human subject studies. The empirical testing can include simulation of a computational model to generate predictions as well as potentially additional human subject testing to validate those predictions. The empirical testing may also incorporate computationally generated stimuli or confederate simulacra in human subject studies. The results of this empirical testing in turn lead to results and data that can be used to reformulate the model or theory.

The lower left and lower right small loops in Figure 6.1 highlight specific ways that research integrates and exploits computational methods. In the discussion that follows, we endeavor to detail the nature of the links in these loops.

Model Formulation and Theory Reformulation

The lower left loop in Figure 6.1 between *Theory* and *Computational Model* depicts that the process of formulating a model is informed by theory (the link from *Theory* to *Computational Model*) but also can lead to reformulation or support of the theory (the link from *Computational Model* to *Theory*). We discuss these links in turn.

Consider first the link from *Theory* to *Computational Model*. Emotion theory commonly informs the development of computational models and technologies by defining the constructs that form the basis of the model, including what comprises an emotional state such as anger, as well as the antecedents and consequents of that emotion. Those constructs will in turn be manipulated as part of the empirical testing of the model. Such a close connection between theory and model fundamentally impacts the formulation of the model.

For example, theories differ considerably as to which constructs are treated as intrinsic to an emotion (such as cognitions, somatic processes, behavioral tendencies, and responses), the relationships between these constructs (such as whether cognitions precede or follow somatic processes), and representational distinctions (such as whether anger is a perceiver-dependent category or natural kind; Barrett, 2006, 2012).

Such theoretical differences impact the computational mechanisms that are used to formulate a model. The constructs of the theory must be mapped to the model's computational representations and algorithms in the model. Since theories of emotion have fundamental differences with respect to the constructs they propose, a range of computational mechanisms have been used for models of emotion processes.

For example, appraisal theories (Scherer, Schorr, & Johnstone, 2001) typically argue that emotion arises from an assessment of the person–environment relation from a subjective perspective, specifically persons' beliefs about how their concerns or goals are impacted by the environment. This view fits quite well with the belief–desire–intention (BDI) model of agency, a model common to AI research that argues an agent forms intentions to act based on its beliefs and desires (Bratman, 1987). As a consequence of this fit, the BDI model approaches can readily model appraisal theory (Steunebrink, Dastani, & Meyer, 2007). Constructs in the theory map readily to the computational formalisms. Not surprisingly, appraisal theories have provided the basis for numerous computational models of emotion (see Marsella, Gratch, & Petta, 2010, for a review), not only for their prominence in the psychological literature, but because of their close fit to representational concepts in BDI models of agency, leading to an ease with which appraisal can be incorporated into existing AI systems and cognitive architectures that employ the BDI model approaches.

On the other hand, other theories of emotion emphasize the role of specific neural regions in emotional process, informed by data that reveal the functional role of neural regions and the structure of their connectivity (Yechiam, Busemeyer, Stout, & Bechara, 2005). To realize a computational model, these constructs must be mapped to a computational model's computational mechanisms that model these regions. The researcher may also seek to impose a constraint that the resulting model's mechanisms be implementable in the neural wetware it purports to model (Armony, Servan-Schreiber, Cohen, & LeDoux, 1995). As a consequence, neural network-based computational mechanisms are often employed in these models.

The constructs that a theory posits, and relationships between such constructs, can also impact the ease with which the theory can be computationally modeled. For example, appraisal theories have led to numerous computational models of emotion not only because of their close fit to representational concepts in BDI models of agency (mentioned earlier) but also because some appraisal theories (sometimes referred to as causal, as opposed to constitutive appraisal theories; see Gross & Barrett, 2011; Clore & Ortony, 2013) either support, or can be interpreted as supporting, an essentialist, reductionist perspective to modeling emotion processes. Such an interpretation allows for a computational modularity that treats individual appraisals variables (e.g., desirability, expectedness, control) as independent computations that can be modeled in isolation. In contrast to this modularity, a psychological constructionist view of emotion rejects such an essentialist, natural kind view (Barrett & Russell, 2015). From a constructionist perspective, instances of emotion labeled as anger arise from multiple cognitive, physiological, and situational factors. Further, they may not share the same eliciting mental processes and those mental processes are not unique to emotion elicitations. The explicit modularity that facilitates straightforward breakdown into distinct computational processes is explicitly rejected by the theory, requiring instead approaches to the problem that take into account the complex interplay among these multiple influences. These distinctions between theories of course say little by themselves about the validity of the theories or the models formed from them. Rather, they speak to the nature of the phenomena posited by the theory, the level at which the theory tries to capture regularities in the phenomena, and therefore the potential challenges in formulating a model.

During formulation of a computational model, constructs in the theory (i.e., the structures and processes proposed by the theory) are formally represented and implemented on a computer. This formulation process by itself can lead to reformulations or extensions to the theory.

This reformulation occurs, in part, because the process of realizing a model as working software exposes implicit assumptions, weaknesses, or gaps in the theory. For example, appraisal theories of emotion often argue that a key variable in appraisal is the causal attribution of blame (e.g., Lazarus, 1991). But the process by which a person makes such an attribution, and the related required resources and capacities to perform this assessment, are typically not carefully laid out. And yet this attribution process may in itself be quite involved (e.g., Shaver, 1985; Weiner, 1995). Addressing such a gap would extend the scope of the theory, making the model formulation process an integral part of theory construction (e.g., see Mao & Gratch, 2005, for one example). A computational model that delves into the calculation of blameworthiness, as well as the processes that derive other appraisal variables, essentially extends the theory by filling in the gaps. As these processes are specified, synergies may also be revealed between how the individual appraisals are calculated, even to the extent of reformulation of the dimensions or variables.

Further, formulating a theory as computational processes, such as the derivation of appraisal variables, forces the question of how the derivation processes work, the time course of those processes, and the temporal relation between them. What operates in parallel, what operates in sequence, and what are the dependencies between the various subprocesses in the overall model? Answering these questions in a computational model often highlights issues that are not apparent at the level of the theory and even if they are, may end up being answered differently.

Thus, one of the key benefits of computational modeling is that it forces a mind-set of thinking in terms of the description of processes, and especially distinguishing process descriptions from the description of the output of the process. Of course, psychological theories need to describe or predict the output of a process, but that description is distinct from the process that generates it. As Simon (1969) poignantly argued in his example of the ant's circuitous navigation in sand, the complexity of the path may be due to the ant's reactions to the local topology as opposed to the complexity of the processes driving the behavior (p. 53). A theory of the ant's behavior needs to incorporate how the environment induces the complex behavior but should not seek to explain the complex behavior independent of the environment that evokes it. See a further discussion of this point in the section "Impact of Model Formulation on Theory Reformulation."

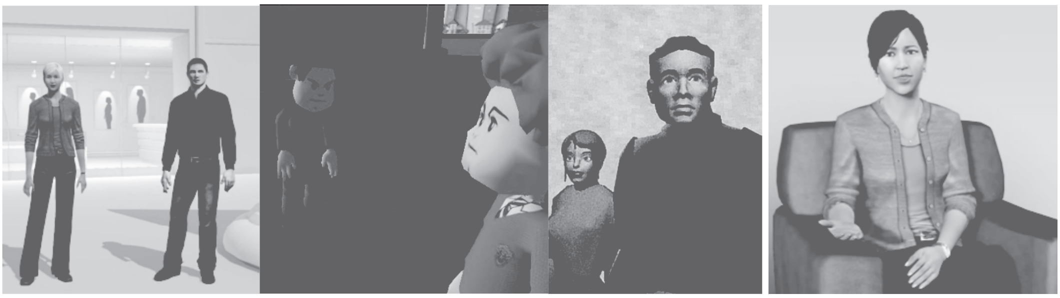
This in turn highlights that we can view computational modeling as also extending the language of emotion theorizing by incorporating concepts, processes, and metaphors drawn from computation, much as concepts such as *information processing* and *symbol systems* impacted cognitive psychology in general. For example, several computational models have recast the appraisal theory in terms of concepts drawn from AI and computer science generally, including knowledge representation (e.g., Gratch & Marsella, 2004), planning (e.g., Dias & Paiva, 2005; Gratch, 2000), neural networks (Sander et al., 2005), and decision making (Lisetti & Gmytrasiewicz, 2002; Ito, Pynadath, & Marsella, 2010; Si, Marsella, & Pynadath, 2010).

Models of emotion processes can also be integrated into larger systems. This can also expose hidden questions behind traditional conceptualizations and extend the scope of theorizing. For example, several computational models of emotion have been incorporated into larger systems that seek to model emotion's relation to other mental processes and behavior (Marsella & Gratch, 2001; Dias & Paiva, 2005; Becker-Asano, 2008; Rank, 2009).

In particular, models of emotion and affective expression have been incorporated into virtual humans—software artifacts that look and act like humans—capable of perception, dialogue, and action in a virtual world that they can cohabit with people and interact with using the same verbal and nonverbal behavior people use in face-to-face interaction. These systems essentially allow for the study of emotion in a virtual ecology, a form of synthetic *in vivo* experimentation (see Figure 6.2).

Integration into larger virtual human systems forces the researcher to explore the relationships between processes in ways that move across traditional academic boundaries in psychology. In the process, the underlying psychological theories that initially drove the design of the model can be transformed as researchers are required to address fundamental architectural questions about the relation of emotion processes to other cognitive processes, perception, behavior, and social interaction (Rickel et al., 2002; Becker-Asano, 2008).

The modeling of emotion and emotional expression in virtual humans has also led to new ways to create stimuli for human subject experimentation. Virtual humans are highly compliant and controllable confederates for experiments. A virtual human can be manipulated systematically to elicit behavior from human subjects. For example, virtual humans have been used to show that subtle changes in physical appearance or behavior can profoundly impact social interaction, including changes to people's willingness to cooperate



Hartholt, Traum, Marsella, Shapiro, Stratou, et al. (2013) | Zoll, Enz, Schaub, Aylett, and Paiva (2006) | Hoyt, Blascovich, and Swinth (2003) | DeVault et al. (2014)

FIGURE 6.2. Examples of virtual humans.

(Krumhuber et al., 2007), the fluidity of their conversation (Gratch, Wang, Gerten, & Fast, 2007), learning outcomes (Baylor & Kim, 2008), and even their level of social aggression (McCall, Blascovich, Young, & Persky, 2009).

Yet another form of integration is to place emotion models in multiagent-based social simulations where multiple autonomous software agents are interacting with one another. In particular, such simulations have been used to study emotional contagion processes (Tsai, Bowring, Marsella, & Tambe, 2013).

The key point here is that the formulation into a computational model can lead to reassessment and reinterpretation of the theory using the computational tools of representation, function, and process. In fact, overly faithfully "reimplementing" a psychological theory may do a disservice both to computational science and the original theory.

Decoupled Theory and Model

In our discussion so far, we assumed a close coupling of theory and model, where the theory provides the constructs that become the starting basis for the model. In practice, there are several ways this coupling can be loosened and even eliminated.

There may not be a theory as the genesis for the model. Rather, the model itself is treated as the theory, forgoing preexisting theory as a central basis for the modeling. For example, the Bayesian model of surprise proposed by Itti (Itti & Baldi, 2005) and the complexity (Kolmogorov) model of surprise proposed by Dessalles (2011) largely start from a computational perspective.

Computational work may also draw on constructs from differing theories. For example, the neural network model of personality by Read et al. (2010) is influenced by several different theories of personality and temperament including approach–avoidance motivational systems, goal-based models of traits, and affective neuroscience work on motivational systems. Some work draws together even competing theories of emotion—for example, Becker-Asano (2008) combines appraisal theories of emotion with pleasure–arousal–dominance dimensional theories (Russell, 1980, 2003).

For these amalgam models (models with multiple theoretic influences), one issue is that coherence across the theories for the model may combine theories that have seemingly inconsistent constructs—for example, the originating theories may have fundamental disagreements about what constitutes an emotion. Somewhat less obvious, however, is that they break or at least complicate the link back from empirical results of the model to the originating theories because the result from any manipulation of the model in a simulation may not be readily attributed to any specific theory used in forming the model. For these reasons, the model de facto becomes the theory.

Empirical Simulation and Validation

The computational realization of a theory can also increase the capacity to generate data and draw predictions from theory by extending empirical methods beyond human subject testing by inclusion of the simulation of the model. Computational models thereby provide an empirical framework for studying emotion processes that goes beyond what is feasible in more traditional laboratory settings. In particular, computational models are commonly process models. Computer simulations of the model *behave*: they provide a means to explore systematically the temporal dynamics of emotion processes and form predictions about the time course of those processes.

Manipulations of experimental conditions may be explored more extensively with a computational model, such as by ablating certain functionalities or testing responses under adverse conditions that may be costly, risky, or raise ethical concerns *in vivo* (e.g., Armony, Servan-Schreiber, Cohen, & LeDoux, 1997). Simulations can reveal unexpected model properties that suggest further exploration.

However, validating these simulated results against human behavior raises interesting, difficult challenges for traditional laboratory studies. A computational model that posits dynamics, for example, may push traditional experimental methodology to derive similar temporal dynamics in human subject studies in order to compare those results against the model's results. Further ablation studies done with the model may simply be impossible to do *in vivo*.

Traditional methods and measurement techniques for the study of human emotion may not in fact be well suited for the validation of computational models. Because computational models are often process models, they can make explicit predictions about the features of situations in which emotions arise and the dynamic interplay of emotion with other mental processes over time as situations evolve. However, existing empirical work on emotion has often shied away from directly exploring or manipulating such features and dynamics. For example, mood-induction studies may shape a participant's mood independently from the situation (such as by listening to happy or sad music; Schwarz & Clore, 1983) or by creating "one-shot" situations (such as watching reactions to the spinning of a roulette wheel; Reisenzein, 2000), as they provide experimental control. To explore a model's prediction about how emotions arise in an evolving situation, and to explore the interplay between emotion and other mental processes, pushes the experimental methodology and measurement techniques beyond such approaches (Butler, 2011).

Further, the construction and simulation of the model may not solely have a goal of accurate prediction but rather be part of a larger theory formation process where the model serves as a platform that can be experimentally manipulated to generate predictions for subsequent study. For example, as we discuss below, Armony et al. (1997) ablated parts of a neural net model of conditioned threat response in rats in order to make predictions about the role those parts play, which were later borne out in studies with real-world rats. As a consequence, it is not simply the predictions of the model that mattered under normal conditions. Rather, for such ablations to be meaningful and useful, there must be a mapping at an internal functional and structural level between the model and the real-world mental processes it is designed to model so that the ablation can be related to the real-world phenomena and ideally have predictive value in studying it.

Models in Actual Practice

A broad range of computational work has leveraged theories of emotion. Here we focus more selectively on work that illustrates a tight coupling of emotion research and computational approaches that was discussed earlier. In illustrating these examples it is useful to distinguish work on intrapersonal emotion from work on interpersonal emotion, not only because they explore phenomena from a system as opposed to individual perspective but because the interpersonal perspective employs different computational approaches. For example, a theory or model of social interaction can be specified at the individual level or the systems level.

Intrapersonal Emotion Modeling

Emotion modeling on intrapersonal phenomena seek to explore emotion from the perspective of the processes operating in the individual as that individual interacts in the physical or social environment. As we noted earlier, computational modeling of these internal processes can benefit emotion research in a variety of ways, including exposing gaps in theories and generating predictions through simulation. Additionally, models provide a framework in which processes can be described, employing a range of computational and mathematical frameworks often in part because theories differ in terms of the conceptual levels used to describe them.

To illustrate the various ways computational models can benefit intrapersonal emotion research as well as the computational frameworks employed, we consider two illustrative examples.

Model-Driven Experimentation and Fear Conditioning

The Armony et al. (1995) work on auditory fear conditioning (or threat response) provides a powerful example of the use of a computational model in which simulation studies with the model suggest new *in vivo* studies and subsequent reformulation of the theory that informed model formulation. The Armony work is a connectionist model of LeDoux's (2012) dual-route, cortical, and subcortical theory of "fear conditioning"[1] in rats. LeDoux's theory, based on animal studies, argues that the amygdala receives input from the thalamus and the cortex, with the thalamus providing fast but less selective discrimination of audio frequencies, while the cortical response is slower but more selective.

The formulation of Armony et al.'s (1995) connectionist model captures the essence of the theory and associated empirical findings but at a more abstract level. The formulation into a computational model by itself had no ramifications for the original theory. The simulation studies with the model, however, revealed interesting phenomena that did have impact on subsequent animal studies and the theory.

The model was first trained to recognize a range of audio frequencies. When the model was then trained under conditions where fear stimuli was associated with frequencies, the model readjusted its recognition to those frequencies. This result from the model simulation studies was subsequently verified in animal studies. Additionally, an ablation study that removed the cortical pathway in the connectionist model revealed that the cortical pathway was not as critical to the model selective response to stimulus frequencies as one would have expected from the theory. This computational prediction was then validated in animal lesion studies, thus suggesting modification of the original theory's assumptions about the discriminatory capabilities of the subcortical processing.

Impact of Model Formulation on Theory Reformulation: Appraisal Theory and Coping

As we noted earlier, often the formulation of a model can expose important gaps and limitations in a theory, suggesting reformulations of the theory prior to any simulation or empirical testing of the model. Work on the emotion and adaptation (EMA) model of appraisal (Gratch & Marsella, 2004) provides an interesting example of this reformulation process.

At inception, the EMA model was based on Lazarus's (1991) theory of appraisal and coping. It is a symbolic model, cast at a high level in terms of an agent's beliefs, desire, and intentions as opposed to lower-level connectionist pathways seen in the Armony et al. (1995) work. Of course these distinctions are in line with differences in the theories that motivated the two models.

The EMA model is also integrated into the cognitive processes of a virtual human capable of interaction in real time both with physical events as well as high-level social interaction. This integration raised explicit questions about how emotion processes must respond to a wide range of stimuli, and must often do this on widely different time scales, as well as interact with an agent's perception, cognition, language, and behavior in order to achieve this flexibility in response. The integration also provided a computational framework to explore those issues that is unavailable to more traditional theoretical work on appraisal that typically is posited at a more abstract and comparatively less specified level. Addressing those questions led to a formulation of the EMA model that in turn suggested reformulations of theory.

In contrast to the Armony et al. (1995) model, the EMA model attempts to provide a comprehensive model of the causes and consequences of human emotion. Specifically, the EMA model is designed to respond to the wide range of eliciting conditions that give rise to different emotions in people, whether it is a nearby loud explosion that elicits fear, or responsibility for a blameworthy event eliciting guilt. The processes underlying these emotions may be on different time scales and have different causal elements. The explosion reaction is likely to be fast but emotions may have a much slower response, driven by burgeoning beliefs about the consequences of events. The EMA model is also sought to model the myriad consequences of emotion on human cognitive processes and behavior, as befitted the different eliciting conditions.

Like the explosion and guilt examples, the EMA model's emotions needed to be driven by a wide range of eliciting conditions and lead to a variety of coping responses in line with those conditions, spanning physical actions and more cognitive response such as informing belief revision and language response. It is such issues that led to an approach in the model that reformulated constructs in Lazarus's (1991) theory, arguing that appraisal was a very lightweight, reactive feature-detection process that leveraged representations maintained by other mental processes that are not unique to appraisal and emotion elicitation.

Because the EMA model's appraisal leverages other internal and external processes, it argues that the temporal course of the appraisal process is an unfolding interaction between an entity and its environment over time (see Marsella & Gratch, 2009). Rather than reflecting fixed constraints that require explicit reification in the model, the temporal sequencing of appraisals has more to do with the structure of the environment (e.g., Are appraisals self-evident or do they require inference?) and recent experience (e.g., Are appraisals already active in working memory?).

In contrast, consider the multilevel sequential checking theory of Klaus R. Scherer (Scherer, 2001), one of the more recent and sophisticated appraisal theories. This theory of appraisal posits three levels of appraisal processing: innate (sensory–motor), learned (schema based), and deliberative (conceptual), and posits a fixed sequential ordering of appraisals, based on physiological and functional considerations. Specifically, the theory asserts that appraisals unfold in a sequential order beginning with relevance, then goal implications, coping potential, and, finally, normative significance. The relevance check includes assessment of novelty as well as relevance to one's goals. The implication check includes assessments of cause, goal conduciveness, and urgency. Coping potential includes assessments of control (whether the situation is controllable) and power (whether the individual has the power to control it). Finally, normative significance includes assessments of compatibility with internal and external standards.

Arguments can be made for either view proposed by these two approaches. The sequence of appraisals might unfold in the order Scherer (2001) suggests—when confronted with an unexpected threat, it is rational to assess the implications to oneself before considering other social actors—but if social concerns are already salient in the environment, the reverse pattern seems likely (e.g., if we already suspect someone has violated a social norm, if they admit to the crime, it makes sense to jump straight to blame and anger).

The point relevant to the current discussion is that the formulation of the computational model forces one to address questions about how appraisal processes are realized and their time course. In addressing this question by constructing a model, one comes face to face with questions about how the time course of the output of some process arises. Is it explicitly stipulated as is suggested by sequential checking, or is it, like Simon's (1969) ant, an emergent property of a computation in some larger context that spans other mental and environmental factors?

Interpersonal Emotion Modeling

Emotions shape social behavior (Keltner & Haidt, 1999) and computational methods are playing an ever increasing role in informing theories on how emotions and emotional signaling shape social interactions. Most readers will be familiar with the growing use of computational techniques to instrument social interactions—for example, automatic techniques for recognizing facial expressions (Zeng, Pantic, Roisman, & Huang, 2009), speech (Schuller, Rigoll, & Lang, 2003), or paralanguage (Lee & Narayanan, 2005). Social interactions increasingly occur through technology, such as Twitter, Facebook, or Skype, and these create novel opportunities to measure, or even manipulate, emotional signaling (Kramer, Guillory, & Hancock, 2014). There is even growing acceptance that computers and robots serve as social partners and many of the social phenomena that occur between people, to some extent, are manifest in interactions with technology (Reeves & Nass, 1996; von der Pütten, Krämer, Gratch, & Kang, 2010), thereby expanding the scope and impact of social psychological findings. Indeed, researchers in the engineering sciences increasingly draw on psychological theories and imbue their systems with something akin to emotion (Gratch & Marsella, 2013; Lee & See, 2004; Sloman & Croucher, 1981).

These innovations, while important, are complementary but distinct from the notion of computational models outlined above. Techniques like computer sensing can be seen as incremental extensions of the traditional loop of hypothesis generation and testing, albeit with much more sophisticated ways of measuring and manipulating theoretically posited factors. Automatic facial-action annotation can radically transform the efficiency of experimentation over highly trained human coders, but it does not change the nature of the experimental process. In contrast, computational modeling opens up new pathways to theory development through the processes of model formulation and model-driven experimentation. Here we illustrate exemplars of model-driven research in the social domain.

In the *intrapersonal context*, a computational model captures theoretically posited processes operating within the individual. In contrast, in the *interpersonal context*, a computational model must simulate processes acting both within and between individuals, as well as the communication pathways between individuals. Thus, one straightforward way to model social emotional processes would be to take several individual computational models of emotion, allow them to interact through some simulated communication, and see if the unfolding social process conforms to theoretical predictions. This entails a great many complexities so, in practice, a variety of hybrid approaches are considered where only some of these processes are explicitly modeled in automation, where others are "driven" by human participants.

Figure 6.3 distinguishes the traditional approach to study social emotions (Figure 6.3a) from approaches that use computational models. The most ambitious approach, where all aspects are computationally modeled, we refer to as multiagent simulation (Figure 6.3d). However, two other hybrid cases are worth distinguishing. First (Figure 6.3b), Bailenson and colleagues introduced the term "transformed social interaction" to refer to social situations where the communicative processes between individuals was computational modeled and subject to experimental manipulation (Bailenson, Beall, Loomis, Blascovich, & Turk, 2004). Second (Figure 6.3c), building on the idea of human confederates in social science research, researchers are increasingly exploring social interactions where one of the parties is a computer model, with either a digital or robotic manifestation. We give examples of the use of computational models for each of these variations and illustrate how they exercise some of the paths outlined in Figure 6.1.

Transformed Social Interaction

Transformed social interaction is a technique that uses models to illuminate social theories, a class of modeling methods that can illuminate social theories, especially theoretical mechanisms associated with the form and frequency of interpersonal signals. This line of modeling approaches takes advantage of the fact that social interactions increasingly occur through technology, such as video teleconferencing or virtual worlds like Second Life. This creates opportunities to "hijack" these communication channels to shape and alter the way in which information is exchanged. Of course this is not an entirely new idea. For example, Murray and Trevarthen (1985) manipulated videoteleconference delays to examine the importance of contingency in social interactions between parents and infants. What has changed is the level of sophistication by which communicative signals are modeled and manipulated, including subtle dynamic and interactional features. Rather than

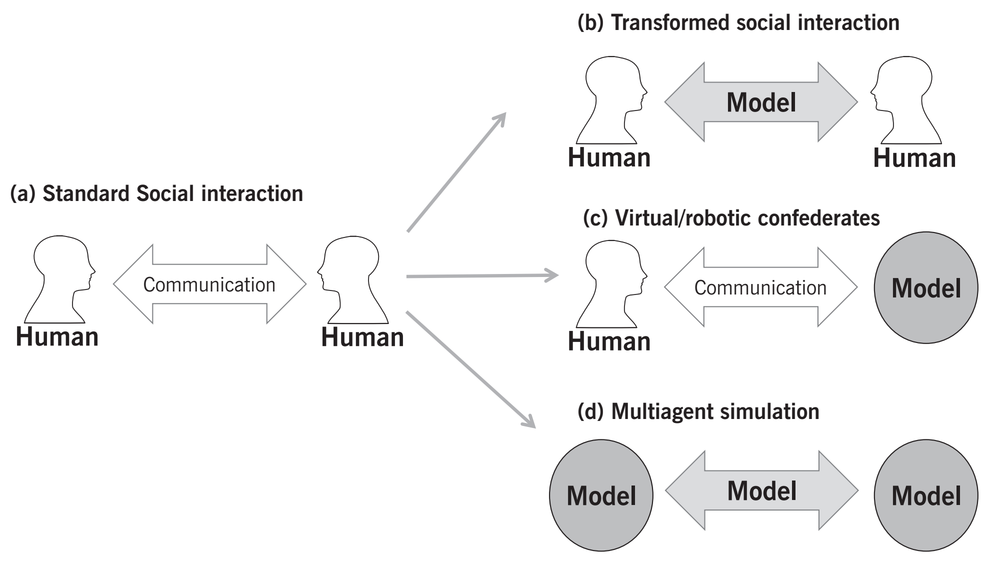


FIGURE 6.3. An illustration of the different approaches to computationally modeling interpersonal emotional processes.

blunt manipulations, like adding a communication delay, researchers are increasingly creating detailed computational models of the communication process and ablating this model to assess the impact of specific theoretical mechanisms.

Facial expressions are prominent in many theories of social emotions, so it is not surprising that the face is a central focus of modeling efforts. Many tools now exist to create life-like digital faces, and these are increasingly used in psychological research (Mumenthaler & Sander, 2012; Todorov, 2008). The developers of these tools often adopt theoretical principles in formulating these models (though this is not always done in an explicit way and rarely in collaboration with psychologists). For example, to animate a face, one has to define a set of parameters and these parameters could be informed by theories that suggest discrete emotions, by dimensional approaches, or as a set of facial action units. In that faces move, modelers must formulate models of motion dynamics, and here emotion theory offers far less guidance (cf. Krumhuber, Cosker, Manstead, Marshall, & Rosin, 2005).

Given a computational model of the face, one can transform this model in actual social interactions to test theoretical assumptions. For example, several lines of research suggest that the level of emotional expressivity can shape the nature of social interactions, for instance, by altering perceptions of trustworthiness (e.g., Boone & Buck, 2003; Parkinson, Fischer, & Manstead, 2005; Schug, Matsumoto, Horitaa, Yamagishi, & Bonnet, 2010). Such studies are correlational in nature, or involve manipulations, such as telling participants to be more or less expressive (Parkinson, Phiri, & Simons, 2012), that have obvious confounds. An alternative is to use social interaction where participants are blind to the fact that their facial expressions are being altered. Boker and colleagues demonstrate one approach along these lines. They use automatic facial recognition techniques to "puppet" a digital model of the face. Participant facial expressions are used to drive the motion parameters of this digital model, however, they then process this signal, experimentally suppressing or amplifying the emotional expressivity to investigate the impact of this factor on social interactions (Boker et al., 2009).

As social interactions move more into the digital world, such transformations are increasingly possible. One recent and controversial example involved the use of computer technology to examine the possibility of emotional contagion in online social networks. Researchers at Facebook altered the way emotional information is communicated among their users. Using Pennebaker's linguistic inquiry and word count tool (Pennebaker, Francis, & Booth, 2001), they automatically detected emotionally positive and negative postings, systematically altered the percentage of positive or negative posts that users saw, and measured their social responses.

Confederate Models

Manipulating interparty communication is but one way to simulate and manipulate social systems. A second approach is to replace one of the parties in a social interaction with a computational model. As in transformed social interaction, elements of this approach have a long tradition in psychology. For example, studies of emotional mirroring might employ a human confederate that, in a sense, acts as an automaton—for example, by being "programmed" to "model" certain theoretical processes (e.g., mimic the facial expressions of participants). Confederates allow a measure of experimental control but come with their own host of methodological concerns (Rosenthal, 1966). Replacing human confederates with a computational model can address some of these concerns (e.g., see de Melo, Carnevale, & Gratch, 2014, for a more complete discussion of these tradeoffs).

Social interactions involve a number of processes—social perceptions, social cognitions, and social behavior—and models could be used to automate all of these factors, or perhaps only a subset, leaving other processes unmodeled. Here we illustrate this distinction by considering two different ways to use computation models to attack the same problem. DeSteno et al. (DeSteno, Petty, Wegener, & Rucker, 2000) and de Melo et al. (de Melo, Carnevale, Read, & Gratch, 2014) consider the question of how nonverbal communication impacts cooperation in economic exchanges. The former uses computer models that capture the low-level physical aspects of nonverbal behavior (this is similar to research on transformed social interaction, but here they use automation, rather than another participant, to drive the interaction). The latter attempts to model the cognitive processes that precede communicative acts.

In the first approach, DeSteno and colleagues (2012) use a robot confederate to unpack how the surface realization of communication gestures impact trust decisions. A rich tradition of research has shown that people can infer, with some accuracy, a person's trustworthiness from "thin slices" of behavior. For example, people can distinguish those who will cooperate from those who will defect in Prisoner's Dilemma through a short off-task interaction before the game (Brosig, 2002; Frank, Gilovich, & Regan, 1993). However, finding the "golden cue" that predicts trustworthiness has been elusive (e.g., Todorov, 2008). DeSteno et al. proposed the innovative use of a robot to validate a model of nonverbal trust signaling.

To address the problem of finding cues of trustworthiness, DeSteno and colleagues (2012) use a two-stage approach: first, they formulate a statistical model of nonverbal cues; second, they engage in model-driven experimentation—they insert this model into an anthropomorphic robot and show that the behaviors, indeed, evoke trust in human interaction partners. For the first portion, they collected a large corpus of nonverbal behaviors that preceded a variation of a trust game. Using stepwise regression, they constructed a model of behaviors that predicted trust (including head motions, gestures, and postures). Next, they programmed a robot to exhibit these behaviors in a pregame "ice-breaking" interaction. These robot behaviors reliably influenced trust impressions and trusting behavior when people subsequently played a trust game with the robot, lending support for their communicative model.

The work of de Melo, Carnevale, Read, and Gratch (2014) illustrates a different approach to using models to explore social interactions. Whereas DeSteno et al. (2012) model the communication signal, de Melo, Carnevale, Read, and Gratch (2014) model the cognitive processes that underlie nonverbal signals. Their research uses virtual confederates to replicate and extend theories of *social appraisal* (Hareli & Hess, 2010; Manstead & Fischer, 2001). Social appraisal theory builds on appraisal theories of emotion (Scherer et al., 2001) and extends them to social domains. Whereas appraisal theory claims that emotions arise from comparison of world events with an individual's goals (e.g., a score by my favorite sporting team would evoke joy), social appraisal theory essentially turns this process on its head, arguing that people reconstruct how an individual is appraising a situation (and thereby derive his or her goals) by observing his or her emotional reactions to events (e.g., a frown by my neighbor in the sporting arena tells me he or she is rooting for the opposing team).

De Melo et al. (2014) evaluate social appraisal theory using model-driven virtual confederates. Taking inspiration from the EMA computational model of emotion (Gratch & Marsella, 2004; Marsella & Gratch, 2009), he created a digital human face who's expressions could be driven by the emotion model. Participants then played iterated Prisoner's Dilemma games with digital opponents. These opponents either appraised game events as if they had a goal of cooperation or, alternatively, of competition. For example, a competitive character might show joy after successfully exploiting its opponent. People reliably recovered this goal (and acted upon it by either collaborating or competing), as predicted by social appraisal theory. De Melo et al. (2014) were also able to show this was statistically mediated by attributions of appraisals to the virtual agent, again supporting the theory.

Collectively, these two approaches illustrate the variety of ways that models can drive the behavior of simulated social partners. DeSteno et al. (2012) modeled the communicative signal. De Melo et al. (2014) modeled the cognitions that precede these signals. These approaches also illustrate the variety of ways that computers can help realize such experiments. DeSteno et al. (2012) had people interact with a physical robot, whereas de Melo et al. (2014) used a "virtual" robot. In either case, they illustrate how model-driven experimentation allows systematic manipulation of key theoretical principles.

Multiagent Simulations

So far we have considered models where some aspect of social interaction is computationally modeled (e.g., the communication channel or one of the participants) with other aspects of the social situation left in the control of human participants. Multiagent simulations take this to its logical conclusion by modeling all aspects of a social interaction. This approach is most common in sociology, where agents tend to be very simple (e.g., finite-state automata) but incorporate large numbers of agents (Macy & Willer, 2002). Such models can be used to explore macro-sociological theories, for example, by experimentally manipulating structural factors within a simulated society, such as social mobility, and observing how patterns of behavior evolve over time (e.g., Roos, Gelfand, Nau, & Carr, 2014). However, such models can be applied to smaller social units such as crowds (Tsai et al., 2013), small groups (Li, Chang, & Maheswaran, 2013), or even dyadic interactions (Traum, Rickel, Gratch, & Marsella, 2003), and here we illustrate this through an agent-based model of emotional contagion in crowds.

Several empirical studies suggest that people "catch" the emotions around them (Hatfield, Cacioppo, & Rapson, 1994), though the specific mechanism by which this occurs remains controversial. Bosse and colleagues (2010) sidestep the question of cognitive mechanisms but attempted to model the temporal dynamics of contagion in crowds. Specifically, they were interested in predicting how panic spreads through a crowd and shapes their movement in disaster situations. Such a model could be important for engineering purposes (e.g., informing the placement of exits in a building to facilitate safe egress).

Bosse et al.'s (2010) modeling efforts were informed by Barsade's (2002) theory of contagion in groups. Barsade adopts a dimensional approach to emotional signaling, characterizing emotion in terms of valence and arousal, and also posits the mediating role of attention. Specifically, people will tend to adopt an emotional state with the same valence as their neighbors, and this is moderated by the intensity of the neighbors' responses and the level of attention given to the neighbors. In formulating a model based on this theory, Bosse and colleagues mapped these principles into computational models of particle systems. The resulting model essentially reformulates Barsade's theory into a model of heat dissipation in physical materials: in thermodynamics, heat dissipates to a state of maximum entropy and the speed of this dissipation is dictated by the material's specific heat capacity; by analogy, emotion dissipates through a crowd and people have different susceptibility to catching emotion.

After developing this model, Bosse et al. (2010) evaluated it through model-driven experimentation. They examined if a simulation of the model produces temporal dynamics similar to a real-world event. For this, they compared their model with a real-world panic that happened on Dam Square in Amsterdam in 2010 under full view of several cameras. The panic resulted from a man screaming (apparently due to mental illness) and produced a stampede that resulted in several injuries. The videos were hand analyzed, tracing the movement of 35 individuals throughout the panic. These trajectories were then compared with the simulation results and showed good correspondence.

Trends and Directions

As we have seen, the work on computational models of emotion phenomena span a considerable range and differ along several dimensions. Fundamentally, they differ in the empirical phenomena and theories they seek to model and explore, not surprisingly, given the range of theories and empirical work that addresses the causes and consequences of emotion. A range of computational representations and processes have been employed, again, often in keeping with the constructs that the underlying theory or empirical work posits, from cognitive constructs like beliefs and desires to specific neural pathways.

The differing computational mechanisms and the range of phenomena explored is indicative of a vibrant research community. On the other hand, there is a cautionary tale here as well. Often, computational models are developed in isolation, with little comparison between alternative models—computational models are often crafted from whole cloth, with comparatively little effort to compare to, or build on, prior work. There are, for example, numerous models of appraisal theories but concrete comparisons between them have been quite rare. The existence of alternative models that have not been compared in turn limits their impact on psychological theories.

And yet, a key benefit of computational models is that they *behave*. They can be simulated and thereby readily generate predictions that can be very concretely compared across models. Research may identify differences at a structural, descriptive level but not at the level of predictions. Realizing the full empirical potential role of models presumes that research goes beyond studying models in isolation to comparing alternative models' predictions.

On a positive note, however, there are notable exceptions that do highlight the empirical capabilities of computational work. Alternative models of Ledoux's (2012) dual-pathway model, for example, have been undertaken (Armony et al., 1995; den Dulk, Rokers, & Hans Phaf, 1999; Lowe, Humphries, & Ziemke, 2009), including work that very explicitly reimplemented the Armony et al., 1995; model and then contrasted alternative extensions (Lowe et al., 2009).

For complex models that span multiple phenomena, however, the reimplementation required to compare alternative models may be a considerable challenge. Efforts to compare models may also be impeded if alternative models cover overlapping but not identical phenomena. An alternative to reimplementation of entire models is to decompose the model along theoretical lines and evaluate the resulting components in isolation. Marsella et al.

(2010) propose, in particular, that appraisal-based models can be decomposed into components of the overall appraisal process, the modeling of the *person–environment relationship*, the process of *appraisal derivation*, the set of *appraisal variables* the model assumes, the processes of *affect derivation* and *affect intensity*, how affect is represented, and the modeling of *affect consequents* (the impact that affect has on behavior and cognition). Such a decomposition suggests comparing and evaluating models on a component level, as was done when comparing alternative models of appraisal-based affect intensity calculations (Gratch, Marsella, Wang, & Stankovic, 2009).

Despite the challenge of comparing models, we envision that the use of computational models as a tool for emotion research will continue to grow, for the reasons identified in this chapter. As computers and the software that runs on them becomes more powerful and easier to use, emotion research, like the other sciences and social sciences, will increasingly exploit the research benefits they provide. Through computational models, researchers can explore phenomena at granularities that they have limited access to in standard empirical research, whether it be modeling internal processes in the brain or studying large-scale social interactions through multiagent simulations. Through computational techniques researchers can alter the way processes are implemented, ablate functionality, or transform social interaction. Thus, computational models support the exploration of emotion in ways not feasible in the real world.

Note

1. LeDoux no longer refers to his work as "fear conditioning" (see LeDoux, 2012).

PART II

Biological Perspectives

CHAPTER 7

From Pleasure to Happiness

"Liking" and "Wanting" in Mind and Brain

Kent C. Berridge and Morten L. Kringelbach

The psychological processes of "liking" versus "wanting" are components within many positive emotions. These processes may also be relevant to understanding hedonic aspects of sustained states of well-being in happy people, as mechanisms of pleasure and reward. The liking and wanting aspects of reward often seem to merge together in psychological experience, but evidence from affective neuroscience suggests that the psychological processes of liking versus wanting are quite different from each other, and have separable brain mechanisms within mesocorticolimbic circuitry. Here we examine how these brain mechanisms may help give distinct identity to the two psychological components in ways that impact emotions. In particular, we consider how wanting and liking may help in understanding the brain bases of human happiness, which is sought by nearly all individuals, and to understanding the bases of drug addiction or related addictive disorders, which destroy happiness for some.

Our thesis is that in everyday life, the liking and wanting processes may occur together primarily as relatively transient psychological paired states, which contribute to many rewarding emotions. If the liking component, in optimal balance with the wanting component, is recruited in a more enduring or frequently recurring fashion, these components may also factor into understanding more sustained states of well-being or happiness, which is a goal for many individuals psychologically as well as a societal goal to promote more generally. Finally, liking and wanting can sometimes dissociate in certain situations. When this happens in a fashion that the wanting component becomes specifically and pathologically strong, the resulting imbalance between the two processes may contribute to addictions, which have powerfully detrimental effects on well-being.

Happiness, "Liking," and "Wanting"

We begin with well-being or happiness and the relation to the hedonic psychology of liking and wanting. The first question is "Can explanations of the brain bases of liking and wanting contribute to a better understanding of the hedonic side of happiness?" In Western psychological and philosophical frameworks for over 2,000 years, ever since originally proposed by Aristotle, happiness has been usefully thought of as consisting of at least two aspects: *hedonia* (pleasure) and *eudaimonia* (a life well-lived in terms of meaningfulness; Aristotle, 350 B.C.E./2009). Based on this Aristotelian distinction, some choose to emphasize the eudaimonic side of happiness, positing happiness and well-being to turn solely on a sense of life *meaning*. A purely eudaimonic view can de-emphasize the hedonic side of happiness, holding that a well-lived and meaningful life must be happy regardless of whether the person takes any pleasure in his or her life. An example of the purely eudaimonic view of happiness was famously expressed 150 years ago by John Stuart Mill: "It is better to be a human being dissatisfied than a pig satisfied; better to be Socrates dissatisfied than a fool satisfied" (Mill, 1861/1998, p. 57). By Mill's view as quoted here, a life filled with the most intense pleasures of pigs or fools would never be enough for happiness. Rather, true happiness was presumed by that view to hinge on a superior kind of richness of life meaning and engagement that was possessed fully by the enlightened Socrates, even when facing a death sentence, no matter how much hedonically dissatisfied he might have been.

Yet even Mill (1861/1998) himself seemed to imply elsewhere that hedonic pleasure was important to happiness too. And conversely, other psychologists have emphasized the hedonic side of happiness, sometimes at the expense of eudaimonia. For example, Sigmund Freud (1930) appeared nearly to take a purely hedonic view of happiness in his book *Civilization and Its Discontents.* Freud wrote there, in response to his own question "What do people ask of life and wish to achieve in it?" his personal reply:

> The answer to this can hardly be in doubt. They strive after happiness; they want to become happy and to remain so. This endeavor has two sides, a positive and a negative aim. It aims, on the one hand, at an absence of pain and displeasure, and, on the other, at the experiencing of strong feelings of pleasure. (p. 76)

Freud's answer essentially equates pleasure with happiness. According to this view, the more pleasure you have (while avoiding displeasure), the happier you will be.

It may not be necessary to choose either hedonia or eudaimonia over the other. Most modern psychologists who study happiness tend to fall in between the poles illustrated by Mill and Freud, and hold hedonic factors to be crucially important to well-being (Kahneman, Diener, & Schwarz, 1999; Gilbert, 2006; Kahneman, Krueger, Schkade, Schwarz, & Stone, 2006; Biswas-Diener, Kashdan, & King, 2009; Diener, 2012; Jayawickreme, Forgeard, & Seligman, 2012), even when espousing views that on the whole emphasize eudaimonic factors (Peterson & Park, 2009; Seligman, Railton, Baumeister, & Sripada, 2013). We similarly presume that a capacity for taking pleasure in life is an important feature of happiness, but do not reduce happiness to pleasure nor ignore the importance of eudaimonic aspects of well-being.

However, our main point is simply that if happiness involves a pleasurable or hedonic component, then finding brain mechanisms for pleasure may give insight into the hedonic aspects of well-being. A better understanding of the hedonic component of happiness in turn might be used as a first step toward understanding the brain mechanisms of happiness more generally, given that both aspects tend to cluster together in happy individuals. It is important to note that our focus on the hedonia component of happiness should not be confused with hedonism, which is the pursuit of pleasure for pleasure's own sake, and more akin to the addiction features we describe below. Also, to focus on hedonics does not deny that some ascetics may have found bliss through painful self-sacrifice, but simply reflects that positive hedonic tone is indispensable to most people seeking happiness.

Most important to our suggestion that it is not necessary to choose between hedonia and eudaimonia is the empirical finding that a high correlation actually exists between the pleasurable and the life-meaning aspects of happiness when rated by individuals—that is, the same lucky individuals who tend to score highest on a eudaimonic measure of happiness also tend to score highest on their hedonic ratings of happiness (Diener, Kesebir, & Lucas, 2008; Kuppens, Realo, & Diener, 2008). Those who have one also have the other. Conversely, individuals who are lowest on a hedonic measure tend to also be lowest on the eudaimonic measure. Fortunately, it turns out that most people report themselves to be reasonably happy. For example, in happiness surveys, over 80% of people rate their overall eudaimonic life satisfaction as "pretty to very happy," and 80% also rate their current hedonic mood as positive (e.g., positive = 6–7 on a 10–point valence scale, where 5 is "hedonically neutral"; Diener et al., 2008; Kuppens et al., 2008). A lucky happy few may even live consistently around a hedonic point of 8.

In our view, this tendency of pleasure ratings and meaningfulness ratings to correlate together opens a potential window of opportunity to affective neuroscience in understanding the brain bases of happiness. Hedonic well-being in particular, which can be studied relatively easily, presents a practical gateway to the more difficult-to-study state of eudaimonic well-being (Urry, et al., 2004; Kringelbach & Berridge, 2009). In other words, if both hedonia and eudaimonia co-occur in the same happy people, then identifying neural markers of hedonia may offer a toehold into identifying neural bases of eudaimonia. In this way, studies of hedonic well-being, which tend to be more amenable to neuroscience approaches than eudaimonic meaningfulness of life, may help to identify brain markers that distinguish happy people, including at least some brain markers that will turn out to overlap with eudaimonic well-being.

Many Different Pleasures but One Brain Pleasure System?

Subjectively, the sensory pleasure of a delicious-tasting food feels very different from the sensory pleasures of sex or of drugs. And subjectively there is even more difference between such sensory pleasures and any higher social or cognitive pleasures, such as seeing a loved one or listening to music. Yet affective neuroscience evidence has emerged in the past decade to suggest that brain mechanisms of sensory pleasures overlap to a surprising degree with brain mechanisms of cognitive, cultural, and social pleasures, and even with mechanisms of hedonic well-being. Evidence from neuroimaging studies suggests there is a single shared core process of positive affect shared by many diverse hedonic experiences and positive emotions, even those that may each subjectively feel quite different and unique (Rozin, Haidt, & Fincher, 2009; Kringelbach & Berridge, 2010b; Lindquist, Wager, Bliss-Moreau, Kober, & Barrett, 2012; Wilson-Mendenhall, Barrett, & Barsalou, 2013). The list of brain structures activated by all these pleasures includes several limbic regions within the prefrontal cortex: for example, the orbitofrontal, anterior cingulate, and insula cortices. Brain structures activated by diverse pleasures also include several subcortical limbic structures, such as the nucleus accumbens (NAc), ventral pallidum, amygdala, and mesolimbic tegmentum (which contains dopamine neurons; Beauregard & Paquette, 2006; Harris et al., 2009; Frijda, 2010; Leknes & Tracey, 2010; Skov, 2010; Vuust & Kringelbach, 2010; Salimpoor, Benovoy, Larcher, Dagher, & Zatorre, 2011; Lindquist, Wager, Kober, Bliss-Moreau, & Barrett, 2012; Wilson-Mendenhall et al., 2013). The range of pleasures that activate such overlapping brain structures spans from mere sensory pleasures of food, sex, or addictive drugs to human cognitive, social, and even moral pleasures such as the encounter of favorite music, art, a loved one, or religious ecstasy.

The strong degree of neural overlap in hedonic circuitry gives rise to the hypothesis that there is a shared underlying "neural currency" or mesocorticolimbic mechanism for generating the pleasure of all those psychologically diverse experiences and emotions (Kringelbach & Berridge, 2010b). Evolutionarily, this could be understood by saying that the brain seems to have conserved the mechanisms that evolved originally to generate sensory pleasures, and extended their pleasure functions to higher pleasures that appeared later in human evolution. Rather than having to invent entirely new brain systems for generating abstract social or cognitive pleasures, the human brain seems to have simply adapted original sensory pleasure mechanisms, and integrated them with new cognitive inputs, to produce the higher human pleasures.

This overlap or common neural currency idea implies that what can be learned about the details of how the brain generates one pleasure may also apply to many other forms of pleasure. Most of what affective neuroscience has learned so far about pleasure in the brain has come from studies of sensory pleasures, such as food pleasures or drug pleasures. But based on the common neural currency idea, we suggest that what has been learned about how those sensory pleasures are produced by brain systems may also provide insights into how the same brain systems produce higher pleasures. So for example, conclusions described below about how sensory pleasure is coded by the orbitofrontal cortex or generated by limbic hedonic hot spots may similarly apply the coding and generation of cognitive and social pleasures too. This extension of shared hedonic mechanisms is useful at least as a hypothesis for guiding future studies of higher pleasures.

Of course, it is possible that future studies with improved technology will find subtle differences in neurobiological operation or tiny patterns of subregional anatomical localization within a particular brain structure that may help distinguish different types of pleasures. But alternatively, the reason why they feel so different may have to do with other nonhedonic sensory and cognitive aspects of the pleasurable experiences, which are mediated by other brain structures, rather than hedonic differences in the pleasures themselves.

The common neural currency idea may extend even to the sustained and free-floating pleasant state of happiness itself. Some direct evidence for this idea comes from an intriguing study by Heller and colleagues (2013), which reported that high subjective ratings in response to questions such as "In general, [do] I feel confident and positive about myself?" were correlated with high sustained functional magnetic resonance imaging (fMRI) measures of brain activation in the subcortical nucleus accumbens (ventral striatum). The nucleus accumbens is a major target of the brain's mesolimbic dopamine "wanting" system for reward, and also contains an opioid hedonic hot spot for generating the intense "liking" of a sensory pleasure, as discussed below. Thus there appears to be substantial overlap between brain mechanisms of abstract human pleasures, including hedonic happiness, with the older mechanisms of specific sensory pleasures, shared with animals, which we describe next.

Sensory Pleasures: From Sensation to "Liking" to Hedonic Feelings

What makes a pleasure so nice? Pleasure or positive affect is never merely a sensation, not even for a sensory pleasure such as sweetness (Ryle, 1954; Frijda, 2010; Kringelbach, 2010; Kringelbach & Berridge, 2010b). Instead, the hedonic quality always requires the recruitment of specialized pleasure-generating brain systems to actively paint an additional "hedonic gloss" onto a sensation. Active recruitment of brain pleasure-generating systems is what makes a pleasant experience liked. These pleasure-generating systems have been shown by recent studies to take the form of a network of small "hedonic hot spots" distributed at several layers throughout the brain. Together, those hedonic hot spots interact together to make a sensation become positively liked.

Pleasure is always added to stimuli actively by the brain to make them positively hedonic, and is not an immutable feature of any external stimulus or event itself. The capacity of certain stimuli, such as a sweet taste or a loved one, to reliably elicit pleasure—to nearly always be painted with a hedonic gloss—reflects their privileged ability to activate those hedonic brain systems responsible for manufacturing and applying the gloss.

Hedonic brain systems involving multiple coding sites and generating hot spots are well developed in the brain, spanning subcortical and cortical levels. The basic circuitry wiring pattern is quite similar across humans and other animals (Heimer, Van Hoesen, Trimble, & Zahm, 2008). Why hedonic brain networks are so robust, and why they are relatively similar across humans and other animals, is probably because hedonic reactions have long had adaptive function. The basic hedonic circuits of the brain were formed and selected rather early in mammalian evolution. It seems unlikely so much neural machinery would have been preserved across evolutionary time if it had no function. Basic pleasure reactions have always had objective consequences, and brain mechanisms for hedonic reactions have long been functionally useful—even before any additional mechanisms appeared that characterize any human-unique aspects of subjective feelings of pleasure. In a sense, hedonic reactions have been too important to survival for pleasure to be exclusively in the realm of subjective experience.

Pleasure as an adaptive evolutionary feature is not so hard to imagine. For example, tasty food is one of the most universal routes to pleasure, as well as an essential requirement to survival. Not accidentally, food is also one of the most accessible experimental methods available to psychology and neuroscience studies of pleasure (Rozin, 1999; Kringelbach, 2005; Peciña, Smith, & Berridge, 2005; Berridge, Ho, Richard, & DiFeliceantonio, 2010; Gottfried, 2010; Kringelbach & Berridge, 2010a; Veldhuizen, Rudenga, & Small, 2010). Much of what is currently known about pleasure in the brain comes from such studies, including which cortical sites most faithfully code pleasure and which brain sites are hedonic hot spots to help generate pleasure.

Identifying Pleasure Generators in the Brain

Pleasant experiences such as a sensory pleasure or a positive emotion may appear in experience to be a unitary process, but virtually all are complex composites of affective and cognitive processes (Russell & Barrett, 1999; Clore & Ortony, 2000; Lambie & Marcel, 2002; Ellsworth & Scherer, 2003; Lindquist, Wager, Bliss-Moreau, et al., 2012; Chapter 15, this volume). Affective neuroscience studies have further indicated that even the simplest pleasant experience, such as a mere sensory reward, is actually a more complex set of processes containing several psychological components, each with distinguishable neurobiological mechanisms (Berridge, Robinson, & Aldridge, 2009; Kringelbach & Berridge, 2009; Leknes & Tracey, 2010). These include, in particular, distinct components of reward *wanting* versus reward *liking* (as well as reward *learning*), and each psychological component has both conscious and nonconscious subcomponents. Liking is the actual pleasure component or hedonic impact of a reward; wanting is the motivation for reward; and learning includes the associations, representations, and predictions about future rewards based on past experiences. Each of these components has brain mechanisms that are different from mechanisms of the other components, and each plays a central role in the cyclical time course of a pleasant experience (Plates 7.1 and 7.2; see color insert for plates).

The conscious experience of pleasure is so striking that pleasure has seemed purely subjective by definition to many thinkers. But related to the notion that pleasure naturally evolved, we think that pleasure also has objective aspects that can be detected in brain and behavior. This is related to the underlying similarities of brain limbic mechanisms for generating sensory pleasures across the brains of most mammals, both humans and nonhumans alike. The objective aspect has been invaluable in identifying the brain generators of pleasure described below.

We distinguish between the conscious and nonconscious aspects of these subcomponents because both exist in people (Winkielman, Berridge, & Wilbarger, 2005). And at least the latter can also be studied in other animals in ways that help reveal the underlying neural-generating mechanisms. At the potentially nonconscious level, we use quotation marks to indicate that we are describing objective, behavioral, or neural measures of these underlying brain processes. As such, "liking" reactions result from activity in identifiable brain systems that paint hedonic value on a sensation such as sweetness, and produce observable affective reactions in the brain and in behavior such as facial expressions. Similarly, "wanting" includes incentive salience or motivational processes within reward that mirror hedonic "liking" and make stimuli into motivationally attractive incentives. "Wanting" helps spur and guide motivated behavior, when incentive salience is attributed to stimulus representations by the mesolimbic brain systems. Finally, "learning" includes a wide range of processes linked to implicit knowledge as well as associative conditioning, such as basic Pavlovian and instrumental associations.

At the conscious level, "liking" is the subjective feeling of pleasure in the ordinary sense of the word, which may be elaborated out of (mostly subcortical) core liking reactions by cognitive brain mechanisms of awareness. Conscious wanting includes conscious desires for incentives or cognitive goals, while conscious learning includes the updating of explicit and cognitive predictions (Friston & Kiebel, 2009; Zhang, Berridge, Tindell, Smith, & Aldridge, 2009).

By themselves, core "liking" and "wanting" processes can occur nonconsciously, even in normal people. For example, viewing a subliminally brief happy facial expression or angry facial expression for just one-sixtieth of a second produces no change in people's conscious emotional feelings, and they remain unaware of having seen the emotional expressions. They are unable to pick the photo they saw out of a lineup (especially if the subliminal emotional expression is followed by a longer view of a neutral face, and if the experience is embedded in a task that distracts the viewers because they are concentrated on performing it correctly). Yet subliminal exposures to the happy face can make the viewers subsequently go on to evaluate a new stimulus (e.g., a flavored drink presented as a new marketing product) much more positively and to consume more of that stimulus, whereas exposure to the angry face makes viewers evaluate the new stimulus more negatively and consume less of it, indicating that the subliminal emotional expressions had induced nonconscious "liking" versus "disliking" reactions that never surfaced into conscious emotional feelings but remained able to alter their behavior under particular circumstances (Berridge & Winkielman, 2003). Such observations of nonconscious hedonic reactions suggests that additional brain circuitry is needed to convert a core "liking" reaction into a consciously liked experience of felt pleasure. Of course, it remains a major mystery precisely which brain circuits or neural operations are responsible for generating consciousness, including conscious experiences of subjective pleasure or of subjective feelings of desire. Traditional answers have tended to favor neocortex, and especially perhaps the prefrontal lobe of the cortex. The prefrontal cortex is quite prominent in humans, and includes several limbic regions such as the orbitofrontal cortex, anterior cingulate cortex, and insula (deep in the lateral surface of the prefrontal cortex, buried under the temporal lobe). However, this consciousness assignment to the prefrontal cortex may have more to do with tradition, and with the traditional assumption that what appears anatomically well developed in humans must necessarily have to do with human consciousness, than with any particular evidence.

Indeed, to the contrary, what evidence is available suggests that conscious feelings of liking, wanting, or other emotions can persist surprisingly well even in humans in essentially the complete absence of the prefrontal cortex. For example, a recent study reported remarkably normal emotion in a man who had lost the orbitofrontal cortex, insula, and ventral anterior cingulate (plus hippocampus and amygdala) due to encephalitis (Damasio, Damasio, & Tranel, 2012). He was left with severe memory and cognitive deficits, but still retained a rich emotional life for 20 years as far as could be told, including a remarkable capacity to talk about his emotional feelings. For example, when asked about himself in a social setting, he said, "I have a strong feeling of happiness, that we are here together working on these wonderful games and feeling happy together. I am glad to be here with you." The patient also socially learned to prefer a friendly caregiver to a grumpy one, and learned fears of medical syringe needles and noisy fMRI machines. Similarly, many thousands of patients in the 1950s were subjected to a surgical operation known as prefrontal lobotomy, in which their prefrontal cortex was removed or disconnected from the rest of the brain. Those patients often tended to make bad or risky decisions afterward, but appeared to keep the hedonic capacity for all intense emotions, including strong pleasure and displeasure experiences. Such observations suggest that the prefrontal cortex may not be the sole locus of emotional consciousness, and can lead one to entertain alternative hypotheses that deeper brain structures may be rather competent at generating basic emotional feelings even in people (Damasio, 1999; Berridge & Kringelbach, 2011; Panksepp, 2011; Damasio et al., 2012).

Pleasure Generators: Hedonic Hot Spots in the Brain

How is pleasure as an intense liking reaction actually generated within a brain? This is the question of hedonic causation. The brain appears frugal in mechanisms that that are causally sufficient to generate "liking" or magnify pleasure to high levels. These few mechanisms are candidate brain wellsprings for hedonic happiness.

Compelling evidence for pleasure causation as increases in 'liking' reactions has so far been found for only a few brain substrates, or hedonic hot spots. Those hedonic hot spots may be found in some regions of the prefrontal cortex, but mostly reside—perhaps surprisingly, if one thought pleasure to be exclusively a product of the brain's top-level cortex—in subcortical structures deep below the cortex (though heavily connected with limbic regions of the prefrontal cortex). Our strategy to find such neural generators of pleasure gloss has relied on activating neural mechanisms underlying natural liking reactions to intensely pleasant sensations. Such neural activations can be ethically induced only in animal studies, via painless brain manipulations that excite neural activity or activate neurochemical receptors on neurons. An example of "liking" is the positive affective facial expression elicited by the hedonic impact of sweet tastes in newborn human infants (Plate 7.1), such as tongue protrusions for licking the lips. By contrast, nasty bitter tastes instead elicit facial "disliking" expressions of disgust such as gapes, nose and brow wrinkling, and shaking of the head. These affective expressions are displayed by human infants in the very first days of life (Steiner, 1973). Such "disgust" expressions or "liking" expressions have been called the most basic and earliest stage of emotion exhibited as action patterns in children (Chapter 15, this volume). The infant hedonic expressions are quickly influenced by learning. For example, if infants are regularly fed artificial formula diets made from hydrolized caseins, which are nutritious but can taste more bitter than milk, the formula-fed infants subsequently express fewer "disgust" faces and more "liking" faces to bitter tastes than other infants who have consumed mostly their mother's breast milk or formula made from cows' milk (Mennella, Forestell, Morgan, & Beauchamp, 2009).

Many of these affective "liking" versus "disgust" expressions to tastes by human infants are similar and homologous to facial expressions elicited by sweet versus bitter tastes from orangutans, chimpanzees, monkeys, and even rats and mice (Steiner, 1973; Grill & Norgren, 1978a; Steiner, Glaser, Hawilo, & Berridge, 2001). Homology in the origin of "liking" reactions implies that the underlying hedonic brain mechanisms are similar in humans and other animals (e.g., sharing features such as identical allometric timing laws in each species that scale speed of expressions to body size). That similarity opens the way for an affective neuroscience of pleasure generators that bridges humans and animals.

Subcortical Hedonic Hot Spots in the Nucleus Accumbens, Ventral Pallidum, and Brainstem

We believe that the way to gain the clearest understanding of how the brain produces pleasure is to combine the best perspectives from both human studies and animal studies in affective neuroscience. Human studies provide windows into subjective experience and into neuroimaging identification of the brain structures that underlie diverse uniquely human pleasures. Animal studies provide windows into which neural mechanisms actually cause pleasure, and how they work. Integrated together, the two perspectives form a powerful viewpoint for understanding the nature of pleasure and its sources in the brain.

An example of how the causation of pleasure can be revealed comes from affective neuroscience studies in rodents, which have identified hedonic hot spots that when activated can magnify a sensory pleasure. These help reveal the locations and neurotransmitter identities of the generating mechanism for intense "liking." A hedonic hot spot is capable of generating enhancements of liking reactions to a sensory pleasure such as sweetness, when stimulated by opioid, endocannabinoid, or particular other neurotransmitters, or stimulated by drug microinjections that elevate or mimic those neurotransmitters (Peciña & Berridge, 2005; Smith & Berridge, 2005; Peciña et al., 2006; Mahler, Smith, & Berridge, 2007; Richard, Castro, DiFeliceantonio, Robinson, & Berridge, 2013). In rodent studies, the hot spots can be activated by painless microinjections of tiny drug droplets that stimulate neurotransmitter receptors on neurons contained within the site. Another recently developed way of probing pleasure mechanisms is to activate neurons by optogenetic laser light, shone painlessly on neurons in a hot spot through an optic fiber previously implanted in the brain. Neurons near the fiber also have previously been infected with a virus that gives them a new gene, allowing them to sprout photoreceptors that respond to the laser light, by opening neuronal membrane gates to outside ions and so to suddenly become excited and to fire action potentials. In this way, the laser light electrically stimulates the gene-infected neurons, and so functionally activates the hot spot's circuitry (Castro & Berridge, 2013). Within the hot spot, particular opioid drug microinjections or laser light pulses may activate pleasure-generating circuitry to magnify the hedonic impact of a sweet taste, increasing the number of "liking" reactions elicited by a squirt of sugar-flavored water. Outside the border of the hot spot the same neural manipulations would completely fail to elevate liking. The spatial difference between effective versus ineffective sites for enhancing hedonic impact therefore maps the anatomical location and boundaries of a pleasure-generating hedonic hot spot (Plate 7.1).

The results of such studies reveal a network of several brain hedonic hot spots, distributed as a chain of "liking"-enhancing islands of brain tissue across several deep structures of the brain (Plate 7.2). The network of separate but interconnected hedonic hot spots acts together as a coordinated whole to amplify core pleasure reactions. Activating one recruits the others as a system (Smith, Berridge, & Aldridge, 2011). Each brain hot spot may be merely a cubic millimeter or so in volume in the brain of a rat (and would be expected to be a cubic centimeter or so in a human, if proportional to the larger human volume of the whole brain). The small size of each anatomical hot spot indicates a surprisingly localized concentration of sufficient-cause mechanisms for generating intense pleasure in the brain. The network properties reveal a fragile substrate for pleasure enhancement that requires unanimity across the several parts in order to elevate hedonic "liking" (Peciña, 2008; Peciña & Smith, 2010; Smith, Mahler, Peciña, & Berridge, 2010; Smith et al., 2011).

One major hot spot has been found in the nucleus accumbens, a brain structure at the bottom font of the brain, specifically in its medial shell region near the center of the structure (Plates 7.1 and 7.2). Other hot spots are emerging above in the prefrontal cortex, and have been found farther back in the brain. For example, a very important hedonic hot spot lies in the ventral pallidum, which is near the hypothalamus near the very bottom center of the forebrain and receives most outputs from the nucleus accumbens (Plate 7.2). That ventral pallidal hot spot is especially important in that it is the only one that not only can enhance pleasure to high intensities but also where damage obliterates normal pleasure, so that, for example, even sweetness becomes disgusting (Ho & Berridge, 2014). In the prefrontal cortex, additional hot spots at least able to enhance pleasure may be found in the orbitofrontal cortex and in a lateral bit of frontal cortex called the insula (D. C. Castro & K. C. Berridge, personal communication). Finally, pleasure circuitry may extend deep in the brain, as far as to a hot spot in the brainstem region called the parabrachial nucleus, located near the top of the pons (Soderpalm & Berridge, 2000).

Analogous to scattered islands that form a single archipelago, the distributed network of hedonic hot spots forms a functional integrated circuit, which obeys control rules that are largely hierarchical and organized into brain levels (Grill & Norgren, 1978b; Berridge & Fentress, 1986; Aldridge, Berridge, Herman, & Zimmer, 1993; Peciña et al., 2006). At the highest levels, the hot spot network may function as a more democratic heterarchy, in which unanimity of positive votes across hot spots is required in order to generate greater pleasure (Smith & Berridge, 2007). For example, any successful enhancement that starts in one hot spot involves recruiting neuronal activation across other hot spots simultaneously, to create a network of several that all vote "yes" together for more pleasure (Smith et al., 2011). Conversely, a pleasure enhancement initiated by opioid activation of one hot spot can be vetoed by an opposite vote of "no" from another hot spot where opioid signals are suppressed. Such findings reveal the need for unanimity across hot spots in order for greater pleasure to be produced, and the potential fragility of hedonic enhancement if any hot spot defects (Smith & Berridge, 2007; Smith et al., 2010).

All of the findings above help identify brain pleasure generators capable of generating high hedonic peaks that make an event more "liked." These generators for sensory pleasure are excellent candidate mechanisms for also generating the more abstract pleasures of human cognition and social life, and even for generating hedonic happiness. Future studies that focus on hedonic hot spot networks may eventually be able to confirm whether pleasure-generating networks are truly shared across such diverse pleasures, as we have suggested, and more generally in other pleasant emotions (Barrett & Wager, 2006).

Pleasure Coding in the Cortex

In contrast to the causation of pleasure that may arise chiefly from subcortical brain circuitry, brain regions decoding pleasure and relating it to psychological functions such as cognitive evaluation are found mostly in the cortex. Hedonic evaluation of pleasure valence is anatomically distinguishable from precursor operations such as sensory computations, suggesting the existence of a hedonic cortex proper (Plates 7.2 and 7.3; Kringelbach, 2005). The hedonic cortex involves regions such as the orbitofrontal, insula, medial prefrontal, and cingulate cortices (Craig, 2002; Kringelbach, 2005; Amodio & Frith, 2006; Beckmann, Johansen-Berg, & Rushworth, 2009), which a wealth of human neuroimaging studies have shown to code for hedonic evaluations (including anticipation, appraisal, experience, and memory of pleasurable stimuli) and have close anatomical links to subcortical hedonic hot spots.

Pleasure encoding may reach an apex of cortical localization in a midanterior subregion within the orbitofrontal cortex (Plate 7.3), where neuroimaging activity correlates strongly to subjective pleasantness ratings of food varieties (Kringelbach, O'Doherty, Rolls, & Andrews, 2003)—and to other pleasures—such as sexual orgasms (Georgiadis, Kringelbach, & Pfaus, 2012), drugs (Vollm et al., 2004), chocolate (Small, Zatorre, Dagher, Evans, & Jones-Gotman, 2001), music (Blood & Zatorre, 2001), and other emotions (Wilson-Mendenhall et al., 2013). Most important, midanterior orbitofrontal activity tracks changes in subjective pleasure, such as a decline in palatability when the reward value of one food was reduced by eating it to satiety (while remaining high to another food; Kringelbach et al., 2003; Kringelbach, 2005). The midanterior subregion of orbitofrontal cortex is thus a prime candidate for the coding of the subjective experience of pleasure (Plate 7.3; Kringelbach, 2005).

Another coding site for positive affect in the orbitofrontal cortex may be along its medial edge that has activity related to the valence of positive and negative events (Kringelbach & Rolls, 2004; Wilson-Mendenhall et al., 2013), contrasted to lateral portions that have been suggested to code unpleasant events (O'Doherty, Kringelbach, Rolls, Hornak, & Andrews, 2001), although the activity in the lateral part is more likely to reflect a signal to escape the situation, rather than displeasure per se (Kringelbach et al., 2003; Hornak et al., 2004; Kringelbach, de Araujo, & Rolls, 2004; Kringelbach, 2005).

The medial-lateral hedonic gradient in the orbitofrontal cortex interacts with an abstraction–concreteness gradient in the posterior-anterior dimension, so that more complex or abstract reinforcers (such as monetary gain and loss; O'Doherty et al., 2001) are represented more anteriorly in the orbitofrontal cortex than less complex sensory rewards (such as taste; Small et al., 2001). The medial region does not, however, appear to change its activity with reinforcer devaluation, and so may not reflect the full dynamics of pleasure.

Some studies have also shown lateralization of affect or hemispheric differences in humans, with the left hemisphere of the prefrontal cortex sometimes being implicated more in positive affect than the right hemisphere (Davidson, 2004). For example, individuals who give higher ratings of subjective well-being may have higher activity in the left prefrontal cortex, and left subcortical striatal activity is also more tightly linked to pleasantness ratings in some studies than right-side activity (Price & Harmon-Jones, 2011; Kuhn & Gallinat, 2012; Lawrence, Hinton, Parkinson, & Lawrence, 2012). However, many other studies have found more equal bilateral activity patterns and so the precise role of lateralization in pleasure still remains somewhat unclear.

"Wanting" Mechanisms Are Separable from "Liking" Mechanisms

People typically want things that they like. From the brain's point of view, in addition to liking mechanisms, pleasure must be translated into motivational processes in part by activating a second component of reward, which turns out to be psychologically distinct from pleasure, even if often also associated as occurring together with pleasant events. This second component is termed "wanting" or incentive salience, which is attributed to perceived stimuli and events (or vivid imagery) that are related to rewards. Incentive salience is generated by mesolimbic brain systems, and makes targeted stimuli become attractive and motivating, at high intensities even to the point of compelling temptation (Berridge & Robinson, 2003). Incentive salience depends in particular on mesolimbic dopamine neurotransmission between select regions of the pleasure network, although opioid and other neurotransmitter mechanisms widely distributed throughout the nucleus accumbens and related structures are also involved.

Incentive salience is a "wanting" (in quotes) process that is just one of several types of what is meant ordinarily by the word wanting (no quotes). As a distinct module, incentive salience is psychologically most visible in its cue-triggered "wanting" and motivational magnet effects that cause individuals to be strongly attracted to particular reward stimuli. By comparison, "cognitive wanting," in the more familiar sense of the word, is quite a different form of desire. If one has a cognitive want, one has a conscious desire for a specific reward—one knows what one wants. Cognitive wanting has declarative goals, involving explicit expectations of future outcomes. Incentive salience "wanting" has causes and targets, but not so much explicit goals except to the degree that incentive salience can color cognitive desires. When the two forms of desire are congruent, "wanting" adds a visceral "oomph" to cognitive desires. Ordinarily, "wanting" and wanting work together toward the same incentives, but in certain situations the two psychological processes can be momentarily dissociated. This decoupling may become especially problematic in addiction.

Most important, incentive salience is not hedonic impact or pleasure "liking" (Berridge, 2007). This is why an addicted individual can "want" a reward without necessarily "liking" the same reward. Irrational "wanting" without "liking" can occur, especially in addiction via incentive sensitization of the mesolimbic dopamine system and connected structures (Robinson & Berridge, 2003). At an extreme, the addict may come to "want" what is neither liked nor expected to be liked, a dissociation possible because "wanting" mechanisms are largely subcortical and separable from cortically mediated declarative expectation and conscious planning. This is a reason why addicts may compulsively "want" to take drugs even if, at a more cognitive and conscious level, they do not want to do so.

Motivational Salience: A Building Block Shared Between Desire and Dread?

"Wanting" an object of desire seems a completely different psychological process from fear of something we perceive to be a potential threat. These are diametrically opposite emotions in terms of their affective valence: One is positively valenced, the other negatively valenced. But desire and dread may share something in common at the level of the brain, and possibly at the level of a psychological building block shared by both. A frightening stimulus is attention grabbing and compels a motivated response of avoidance, almost as an incentive stimulus does, but is perceived as threatening or sinister.

Incentive salience may thus have a negatively valenced equivalent in fearful salience. Both may be generated by brain circuitry involving the nucleus accumbens, in the form of a motivational salience process whose affective valence can even be flipped between positive and negative. Affective neuroscience experiments have produced this flexible motivation in rats, by tapping an appropriate emotional key on a limbic keyboard, done through a cortical signal-blocking microinjection placed in the nucleus accumbens. One part of the nucleus accumbens (called the medial shell) is arranged as an emotional keyboard, front to back, that organizes incoming signals about the outside world. Tapping keys in the front of this structure elicits strong desires, for example, stimulating intense eating and creating a desire to return to the place where the keys were tapped (Reynolds & Berridge, 2008). Tapping keys located farther in the back conversely elicits strongly fearful behavior (antipredator reactions to the sight or touch of people, sometimes accompanied by fearful squealing and escape attempts, or even attempts to bite a person who touches the rat that is normally quite tame).

Desire and dread are opposite emotions, but taps in the middle of the accumbens keyboard reliably elicit both together. For example, intense increases in appetitive eating and intense fearful reactions may be emitted by the same rat in the same hour following the microinjection in the middle of its nucleus accumbens. This observation of emotional ambivalence first made us wonder whether a shared motivational salience mechanism might contribute to generate both fear and desire, so that they could closely overlap in the mechanism. If so, we hoped it might be possible to flip the intermediate neural key in the accumbens back and forth between generating fear and generating desire, as a flexible psychological building block, depending on the psychological context in which it was activated (Reynolds & Berridge, 2008).

This shared mechanism possibility was tested by comparing the motivational effects of the nucleus accumbens microinjections in two emotionally opposite situations: either a soothing ambience (the rat's own home room, dark and quiet, and with familiar smells) or a stressful ambience (a brightly lit room that played a loud soundtrack of punk rock music). The results showed that microinjection taps at many middle keys in the nucleus accumbens were found to switch between producing intense desire and intense dread. In the comfortable situation, most taps produced desire. In the stressful situation, the same taps in the nucleus accumbens instead produced mostly fearful reactions. Some brain sites flipped completely, changing from purely fear generating to purely desire generating, or vice versa. This is consistent with the possibility that a common psychological operation exists in both as a truly flexible building block.

The psychological flip involves a neurobiological switch too. Subsequent studies have found that when a nucleus accumbens site psychologically flips between generating desire versus dread, the site also neurobiologically flips in its use of dopamine signals by neurons in the location of the microinjection. Dopamine is used by the nucleus accumbens to generate both emotions, but in different ways (Faure, Reynolds, Richard, & Berridge, 2008)—that is, dopamine is sensed by two different classes of neuronal receptors (called D_1 receptors vs. D_2 receptors) that modulate the neuron in distinct ways. When the nucleus accumbens generates incentive salience, after a rat receives a nucleus accumbens tap in a situation of comfortable ambience, its neurons in the vicinity of the microinjection require only the D_1 type of dopamine signal to produce the intense desire (Richard & Berridge, 2011). By contrast, the same neurons require both the D_1 type and D_2 type of dopamine stimulation to generate dread, after the same microinjection tap in a stressfully stimulating situation (Richard & Berridge, 2011). Thus, the same anatomical building block in nucleus accumbens appears to flip between neurobiological modes in order to generate two emotional states of opposite valence. Although the idea that desires and fears may share the same psychological kernel, in the form of a motivational salience process that is able to flip valence, seems counterintuitive, it does fit with other evidence that the brain shares overlapping circuitry in generating quite diverse emotions (Lindquist, Wager, Kober, et al., 2012).

Conclusion

Brain systems for liking generate many sensory pleasures as well as abstract social and cognitive pleasures that help to make life so rewarding. The same hedonic brain systems may even generate or contribute to the sustained and free-floating sense of hedonic well-being that characterizes human happiness—at least in those individuals lucky enough to be happy.

Thus, one way to conceive of hedonic happiness is as "liking" without "wanting." That would be a state of pleasure without disruptive desires, a state of contentment (Kringelbach & Berridge, 2009). A different possibility is that moderate "wanting," matched to positive "liking," facilitates engagement with the world. A little incentive salience may add zest to the perception of life and perhaps even promote the construction of meaning, just as in some patients therapeutic deep brain stimulation may help lift the veil of depression or the suffering of chronic pain by making life events more appealing. However, too much "wanting" can readily spiral into maladaptive patterns such as addiction, and is a direct route to great unhappiness. Thus, gaining a clearer picture of how the brain mediates pleasure-"liking" and motivation-"wanting" components of reward thus has implications for understanding many emotional experiences. These experiences range from basic sensory pleasures to the most abstract emotions and states of well-being.

CHAPTER 8

Neural Fingerprinting

Meta-Analysis, Variation, and the Search for Brain-Based Essences in the Science of Emotion

Elizabeth Clark-Polner, Tor D. Wager, Ajay B. Satpute, and Lisa Feldman Barrett

Scholars have been interested in the physical basis of emotion for as long as they have been questioning how the human mind works. For the vast majority of this time, their examinations began with phenomenologically inspired categories (called folk psychology categories; Aristotle & Bostock, 1994). Whether they were searching in the heart or the brain, ancient scholars—including Hippocrates, Aristotle, and Descartes—attempted to find a biological "fingerprint" that was specific to each one. In the 19th century, as psychology emerged as a distinct, scientific discipline, researchers began to augment these subjective assessments with more quantitative data, using tools from physiology, neurology, and anatomy. It was merely assumed that the structure of experience would be revealed in the structure of biology so that these fingerprints could be used objectively (without a perceiver) to distinguish one category from another.

A century of experimentation has taught us, however, that there is tremendous variation in the physical manifestations of emotion categories, and that our experiences may not be the best guide for revealing the underlying processes that cause them. For example, there is substantial variation in the autonomic physiology associated with different instances within the same emotion category (Cacioppo, Tassinary, & Berntson, 2000; Siegel, Sands, Condon, Chang, Dy, et al., 2015). Some of this variation is, surely, methodological—the byproduct of weak emotion inductions, poor experimental methods, and insensitive statistical tools (cf. Ekman, 2004; Friedman, 2010; Levenson, 2011, 2014; Stemmler, 1989). Some might also be due to the fact that, until recently, we have been limited to "downstream organs" (the autonomic nervous system, facial muscle movements, vocal acoustics) rather than the source of emotion: the brain. An additional hypothesis, however, is that some of this variation might also be *meaningful* (i.e., inherent in the underlying phenomenon), and thus a feature for which we must account in our theoretical frameworks and methodological approaches (Barrett, 2006, 2009, 2013; Cacioppo et al., 2000; Siegel et al., 2015).

With the advent of modern neuroimaging, scientists are now able to study emotion in ways that previous generations would never have thought possible, peering into the brains of living, breathing humans, in near real time, as they experience and perceive emotion. This has afforded us an unprecedented opportunity to address the physical basis of emotion in humans and ask whether there is there real physical variability within instances of the same category, as well as similarities across categories we believe to be psychologically distinct—possibilities that would fundamentally change the way we've understood emotion for centuries.

In this chapter, we summarize more than 20 years of neuroimaging research on emotion to examine the degree to which (1) positive versus negative affect, (2) individual emotion categories (e.g., anger, sadness, fear), and (3) emotion generation versus emotion regulation are associated with distinct neural fingerprints. In so doing, we emphasize the results of meta-analyses of the relevant literatures. Meta-analyses are powerful tools, both for testing existing hypotheses about the brain basis of psychological phenomena, and also for identifying networks in the brain that show a consistent increase in activity during emotion where none may have been expected. After examining each question in turn, we use the meta-analyses generatively, to offer new hypotheses for examining the brain basis of affect and emotion.

Can Positivity and Negativity Be Distinguished in the Brain?

"Valence"—the dimension that differentiates good from bad, positive from negative, appealing from appalling—is a fundamental psychological property. Every waking moment of life can be described as having some degree of valence (Barrett & Russell, 1998, 1999; Bradley, Codispoti, Cuthbert, & Lang, 2001; Feldman, 1995; Larsen & Diener, 1992; Watson & Tellegen, 1985). Valence is not emotion, but it is related to it. We tend to associate positivity and negativity with particular emotions, but this need not be so. You can feel pleasantly happy or unpleasantly happy, furiously angry or exuberantly angry, dreadfully afraid or excitedly afraid (Wilson-Mendenhall, Barrett, & Barsalou, 2014). The deliciousness of a drink, the distastefulness of the food you dislike, the fatigue you feel after not enough sleep or exercise—these are also moments with positivity or negativity that many scientists would not call "emotion." Valence is universal, unlike emotion, whose universality is debated (see Gendron, Roberson, van der Vyver, & Barrett, 2014a, 2014b; Gendron, Roberson, & Barrett, 2015; Sauter, Eisner, Ekman, & Scott, 2010, 2015; Osgood, 1952; Osgood, May, & Miron, 1975; Russell, 1991; Wierzbicka, 1992, for examples and discussion). Valence is also ubiquitous across the developmental spectrum; from birth, infants can feel pleasure and pain, comfort and discomfort (e.g., Lewis, 1993). From just a few days old, they may also be able to differentiate these states in others as well (Farroni, Menon, Rigato, & Johnson, 2007), although they are not able to differentiate emotions until many months (Kotsoni, de Haan, & Johnson, 2001) or years (Widen & Russell, 2008) later. Despite valence's broad relevance, however, and the hundreds of studies in which it has been a primary focus, there is still little consensus about how positivity and negativity are related to each other (e.g., whether they must be inversely correlated, or whether they can be experienced simultaneously), and how they are each instantiated within the brain (see Barrett & Bliss-Moreau, 2009, for a review).

The Underlying Structure of Valence: Testing the Bipolarity, Bivalence, and Affective Workspace Models

To date, three distinct hypotheses have been advanced for how positivity and negativity are represented in neural activity. The first (and most intuitive) hypothesis is the *bipolarity hypothesis*. The bipolarity hypothesis, originally described by Wundt (1897/1998), proposes that positivity and negativity anchor opposite ends of a single dimension (Barrett & Russell, 1998, 1999; Russell, 1980). It has received support from hundreds of studies of semantics, self-reports of experience, and emotion perception in faces and vocal acoustics, which have reported positive and negative valence to be strongly negatively correlated (see Barrett & Bliss-Moreau, 2009; Larsen & Diener, 1992; Osgood et al., 1975; Barrett & Russell, 1999; Russell, 2003, for reviews). At the level of the brain, the bipolarity hypothesis suggests that neurons that encode affect should encode the relative valence (e.g., increasing in response to positive events and decreasing in response to negative ones). Translated into a neuroimaging context, brain "voxels" (a volume of tissue encompassing approximately 5.5 million neurons) associated with increased positive affect should also be associated with reduced negative affect, and vice versa (i.e., voxels should respond monotonically across affective valence (positive > neutral > negative, or negative > neutral > positive; Lindquist, Satpute, Wager, Weber, & Barrett, 2015).

The *bivalence hypothesis* proposes that positivity and negativity are two *separate*, bipolar, but independent, dimensions—one each for positive and negative valence (Cacioppo, Gardner, & Berntson, 1999; Norris, Golan, Berntson, & Cacioppo, 2010; Watson & Tellegen, 1985). This hypothesis was formulated in response to, and is supported by, the observation that self-reports of subjective positivity and negativity are often uncorrelated—

not negatively correlated (as would be expected based on the bipolarity hypothesis; Larsen, McGraw, Mellers, & Cacioppo, 2004; Larsen, McGraw, & Cacioppo, 2001; Watson & Clark, 1997; Zautra, Potter, & Reich, 1997; although see Barrett & Russell, 1998; Russell & Carroll, 1999, for methodological explanations for the correlational patterns). The bivalence model makes specific predictions about the nature of the physical systems necessary to produce these dimensions, positing that there should exist separate physical mechanisms within the brain (e.g., Cacioppo, Crites, Berntson, & Coles, 1993; Berntson & Cacioppo, 2008; Norman et al., 2011). This could take the form of spatially separate regions or networks, one exclusively responding to represent positivity and one exclusively responding to represent negativity.[1]

Finally, the *affective workspace* hypothesis predicts that both positive and negative affects are the product of a valence-general system, within which neurons combine in a probabilistic and context-dependent fashion (Barrett & Bliss-Moreau, 2009). Whereas the bipolar and bivalence hypotheses originated from behavioral and self-report data, the affective workspace hypothesis is grounded in observations from the neuroscience literature that there is significant heterogeneity (variability) across instances of both positivity and negativity, in terms of how they are represented within the brain (Barrett & Bliss-Moreau, 2009). Specifically, no single region or structure appeared to be consistently and specifically associated with either positive or negative affect, suggesting that the same areas might somehow give rise to both phenomena. The affective workspace hypothesis also draws on the concept of degeneracy, which is the ability of a system to take on "many-to-one" structure–function mappings (Edelman & Gally, 2001). Degeneracy allows a system to be both flexible and efficient, and it has previously been identified within both genetic and immunological systems (Friston & Price, 2003).[2]

As applied to the brain basis of valence, degeneracy means that positivity and negativity can be represented by any number of distinct neural assemblies, the nature of which, in any particular instance, is contextually determined. Within the data from a given experiment (or set of experiments) therefore, one would expect valence-responsive regions to be associated with both positive and negative affect. One would also expect significant variation across specific instances (trials, or studies), in terms of how positive and negative affects are represented. For example, a specific set of voxels need not participate in every instance of, say, positivity, or even in the exact same instance at two different points in time. Rather than a one-to-one structure–function mapping between specific brain networks and positivity or negativity, therefore, the affective workspace hypothesis proposes that instances of positivity and negativity are represented probabilistically as different neural assemblies within a population of neurons (the workspace), so that instances of positivity or negativity should be modeled as a "brain state"[3] rather than as activity in a specific region or network (see Lindquist, Wager, Kober, Bliss-Moreau, & Barrett, 2012; Salzman & Fusi, 2010; Edelman, 1989, for a discussion of brain state or workspace reasoning).

Evidence for the Affective Workspace Hypothesis

We recently completed a meta-analysis to test these three hypotheses about the brain basis of positivity and negativity, using a database of 397 neuroimaging studies (functional magnetic resonance imaging [fMRI] and positron emission tomography [PET]) of affective and discrete emotional experiences and perceptions published between 1993 and 2011 (Lindquist et al., 2015). First, we identified voxels that consistently showed an increase in activity during both positivity and negativity (*both* positive > neutral and negative > neutral contrasts; see Table 8.1). Voxels fitting this profile would be consistent with the pattern predicted by the affective workspace hypothesis, which predicts that both positive and negative affect are the product of a single, valence-general system. A wide swath of regions were identified, including many of those that we typically think of as related to affect: the anterior insula, orbitofrontal cortex (OFC), amygdala, ventral striatum, thalamus, and dorsal anterior cingulate cortex, plus a few others, such as the dorsomedial prefrontal cortex, ventrolateral prefrontal cortex, and lateral portions of the right temporal/occipital cortex (Plate 8.1; see color insert for plates).

To test the remaining hypotheses, these voxels (responding during both positive affect and negative affect relative to neutral affect) were first masked out, since they violate both the monotonic relationship predicted by bipolarity, and the independence criterion central to bivalence. To identify regions that fit the profile outlined by the bipolarity hypothesis, we searched for voxels in which there was greater activity when one type of valence was contrasted with the other as opposed

TABLE 8.1. Hypotheses Regarding the Structure of Valence

Hypothesis	Description	Support would be found if . . .	How this has been operationalized
Bipolarity	Valence is a single, bipolar dimension, anchored at either end by positivity and negativity.	A given region, network, or population of neurons responds monotonically as affect changes from positive to neutral to negative (or vice versa).	1. Mask out voxels responsive to both positive and negative affect inductions. 2. Identify voxels in which there is greater activity when one type of valence was compared against another as opposed to against neutral (e.g., *positive affect vs. negative affect* > *positive affect vs. neutral*).
Bivalence	Valence comprises two unipolar dimensions, ranging from neutral to positive and neutral to negative.	Spatially independent regions, networks, or populations of neurons could be identified that demonstrated consistent changes in activity for either positivity, or negativity, but not the other.	1. Mask out voxels responsive to both positive and negative affect inductions. 2. Identify voxels outside of this area that are more responsive to positive versus negative affect, and negative versus positive (e.g., *positive affect vs. negative; negative affect vs. positive*). 3. Compare the positive versus negative and negative versus positive contrasts to contrasts of positive affect versus neutral, or negative affect versus neutral (e.g., *positive affect vs. neutral; negative affect vs. neutral*). Keep only those regions that are more responsive to positive versus negative than positive versus neutral (and the same for negative contrasts).
Affective workspace	Valence is realized in a probabilistic, whole-brain fashion, where the specific population responsive to positivity or negativity in a given instance is dependent on context.	Regions, networks, or populations of neurons were shown to be responsive to both positivity and negativity, with their functional preference dependent on the context in which the response was elicited.	1. Identify voxels responsive to both positive and negative affect inductions. Compute a conjunction of positive versus neutral and negative versus neutral contrasts (the "affective workspace"). 2. Identify voxels with functional specificity for positivity or negativity, by searching *within* the affective workspace for regions sensitive to positivity (*positive vs. negative*) and negativity (*negative vs. positive*). (Lindquist et al., 2015)

Note. This violates the expectations of both the bipolarity hypothesis, which would not allow for positivity and negativity to be encoded at once, and the bivalence hypothesis, which would allow for the simultaneous representation of both positive and negative valence, but not in the same cells.

to with a neutral stimulus (e.g., positive affect vs. negative affect > positive affect vs. neutral). Only one set of voxels met this criterion: a cluster in the ventromedial prefrontal cortex (vmPFC) with adjacent voxels in the anterior cingulate cortex (ACC); these voxels were more frequently active in response to positively relative to negatively valenced stimuli.[4] To identify regions that fit the profile for bivalence, we compared negative affect > positive affect, and further compared the probability of these activations to study contrasts of positive affect > neutral affect. No voxels were found that matched the hypothesized pattern.

Even if individual voxels are not selective for positive or negative affect, however, it is still possible that affect is represented at the population level, in terms of patterns of activity distributed across voxels and networks. To investigate this possibility, Lindquist and colleagues (2015) performed a classification analysis using the same meta-analytic database, in which they tried to differentiate negative versus neutral and positive versus neutral contrasts using a simple support vector machine (Chang & Lin, 2011). They found that the classifier was unable to diagnose whether individual contrast maps represented activation during negative versus neutral or positive versus neutral contrasts, with an average accuracy of only 53%. Together with the other results, this suggests that across paradigms, stimuli, modalities, and populations, the representations of positive and negative valence cannot be differentiated in the brain, at least at the level of granularity that one is able to achieve with this kind of database.

These results are largely in line with those reported by previous meta-analyses of positive and negative affect (e.g., Hayes, Duncan, Xu, & Northoff, 2014), in which there was spatial overlap between the brain activity correlated with experiencing and perceiving positively and negatively valenced stimuli. The results reported by Lindquist et al. (2015) differ from previous meta-analyses, however, insofar as these previous analyses also find additional regions that are interpreted as being functionally selective for either positive or negative valence. These analyses, however, were not specifically designed to compare different theoretical predictions regarding the nature of valence. In contrast, Lindquist and colleagues (2015) utilized more specific inclusion criteria for contrasts, which allowed us to better test competing hypotheses, and which may account for this difference in the results.[5] These findings of spatial overlap between the brain activity correlated with experiencing and perceiving positively and negatively valenced stimuli are also similar to those reported by meta-analyses that have used different operationalizations of positivity and negativity—including approach–avoidance (Murphy, Nimmo-Smith, & Lawrence, 2003),[6] reward–loss (Liu, Hairston, Schrier, & Fan, 2011), and subjective value (Bartra, McGuire, & Kable, 2013). It is also notable that, although the identification of valence selectivity within the vmPFC/ACC is consistent with other recent findings (Shenhav, Botvinick, & Cohen, 2013; Roy, Shohamy, Wager, 2012), these analyses do not exclude regions that respond during both positivity *and* negativity, as would be required in a rigorous test of the bipolarity hypothesis. There are furthermore additional studies within the literature showing that—*at the regional level*—these areas are activated by both positive and negative valence (e.g., Chikazoe, Lee, Kriegeskorte, & Anderson, 2014), suggesting that they are not specific to either valence, in a strict localization sense.

This pattern of results—and the affective workspace hypothesis by which it was predicted—is also in agreement with evidence from other methods including electroencephalography, lesion, electrical stimulation, and neurochemical studies in humans, and single neuron recordings in nonhuman animals that show that neural responses to positive and negative valence may be more flexible and context specific, than previously understood. For example, the human P300 event-related potential responds to both positively and negatively valenced stimuli (Olofsson, Nordin, Sequeira, & Polich, 2008). Similarly, electrical stimulation of the human medial temporal lobe (Halgren, Walter, Cherlow, & Crandall, 1978) has been shown to produce both pleasure and displeasure, and a recent review of human intracranial electrophysiological recordings reveals that when stimulated, the limbic, paralimbic, and cortical regions produce both positive and negative affective responses across instances (Guillory & Bujarski, 2014). Finally, some neurons in monkey OFC (area 13) have been shown to respond equally to appetitive and aversive stimuli (Morrison & Salzman, 2009). This violates the expectations of both the bipolarity hypothesis, which would not allow for positivity and negativity to be encoded at once, and also the bivalence hypothesis, which would allow for the simultaneous representation of both positive and negative valence, but not in the same cells (see Belova, Paton, & Salzman, 2008; Paton, Belova, Morrison, & Salzman, 2006, for other examples).

All together, these results suggest that valence is represented flexibly, and that instances of both positivity and negativity are represented as probabilistic assemblies of neurons within a single neural reference space, in line with the concept of degeneracy. In contrast, these results provided little support for bipolar or bivalent organization of affect. However, these conclusions are limited to the voxel (or voxel cluster) level of analysis. It remains possible that examining processes that are currently impossible to resolve using fMRI—such as neurochemistry or single-circuit or neuron activity—might reveal a different pattern. Single-neuron recording studies in animals, for example, have demonstrated specificity with respect to positive or negative valence at the level of the individual neuron (Morrison & Salzman, 2009; Namburi et al., 2015) and circuit (Tye & Deisseroth, 2012). Others have identified cells whose relative preference for positive versus negative stimuli appears to shift, depending on the presence of specific neurochemicals (Reynolds & Berridge, 2008; Tsunozaki, Chalasani, & Bargmann, 2008). Recently, it has been argued that optogenetic and pharmacogenetic methods provide superior ability to infer circuits when compared with classic neuroscientific methods (lesions, electrical stimulation, microinjections), and these methods clearly show that the neuronal circuits mediating positivity and negativity are separable within the same neural population, but not always separate in a spatial or even temporal sense (see, e.g., Tovote, Fadok, & Luthi, 2015; Lammel, Ion, Roeper, & Malenka, 2011; Lammel, Lim, Ran, Huang, Betley, et al., 2012). It is important to bear in mind, therefore, that a complete picture of valence must account for patterns across multiple levels of architecture. This notwithstanding, these results have important implications for the study of emotion in humans, as the voxel (or "region") level is the one at which human neuroimaging results are currently interpreted and communicated.

Whereas the meta-analysis conducted by Lindquist et al. (2015) found no support for consistent coding of positivity versus negativity, it is important to note that this was an analysis that averaged studies over many different contexts. Conceiving of valence as being flexibly assembled by a more general affective workspace does not rule out the potential for differentiating between positivity and negativity within a single study (which necessarily holds context constant). Chikazoe et al. (2014) recently demonstrated this. In this study, participants viewed picture stimuli and rated their positivity and negativity while neuroimaging data were collected. The authors first conducted a canonical univariate analysis, using positivity and negativity as independent predictors. The authors reported that a large proportion (>75%) of known valence-sensitive regions in medial and lateral OFC were responsive to *both* positivity and negativity, consistent with the results reported by Lindquist et al. (2015). The authors then employed a novel multivariate technique (representational similarity analysis) that identifies patterns of activation that may be distributed across voxels, rather than grouped together contiguously, in an anatomical fashion (as would be required for them to be identified in typical univariate analysis; Kriegeskorte, Mur, & Bandettini, 2008; Kriegeskorte & Kievit, 2013). This approach is therefore sensitive to representational properties underlying multivariate data. If the brain supports a valence code, then increasing dissimilarity in valence experience (which Chikazoe et al. [2014] reported to be negatively correlated: $r = -.53$) would be associated with increasing dissimilarity in population activity as well.

Using this approach, Chikazoe et al. (2014) were able to identify specific patterns with significant correlations to the degree of positivity and negativity reported by participants, in the ventral temporal and anterior insular cortex, as well as the medial and lateral OFC. They furthermore demonstrated that the representations within the medial and lateral OFC were independent of the sensory modality of the stimuli (visual vs. chemosensory). Finally, they reported that representations of valence within the OFC were also independent of the individual *subjects*. In other words, the patterns associated with positivity and negativity within one subject's OFC could be used to correctly classify the valence within other subjects' data as well, suggesting that these patterns displayed a significant degree of similarity across individuals.[7]

Together, the Chikazoe et al. (2014) findings demonstrate that—at the level of the region—areas typically associated with valence (e.g., OFC) may respond to both positive and negative stimuli. These findings are contrary to the predictions made by the bipolarity and bivalence hypotheses, but similar to the results reported by Lindquist et al. (2015). They also show that the encoding of positivity and negativity within these regions are best represented at the population level, as a pattern distributed across the brain as a whole, as predicted by the affective workspace hypothesis. It is important to note, however, that these results do *not* suggest that there is a single pattern or representation of positive or negative valence that should appear in every instance, and that is not what Chikazoe et al. (2014) demonstrate. A pattern classification analysis that can diagnose cases for positivity and negativity above chance does not produce a fingerprint or an essence for positivity or for negativity; each pattern is not a representation of voxels that can be actually found in every (or even any) individual subject's data, or across stimulus modalities.[8] The pattern of voxels for category (positivity or negativity) is a statistical summary of a sample of varying instances, and the pattern itself need not (and does not) appear in any individual instance within the category, in the same way that the mean of a population is an abstract representation and does not appear in any of its instances. We return to a discussion of this "population thinking" in greater detail in the next section.

All together, these results therefore support the affective workspace hypothesis, and provide evidence that the predictions made by the bipolarity and bivalence models may be misguided. In so doing, they also highlight somewhat counterintuitive inference: Specifically, the affective workspace hypothesis and the variable, context-dependent encoding it predicts, allows for the possibility that positivity and negativity may not be single constructs, as we typically think of them, but rather broad *categories*, each comprising a wide range of instances. In other words, whereas we tend to think of positivity and negativity as specific things—clearly definable, and differentiable characteristics—they may be more akin to fuzzy categories, within which the characteristics of any given instance are tied to the context in which it is realized. This is important not only for how we think about localizing valence within the brain, as reflected in many and varied neural representations, rather than by the activity of a single region or structure alone, but how we think about valence from a psychological standpoint as well.

There are also important conclusions to be drawn from the distribution of the valence sensitive voxels identified in these studies. The affective workspace, as described empirically above, contains regions that are part of the traditional (but outdated) "limbic system" concept. Of note, the workspace contains limbic cortical structures (agranular and dysgranular in structure; Barbas, 2015). Some of these regions form an intrinsic interoceptive network, so named because their anatomical and functional connections clearly indicate that they control and represent autonomic, hormonal, and inflammatory systems in the body (Barrett & Simmons, 2015). This network helps to maintain homeostasis and allostasis, and issues the interoceptive predictions that become your experience of affect. These regions fall into several canonical intrinsic or "resting state" networks, known as the "salience network" (Seeley et al., 2007), the default mode network (Andrews-Hanna, Smallwood, & Spreng, 2014), and the ventral attention network (e.g., Corbetta & Shulman, 2002). Narrowly, the regions in the workspace perform a salience function by directing the brain's resourcing capacities toward the most homeostatically and metabolically relevant information, particularly when incoming input is ambiguous and the brain needs to learn about them to encode information and better prepare its response next time. If based on past experience, your brain predicts that something will be metabolically costly, or if the cost is uncertain, then the brain will sample more information about that thing (i.e., it will pay more attention to it), encode it better, and prioritize action toward it. This is what it means to say that something is salient. In this sense, the "salience" network is a body-oriented source of attention within the human brain (Barrett & Satpute, 2013). More broadly, many of the regions in the affective workspace are considered to be "rich club hubs" (van den Heuvel & Sporns, 2013), meaning that they are among the most connected regions of the brain. All other networks in the brain are connected to these hubs. So, we would expect the affective workspace to be engaged during many other psychological phenomena, even those that are not explicitly "affective" in nature. And indeed it is (see Plate 8.2). This may explain why the concept of affect is relevant to virtually all phenomena in psychology (see Barrett & Bliss-Moreau, 2009) and it suggests that regardless of what folk psychology categories we use, psychological phenomena like reading, memory, decision making, language, attention, and so on are, at their basis, homeostatic processes.

Can Emotions Be Distinguished in the Brain?

Perhaps the question that has garnered the most interest in the science of emotion is whether each emotion category has specific, dedicated neural circuitry in the brain (e.g., Barrett, 2006, 2013; Barrett, Lindquist, et al., 2007; Izard, 2007; Panksepp, 2007; Tracy & Randles, 2011). Emotions, for example, play a crucial role in the formation and maintenance of social relationships by facilitating the communication of needs (Parkinson, 1996). They are also central to the diagnosis and treatment of every major mental disorder (Kring, 2008). The autonomic and neuroendocrine changes that accompany emotion may furthermore play an important role in physical health via peripheral gene expression pathways (e.g., Irwin & Cole, 2011). Because of their broad relevance, there have been tremendous empirical efforts to resolve ongoing debates over the brain basis of emotion. Nonetheless, there is still a lack of agreement across scientists, in terms of what the data demonstrate, and how this supports (or fails to support) existing theories. Meta-analysis is particularly useful for answering this question because it can potentially identify emotion-associated brain patterns that generalize across studies and experimental contexts.

The Classical versus Construction Theories of Emotion

As with valence, one barrier to a consensus based on the current literature is the existence of multiple models of emotion and predictions as to their neural bases, but a lack of systematic comparisons among them. With regard to emotion, whereas there are a multitude of individual theories, these can be grouped into two main schools of thought: The first—the *classical view of emotion*—posits that individual emotions have diagnostic psychological and neurobiological features, in which there should be relatively little (if any) variation across instances. Adhering to this viewpoint are, most notably, the basic emotion theories (e.g., Panksepp, 1998; Tomkins, 1962, 1963; Ekman, 1972; Izard, 1993), which propose that emotions are (a limited) set of universal programs, evolved to deal with recurrent challenges faced by our ancestors (Cosmides & Tooby, 2004). According to this perspective, emotion categories are natural kinds (Ekman & Cordaro, 2011) where the instances of each category emerge from a dedicated, specific neural circuit or network. For example, recently in their review of basic emotion theories, Tracy and Randles (2011) stated that an agreed-upon gold standard for the existence of basic emotions is "the presence of neurons dedicated to the emotion's activation" (p. 399). Others further specify that the distinct neural circuits must be subcortical in nature (Ekman, 1999; Panksepp & Watt, 2011). It has also been suggested that these circuits must be heritable, and homologous in nonhuman animals. From the basic emotion perspective, therefore, evidence for emotion "fingerprints" would have to demonstrate that (1) each emotion can be localized to a specific brain region or network; (2) is modular (because it should not involve regions involved in processing language), preferably subcortical, and inheritable; and (3) homologous in nonhuman animals.

Some versions of the more recent "appraisal" theories—the "causal" appraisal theories—also fall into the classical view of emotion as well (Barrett, Mesquita, Ochsner, & Gross, 2007; Gross & Barrett, 2011). In contrast to basic emotion theories, which posit that emotions are elicited by specific types of stimuli whose meaning is evolutionarily conferred, appraisal models suggest that meaning is assigned by the individual (the person experiencing or perceiving the stimulus), by cognitive evaluations (i.e., appraisals) of the eliciting stimulus, of the context in which it was encountered, and his or her own coping potential (Frijda, 1986; Lazarus, 1991; Roseman & Smith, 2001; Scherer, 1984; Smith, 1989). These appraisals produce, in turn, the physical response associated with the emotion. Within the brain, one should therefore expect emotions to manifest as activity distributed *across* different structures and/or functional networks, including those associated with higher-order thinking (contrary to the predictions made based upon basic emotion theories.) Similar to basic emotion models, however, causal appraisal theories provide reason to believe that these distributed signatures should be highly *reproducible*, with a specific pattern of activation that occurs in all instances of a given emotion category. Specifically, they suggest that different types of appraisals are synchronized during an emotion episode (Scherer, 1984, 1993, 2001). To the extent that the dimensions along which eliciting events are appraised are consistent across people and across cultures (Mauro, Sato, & Tucker, 1992), and to the extent that an appraisal along a specified dimension (e.g., novelty) consistently draws on the same neural substrate each time it is performed, we should therefore expect to see highly reproducible distributed signals within the brain.

In contrast to the classical view, the *construction view of emotion* proposes that emotions are not natural kinds, but rather folk categories within which there is significant variation across instances. "Anger," in other words, refers not to an individual stimulus, thought, or reaction, but instead a population of many different experiences, each of which cannot be disentangled from the situations in which they are realized. As a result, emotion categories are unlikely to have distinct and innate physical correlates within the brain that are replicable across different contexts. Rather, instances of emotion are proposed to emerge from the flexible combination and recombination of more domain-general core systems (e.g., perception, categorization, memory), and the functional neural architecture underlying them. This is called the conceptual act theory of emotion (Barrett, 2006, 2009, 2013; Barrett & Satpute, 2013; Lindquist & Barrett, 2012; Oosterwijk, Touroutoglou, & Lindquist, 2015). As a result, different instances of the same emotion category will be variably represented in the brain and instances belonging to different emotion categories (or even nonemotional categories, such as cognitions or perceptions) have some degree of similarity to one another. Appraisal models that view cognitive evaluations as part of the experience of an emotion, which are themselves composed of more basic functions instead of indivisible processes that define when an emotion is experienced ("constitutive appraisal models"), also fall into this category (e.g., Clore & Ortony, 2013; Smith & Ellsworth, 1985; see also Barrett, Mesquita, et al., 2007; Gross & Barrett, 2011). (Other neutrally inspired constructionist theories of emotion exist; see, e.g., LeDoux, 2012; Cunningham, 2013; Thagard & Schroder, 2013).

Emotion Categories Can Be Summarized as Distributed Patterns of Activity

Though there are now more than 300 neuroimaging studies on emotion (Lindquist et al., 2012), meta-analyses examining this literature have generally been unable to pinpoint unique identifiers of individual emotion categories (anger, sadness, happiness, etc.; Kober et al., 2008; Lindquist et al., 2012; Phan, Wager, Taylor, & Liberzon, 2002; Wager, Phan, Liberzon, & Taylor, 2003; Vytal & Hamann, 2010). Indeed, many of the regions most commonly activated (e.g., the anterior cingulate, anterior insula, amygdala, and OFC) are implicated across a wide *range* of emotions (Lindquist et al., 2012), and are also associated with many other sensory, perceptual, and cognitive (i.e., "nonemotional") tasks (LeDoux, 2012; Yarkoni, Poldrack, Nichols, Van Essen, & Wager, 2011), suggesting that they are fundamentally nonspecific. Beyond this, it is furthermore not obvious that the patterns identified in any single study as representative of an emotion category, or as differentiating one category from another, are *reproducible* across experiments.

The extant literature therefore suggests that the primary hypothesis of the classical view of emotion, that there should exist a consistent and specific region or anatomically prescribed network within the brain for each emotion category, has little support. Studies of intrinsic brain networks (Touroutoglou, Lindquist, Dickerson, & Barrett, 2015) and intracranial brain stimulation in humans (Guillory & Bujarski, 2014) further support this observation. Until recently, however, the alternative hypothesis proposed by appraisal and constructivist theories, that emotion-related activity is distributed across the whole brain and draws on a mix of structures and networks, had not been similarly tested. Using a database of 148 neuroimaging studies, Wager et al. (2015) did just this, analyzing patterns of brain activity associated with different emotion categories. To do this, they used a novel hierarchical Bayesian model that captures patterns of both activation and coactivation between different regions. The model incorporates both activation and coactivation into a generative model for each of five emotion categories—a model of the brain configuration associated with each category on average. This approach can be contrasted with previous approaches, which have usually either (1) looked for either activation or coactivation-related features without integrating them into a model, or (2) used a series of data-driven classifier models to decode emotion categories without developing a model for what a particular category "looks like" in the brain.

Thus, the Bayesian generative model approach allows for a better test of the construction models in particular, as they can help specify the brain configuration that is most strongly associated with each emotion category, and which brain features are needed to identify an emotional instance's category (e.g., activation and coactivation in specific cortical and subcortical networks). For instance, the conceptual act theory (Barrett, 2014; Lindquist et al., 2012) predicts that emotion categories are characterized by widespread patterns across the brain, including regions that are not specific to emotion at all. Basic emotion theories predict that emotion categories are characterized by differential patterns within regions and networks specific to emotional processes, and that with enough resolution and data quality, there should be brain features (e.g., regions) activated by one and only one emotion category.

Using the Bayesian spatial point process model, the authors were able to identify the emotion category into which each individual study and/or contrast in their database fell, with 66% accuracy on average (range 43–86%, chance = 20%; see Plate 8.3 for classifier maps). This demonstrated that emotion categories can be represented by distinct patterns of activity and coactivity—patterns that are sufficiently robust such that they can be used to classify emotion categories from studies across the meta-analytic database. These representations were, notably, distributed across many regions that (1) are unlikely to have emotion-dedicated neurons; (2) serve a wide variety of basic perceptual, cognitive, and motor functions; and (3) were involved in creating instances of multiple emotion categories. These results are inconsistent with the classical view of emotion, which purports that emotion categories are distinct biological types, or that there are individual brain systems corresponding to specific types of cognitive appraisal (e.g., valence, novelty, coping potential). They are more consistent with constructionist theories, which hypothesize that anger, sadness, fear, disgust, and happiness are not biological types arising from dedicated brain modules, but arise from interactions of anatomically distributed, core systems within the functional architecture of the brain (see also Cunningham, 2013).

It is important to note, however, that these representations of emotion categories do not reflect the "essence" of these emotions. Whereas the patterns identified by Wager et al. (2015) are reliable in the sense that they can predict the emotion category targeted in a study across multiple paradigms and imaging methods, they are not reliable insofar as they could be used to predict what any individual instance of emotion might look like (i.e., a pattern for a category cannot provide any evidence for how each of its instances was computed). In representing the patterns of brain activity associated with different emotion categories, our results do not imply that those categories are homogeneous (i.e., that all instances of "anger," "fear," and so on share all of the category level features we identify). Thus, each activation map correctly classified as representing anger does not have to contain the entire pattern for anger; it only has to contain a set of voxels that is closer to this pattern than to the pattern for any other emotion category. Different instances of anger are likely to contain unique subsets of the category-level pattern that are *sufficient* for anger, without implying that all instances of anger are the same pattern. Rather than capturing a dedicated, obligatory pattern for one emotion category, the category-level maps we identify are *statistical summaries*. This is a basic aspect of population thinking that is the foundation of evolutionary thinking as well (Mayr, 1984). In the same way that no American family consists of 3.13 people (the size of the average American family in 2014), not every instance of an emotion category must involve the pattern that is used to diagnose the category. A statistical summary of a category need not actually exist in nature (Mayr, 1984). For example, one might identify the features of a prototypical chair, but no real chair need have *all* those features to be a chair. Neither does the brain need to have an innate, biologically preprogrammed "chair system." Rather, each instance of the category has some set of features that are sufficient for category membership, but none of them are necessary for category membership, and they don't co-occur anywhere but in the abstract representation that summarizes the category (Posner & Keele, 1968).

This is an important point, and one that is often overlooked: Take, for example, Kassam, Markey, Cherkassky, Loewenstein, and Just (2013). Here, using multivoxel pattern analysis, the authors report that they were successful in distinguishing different types of emotion experience, with average rank accuracies of between .72 and .90 across the different emotions—above the chance level of .51. These results also extended across individuals and across modalities; the authors were able to train classifiers on one set of subjects and word-cued emotion simulations, and use those to classify with accuracy above chance experiences in other individuals and experiences elicited by emotional pictures as well.

These promising results lead to a number of important questions about what the results mean for theories of emotion. Are they reflections of "essences" for each emotion category? Can they be used to identify the category of an emotional response (e.g., Is someone feeling sad?) or category-specific emotional intensity (e.g., How sad does someone feel exactly?)? Kassam et al. (2013) suggest that the neural "signatures" of different emotions—identified in analyses such as the one they conducted—could be used to produce "a generative model that could predict an individual's emotional response to an arbitrary stimulus." Saarimaki, Gotsopoulos, Jääskeläinen, Lampinen, Vuilleumier, et al. (2015) conclude that "basic emotions are encoded in discrete activation patterns" that function as "distinctive fingerprints" (p. 8).[9] Other studies make similar claims. Park, Jang, Chung, and Kim (2013) write about identifying a "core set of features." Yuen et al. (2012) claim that their classifiers represent "important neural signatures corresponding to a cognitive/affective state." Finally, Kragel and LaBar (2014) describe the results of analyses as "emotion specific biomarkers." In each of these cases, the researchers appear to be conceptualizing the patterns identified by classification analyses as essences (a fundamental property that occurs in every instance), when these are, in actuality, a statistical summary of the category (which can be useful in differentiating instances into categories, but which may not appear in any instance at all; Posner & Keele, 1968).

More broadly, the BSPP findings reported by Wager et al. (2015) suggest that understanding the brain basis of emotion will not necessarily be accomplished by searching for emotion-specific modules at ever finer-grained levels of analysis, but instead by understanding the complex interactions among networks during emotional episodes. To this end, these results also highlight some potentially interesting new observations from that meta-analysis. First, there were few differences between emotion categories in terms of their overall level of cortical or subcortical engagement. Emotion categories were furthermore not differentiable based on the frequency with which they activated intrinsic activity networks.[10] Emotion categories *could*, however, be distinguished by their profiles of relative activation *across* networks. For example, anger and fear categories were characterized by relatively greater activation within the limbic, default mode, dorsal attention, visual, and frontoparietal networks. In contrast, the disgust, sadness, and happiness categories were characterized by relatively lesser activation within this group of networks, and greater activation within the salience and somatomotor networks. This is notable, because the grouping of emotion categories these data suggest do not match those that might seem to be obvious, phenomenologically. For example, the happiness and disgust categories differ in valence (one positive, and one negative, respectively)—a feature of phenomenological importance—but are similar in their neural summary pattern. Similarly, the disgust and fear categories differ in terms of their summary neural patterns, but are both designated as “high” in arousal, another phenomenologically based property commonly cited within the emotion literature. It is furthermore notable that the existence of clearly differentiable “summary patterns” of activation across networks for different emotion categories could be seen within subcortical zones as well.

Observations like this are important, because they cause us to rethink the nature of emotion. These results, reported by Wager et al. (2015), lend additional weight to the conclusion that emotion categories may be best characterized by the relative degree to which they recruit networks throughout the brain—rather than by the magnitude of activation within a single, anatomically defined region, or within a single network (see Baucom, Wedell, Wang, Blitzer, & Shinkareva, 2012; Kotz, Kalberlah, Bahlmann, Friederici, & Haynes, 2012, for similar examples). This suggests that rather than indivisible entities, instances of emotion may be more productively conceptualized in terms of the relative degree to which they draw upon different domain-general functions with which these intrinsic networks are associated.

Other studies using similar methods have now started to appear, reaching similar conclusions. Saarimaki et al. (2015), for example, demonstrated in a single set of participants that multivariate pattern analysis could be used to classify six emotion categories, and that the resultant classifiers could be used to identify emotions across different individuals, and different methods of emotion induction (movies vs. mental imagery). The classifiers reported by Saarimaki et al. (2015), like those reported by Wager and colleagues (2015), draw on the pattern of activity across a range of networks performing domain-general functions. Specifically, they found the core nodes of the default mode network (the medial prefrontal cortex [mPFC], precuneus, and posterior cingulate cortex [PCC]; Andrews-Hanna et al., 2014); core nodes of the salience network (e.g., the ACC and amygdala), and the somatosensory, supplementary motor, and premotor regions; as well as the posterior insular (which is the primary interoceptive cortex). The default mode network is associated with many different task domains (Barrett & Satpute, 2013; Lindquist & Barrett, 2012), including self-referential processing (Amodio & Frith, 2006; Northoff et al., 2006; Buckner & Carroll, 2007), as well as the semantic representations that underlie conceptual processing more generally (Binder & Desai, 2011; Binder, 2009; see also Barrett, 2015a; Lindquist, Satpute, & Gendron, 2015). In other works (Barrett, 2009, 2015b), we have proposed the default mode network is one network that is at the core of the active inference process by which the brain perceives and acts in the world. It helps to initiate the construction of all mental events by issuing predictions to the sensory and motor systems. This network is well-known for constructing representations of the past and the future (Buckner, 2012; Schacter, Addis, Hassabis, Martin, Spreng, et al., 2012; Mesulam, 2012), but we have hypothesized that it also helps to construct representations of the present. Think about it this way: A human brain carries around a model of the world. This network is at the core of that model. This network contains the conceptual knowledge needed to categorize and make sense of the sensory inputs in the present moment so a person knows how to act on them. In the process, perception and experience is constructed. This is logic of the active inference framework to understanding the brain (Barrett & Simmons, 2015). The binding of conceptual and body-based representations constitutes a key feature of an emotional category. Although Saarimaki et al. (2015) interpreted these findings as evidence for “basic emotions,” their results showed no evidence that would actually support basic emotion theory (i.e., they were not able to localize each emotion category to a specific, modular brain region that is inheritable and homologous in nonhuman animals). These results are exactly what has been predicted previously by the conceptual act theory, which has posited that the default mode network and regions representing internal states are integral to the experience of emotion (Lindquist et al., 2012; Lindquist & Barrett, 2012; Barrett, 2009).

Emotion Regulation and Emotion Generation

The last question we address in this chapter is the degree to which emotion generation is distinct from emotion *regulation* (Gross & Barrett, 2011)—or the techniques we use to influence what emotions we experience, when we have them, and whether and how we express them (Gross, 1998). For as long as people have been interested in how emotions are generated, they have also been interested in how they are regulated (Gross, 2007, 2010). One reason for this interest is that regulation can have a significant impact on both psychological and physical health. Individual differences in the use of regulation strategies, for example, are predictive of the experience of positive affect, better interpersonal functioning, and general well-being (Gross & John, 2003). Emotion regulation is also integral to the practice of cognitive-behavioral (Beck, 2005), dialectical-behavioral (Lynch, Trost, Salsman, & Linehan, 2007), and psychodynamic (Bateman & Fonagy, 2006; Maroda, 2010; Have-de Labije & Neborsky, 2012) therapies, all of which are widely used in the treatment of mood and anxiety disorders.

The Classical versus Construction Theories of Emotion Regulation

How one defines emotion generation is necessarily dependent on how one defines emotion generation. Here again, the differentiation between the classical and the construction viewpoints is important. From the classical perspective, emotions are indivisible modules of automatic and coordinated responses to specific stimuli. Emotion regulation, in this case, would involve separate processes that either prevent the emotion from being triggered (e.g., situational selection or modification), or that attenuate its expression after it has been realized (Gross & Thompson, 2007). Basic emotion theories, and hypotheses about regulation based on these theories, maintain a clear distinction between generation processes and those that would be required to regulate the emotion produced—at no point are these regulatory processes changing the fundamental nature and action of the affect program that defines the emotion. As a result, one should expect that the neural mechanisms underlying these processes should be independent as well. More specifically, one would expect to see emotion-related activity focused within the subcortical regions (as predicted by the basic emotion theories), and regulatory activity within the cortex (Gross & Barrett, 2011). Causal appraisal models make a similar prediction. These models conceive of appraisals as antecedent to the emotion—necessary evaluations that had to be made, after which the emotion that best fit the appraisal pattern would be produced—in a relatively strict, deterministic form, similar to, but more flexible than, affect programs (Arnold, 1960a, 1960b; Lazarus, 1991; Roseman, 1991). Given the similarity of the emotion production pattern in these early appraisal models to that proposed by basic emotion models, one might expect a similar relationship between this emotion generation and emotion regulation, with the two cast as relatively distinct processes.

In contrast, from the construction standpoint, emotion generation and emotion regulation involve the same processes, and ones that are not limited to either cortical or subcortical tissue alone. For example, constitutive appraisal models define appraisals not as causes, but rather constituents of emotion, along with the bodily changes produced in response to these appraisals, intended to prepare the individual to respond to the eliciting stimulus (Ellsworth & Scherer, 2003; Clore & Ortony, 2008). In these models, emotions are dynamic and can evolve, changing as one's evaluations of one's environment changes. Emotion regulation can take the form not only of situation selection, and modification, but also of cognitive change, or "reappraisal," wherein one changes one's evaluations of the situation in a way that would also change one's emotional response to it. In this case—where regulation could be realized by additional iterations of the same systems that are involved in emotion generation—one should not expect to be able to differentiate emotion generation from emotion regulation, at a neural level, as these processes should draw on the same underlying mechanisms. The same is true for newer construction models (e.g., the conceptual act theory). Whereas appraisal theories conceive of appraisals as evaluations of one's external surroundings, with internal bodily changes occurring in response to the outcomes of these evaluations to prepare the organism to respond to the eliciting stimulus, constructivist theories focus on meaning making based on the internal bodily sensations themselves. Nonetheless, despite the difference in focus, both theories view emotion as being *continually constructed*—meaning that subsequent acts of meaning making ("reappraisals") are part and parcel of the definition of the emotion—not a separable component. Indeed, according to this viewpoint, as with the appraisal theories, regulation is constantly occurring as the emotion evolves. As a result, one would not expect there to be independent neural bases for emotion generation and emotion regulation.

Emotion Generation and Emotion Regulation Share Similar Neural Bases

To date, there has only been a systematic investigation of the brain basis of reappraisal as an emotion regulation strategy. Buhle, Silvers, Wager, Lopez, Onyemekwu, et al. (2014) conducted a meta-analysis of 48 neuroimaging studies involving reappraisal. Comparing their findings with the latest meta-analytic summary of emotional experience (Satpute, Wilson-Mendenhall, Kleckner, & Barrett, 2015; cf. Lindquist et al., 2012; Wager et al., 2008) shows several areas of overlapping activity. As shown in Plate 8.4, these include key regions of the salience and ventral attention networks including the ventrolateral prefrontal cortex, anterior insula, ACC, supplementary motor area, and the posterior superior temporal sulcus. These overlaps suggest that reappraisal and emotional experience share similar underlying mechanisms, consistent with the conceptual act theory. However, there are also differences. Reappraisal reliably engaged a posterior portion of the middle frontal gyrus and intraparietal lobule. These areas are nodes in a dorsal attention network, considered to be important for selecting goal-relevant stimuli from the environment (Corbetta & Shulman, 2002; Corbetta, Patel, & Shulman, 2008). In comparison, emotional experience reliably engaged parts of the default mode network, including the mPFC and PCC. Proponents of a more classical view may point to these areas of nonoverlap as being more selectively important for the regulation or experience of emotion. However, an equally likely account from a constructionist perspective is that these differences are due to differences in the attentional orientation of the task paradigms most frequently used in tasks that elicit regulation or experience. For instance, reappraisal may engage a handful of strategies, including searching a complex graphic image for aspects that feed a reinterpretation or use semantic interoceptive information to retrieve concepts that update an affective state. These strategies may sometimes recruit the dorsal attention network, or the default mode network, respectively. Emotional experience, too, may be elicited in a variety of ways, which have been shown to engage different cortical areas (e.g., Ochsner et al., 2009) that may also recruit these networks to varying degrees.

To the extent that these results suggest that the neural bases for emotion regulation are very similar to those for emotion generation, it also raises an interesting question: Specifically, why are there not more targets for regulation, beyond the amygdala? Buhle et al. (2014) reported strong evidence that reappraisal modulates activity in the bilateral amygdala, but no evidence of similar regulation of other regions integral to the generation of emotion, including the anterior insula, periaqueductal gray, hypothalamus, thalamus, OFC, temporal pole, and rostral and subgenual anterior cingulate. If emotion regulation is realized via iterations of the same mechanisms involved in emotion generation versus a direct attenutation/enhancement of a single node in an emotion-related network, then we should expect modulate to be measurable within the whole of the emotion network, not just the amygdala. Uncovering such modulation, however, may require conducting additional, and different, emotion regulation experiments, using a wider variety of emotion inductions and data analysis. A non-negligible number of the studies within this database furthermore used return on investment (ROI) analyses focused on the amygdala—an approach that would bias any meta-analysis in terms of identifying this region as a particularly important target for regulation relative to others. Finally, is also possible that emotion regulation may be realized not only in terms of the absolute value of the activation of specific regions or networks, but also in the connectivity between them, as has been shown to be important in emotion generation. Future studies should strive to conduct and report both whole-brain analyses that examine the impact of regulation on the full range of regions and networks, and analyses of connectivity—in particular, cortical–subcortical connectivity.

Conclusion

Overall, the meta-analytic studies we review in this chapter make it clear that the brain's "emotion architecture" looks nothing like what our phenomenology, and the classical view of emotion on which it is based, would lead us to expect. First, we addressed the question of whether valence—or that which differentiates positivity from negativity—was encoded within the brain, and if positivity and negativity could be differentiated. Despite having long been treated as a dimension so fundamental and obvious in both nature and importance that these qualities need not be belabored, we reviewed convincing evidence that, across the literature as whole, positivity and negativity did not differ in any substantial way, in their representation within the brain. Second, we applied the same question to emotion: Here the evidence suggests that they can be distinguished (a surprising result, given the lack of discrimination for valence[11]), but, contrary to common assumptions, this discrimination relies not on the absolute value of activity within individual anatomically defined regions but rather on the relative degree to which emotions engage a range of different large-scale networks, and on the *connectivity* of regions and networks throughout the brain. Finally, we turned to the distinction between emotion generation and emotion regulation. Here, despite a more limited literature from which to draw, the data suggest that the generation and regulation of emotion, though experientially dissimilar, likely draw on largely overlapping or self-same neural mechanisms.

Together, these data suggest that emotion's basis within the brain is far more complex than commonly assumed. Yet, scientists still talk and write about the "emotional brain," talk about emotion and cognition "interacting" in the brain, and understand emotion regulation as cortical sites regulating subcortical structures. This is not to say that experientially based differentiations may not be of value subjectively or behaviorally—they may very well be (Barrett, 2009, 2012); nor is it to imply that we should dismantle our phenomenological frameworks when it comes to experimental design and data analysis, either—this may not be possible or desirable. Rather, these results highlight the fact that previous theories on emotion have been *underconstrained* by brain data. The findings presented here constitute a specific set of constraints that may be integrated into future experiments and future models.

Specifically, these data demonstrate the importance of accounting for significant variation within the traditional "folk" categories of emotion. As the meta-analyses described here have demonstrated, there is significant heterogeneity (variability) across instances of both valence and emotion, in terms of how they are represented within the brain. This suggests that there is likely important variability behaviorally and experientially as well. In contrast to indivisible constructs, therefore, it is likely more fruitful to think of positive and negative valence, and emotions, as broad categories within which the characteristics of any given instance are tied to the context in which it is realized. This is important not only for how we think about localizing valence within the brain—as reflected in many and varied neural representations, rather than by the activity of a single region or structure alone—but also how we think about valence from a psychological standpoint. Future research should emphasize and examine the variability within these categories, in order to better understand them. With respect to neuroimaging, this will require approaching representations of emotions in terms of whole-brain states (including not only voxel-level metrics but also measures of network activity, coactivation, distributed representations, and timing), in order to more fully capture their complexity.

In sum, this is an important time for the literature on emotion. We have a developing awareness that its basis within the brain may be more complex than commonly assumed, and we have enough information to start generating more data-driven hypotheses that might never have been possible based on phenomenology alone. We also have new and quickly developing tools that are more sensitive than ever to the complex, multidimensional patterns that may prove to be the best way to test these new hypotheses, and characterize any new constructs they may identify. Together, these developments afford an opportunity for significant progress in further understanding the physical basis of emotion.

Notes

1. An intermediate position between the bipolar and bivalence hypotheses could involve functional selectivity, instead of exclusivity, such that regions or networks respond during both positive and negative valence, but that demonstrate a functional preference during positivity or negativity. A mechanism in which there were two spatially independent sets of neurons/regions/networks supporting positive and negative valence, but where these sets activate reciprocally, would also fall in between a bipolar and bivalent model.
2. Degeneracy is thought to be a ubiquitous biological property, with it becoming increasingly evident that biological functions as a whole cannot be assigned to individual (cellular) components in a one-to-one manner. For example, there are many more DNA codons than there are amino acid residues for which they code, suggesting that many different sequences could produce the same amino acid sequence. As a result, a gene could be inactivated completely, and yet not impact the phenotype of the organism. As applied to the brain basis of emotion, a degenerate architecture would explain the failure heretofore to find consistent and specific fingerprints for valence or emotion categories, insofar as it would suggest that the mechanisms underlying these phenomena may be many, and which is utilized in any given instance may be context dependent.

3. A "brain state" refers to the full set of variables that describe the neural circuits of the brain. Because the neural underpinnings of valence and emotion may be degenerate, is it insufficient to describe them solely in terms of gross anatomical or regional terms; these units are too imprecise. Rather, in order to understand the magnitude of the variability in the brain basis of difference instances of valence or emotion, or the similarity of any two instances, it is necessary to quantify these instances in terms of brain states.
4. Because information about deactivation is typically not included in such analyses, it is possible to only examine whether there is more consistent activation for a positive > negative contrast, relative to a positive > neutral one; the strongest test of the bipolarity hypothesis would require a demonstration of *decreasing* activity during negative affect.
5. Whereas Lindquist et al. (2015), and previous meta-analyses identify regions associated with both positive and negative valence, previous analyses also identified regions of greater specificity. This difference may be attributable to two factors: First, Lindquist et al. were more selective in their selection criteria for study contrasts. Specifically, they included only contrasts where the baseline stimuli were neutral and of the same type as the target stimuli (e.g., angry vs. neutral faces were included; angry faces vs. fixation contrasts were not). They also excluded contrasts from studies that reported only return on investment (ROI) analyses, because the selection of ROIs may reflect experimenter bias. Second, in contrast to previous analyses that analyze all contrasts together, regardless of baseline condition, Lindquist et al. computed Multilevel Kernel Density Analysis (MKDA) maps for different baselines separately.
6. Although Murphy et al. (2003) failed to find any difference in the distribution of activation for positive versus negative emotions generally ("we . . . tested for a difference in the 3-D distributions of neural activity associated with positive and negative emotions, only to confirm the null hypothesis of no difference between the two conditions" [p. 223]), they do claim to identify some specificity for the neural bases of individual emotions within these categories (disgust, fear, and anger), and upon this basis claim to have identified support for "affect program emotion accounts."
7. These neurons are multimodal, and therefore put valence (as interoceptive changes) from different sources on a common scale. In principle, this means that objects and events that differ widely in their sensory properties could be compared according to how they influence a person's positivity or negativity, allowing affect to function like a common currency in decision making (Chikazoe et al., 2014). Similarly, Clithero and Rangel (2013) report a meta-analysis of 81 neuroimaging studies, showing that similar regions are routinely engaged when participants are deciding whether they are willing to work or pay for one item over another (i.e., computing value, or when receiving things they value but not necessarily what they like [affect]). Neuroeconomists propose that neurons in the ventromedial frontal cortex (vmPFC) compare different classes of objects (food, money, trinkets) on a common currency, so that the brain can decide which are preferred.
8. Also, we should add that effects were both relatively weak (they were significant in only one of the regions examined), and they were obtained in a situation where the context was held constant. Indeed, despite the aforementioned changes in modality and individual subjects, all other situational characteristics—that individuals were lying down during a magnetic resonance imaging (MRI), with the same experimenter giving them the exact same instructions, as to how to view the exact same stimuli, and rate them in the exact same task—remained unchanged across the experiment.
9. Strong claims based on current empirical tests, however, drastically underestimate how much context can vary, and how influential contextual variables can be in shaping emotion experiences. Though Kassam et al. (2013) looked at predictive accuracy across individuals and stimulus types, they still used the same experimental set-up, with the same experimenters and the same instructions across conditions. There is little reason for confidence, therefore, that the classifier will prove to be diagnostic outside of this context. Making such a claim would require instead a demonstration that these patterns persisted, despite variation in each one of these task- and context-related variables. A similar observation can be made about the Saarimaki et al. study.
10. As people have been moving away from the once popular "region of interest" analyses in which they focus on a single anatomically defined section of the brain, they have started to adopt a conceptually similar approach, but simply substituting intrinsic connectivity network boundaries for anatomical ones. This suffers from the same limitations as the original ROI analyses did, and here was demonstrated to be insufficient.
11. One reason cited for the failure to discriminate positivity from negativity in the meta-analysis reported by Lindquist et al. (2015) was that the realization of valence may be context dependent, taking different forms in different situations. This highlighted the counterintuitive hypothesis that valence may not be a "thing" but rather a collection of representations—with enough variation between them

such that they may not be measurable across a large and varied database like that used by Lindquist et al. Applied to the results reported by Wager et al. (2015)—in which the authors *were* able to differentiate states based on their neural correlates—this suggests that emotion states, as we typically study them, may be *less* variable than affect (positive/negative) states, despite the common conception of them as more complex.

To this end, it is notable that studies focused on positive versus negative affect are often relatively unconstrained, from the perspective of the participant; many and varied stimuli are presented, with relatively few instructions as to how they should be evaluated. In contrast, experiments designed to measure emotion states are often far more stereotyped, using a smaller range of paradigms and stimuli, and provide significantly more information to the participant, in terms of how he or she is to evaluate and respond to what is provided. Future analyses should strive to account for such differences.

CHAPTER 9

EMOTION AND THE AUTONOMIC NERVOUS SYSTEM

Wendy Berry Mendes

A glance at some of the classic review papers and chapters on emotion and autonomic nervous system (ANS) physiology reveals a common thread—evoking William James's (1884) quote on the essential conditions for what should be considered an emotion: "the only emotions I propose expressly to consider here are those that have a distinct bodily expression" (p. 189). It is no wonder that emotion researchers and theorists who consider the biological underpinnings of emotion use this quote as justification for looking "under the skin" at bodily responses as a window into affective and emotional states.

James's perspective is but one of many factors that sets the stage for examining how ANS responses change during emotion states. ANS responses and emotion reactions share similar temporal features; emotion responses are described as short-lived, experiences that, on average, last seconds to a couple of minutes. This temporal window aligns well with typical ANS changes as opposed to neural activation often measured in milliseconds or neuroendocrine and immunological changes measured over hours or days. Additionally, emotion responses are perceived as being "felt" in the body and folk language implicates bodily changes in these processes. Feeling sick to your stomach when experiencing disgust; a racing heart when walking down a dark, deserted street; or hot, sweaty palms when furious seem to effortlessly couple the emotional state and the bodily change. Given this apparent natural coupling it is not surprising that a large literature has amassed examining the relation between emotion experiences and ANS changes.

There are, however, many factors that modulate the *emotion–physiology link* limiting the straightforward conclusion that a discrete emotion experience is reliably and universally associated with specific changes in ANS responses. Rather than viewing the many factors that moderate the emotion–ANS link as obstacles, it may be more useful to consider the moderators as opportunities to understand how emotions are manifested in the brain and body, and how contextual factors extend our knowledge about emotion. In this chapter, I provide an overview of research examining the links between emotion and peripheral physiology, ignoring neuroendocrine and immune responses, which are covered in Chapter 37 (see Prather, this volume) and neural activation, covered in Chapter 8 (see Clark-Polner, Wager, & Barrett, this volume). First, I review research that examines relations between emotion and peripheral physiology, and then address the moderators that can alter the emotion–physiology link, specifically, context, developmental factors, and sociocultural environments. Due to space constraints, the literature reviewed is illustrative rather than comprehensive. The chapter begins with a primer on psychophysiological theory and ANS functioning that serves to both orient the reader to the most commonly measured physiological systems used in the study of emotion, and identifies some of the limitations inherent in examining physiological responses to understand emotion and emotion processes.

Peripheral Physiological Systems

A number of biological systems have been implicated in emotional experiences, including sympathetic and parasympathetic nervous systems, hemodynamic, enteric, neuroendocrine, immune, and neural. A common feature of these biological systems is that their *primary* functions have little, if anything, to do with emotions. The sympathetic nervous system (SNS) is designed to provide oxygenated blood to the brain and body to support movement; the parasympathetic system can coregulate SNS responses and supports homeostasis during sleep; the gastrointestinal system breaks down food for energy and excretes waste. These biological systems can change during emotion experiences, providing the foundation for these systems to be examined in emotion research, but the presence of changes in any of these systems does not indicate that an emotional experience occurred, and the reverse is true as well—a lack of response does not indicate the emotion did not occur.

As described in the first chapter of the *Handbook of Psychophysiology* (Cacioppo, Tassinary, & Berntson, 2000, 2007), inferring mental states from physiological changes poses several challenges, including the idea that *many* mental states can influence specific physiological changes and that a specific mental state is related to *many* physiological responses. In adopting a biological systems approach to understanding emotions, the literature is clear that one-to-one invariants of emotional states and physiological changes that exist across contexts and people are rare, if not nonexistent (e.g., Cacioppo et al., 2007; Kreibig, 2010; Siegel et al., 2016). The pursuit of unearthing invariants between emotion and psychophysiology might be a noble one—the entire field would benefit if a single channel of physiological responses changed predictably and precisely with the presence of an emotional state, regardless of context, culture, or character—but it is also likely misguided. Patterned physiological responses, looking across a variety of physiological changes, linked to emotion states provides a step in the right direction (e.g., Friedman, 2010; Kreibig, 2010; Levenson, 2014; Stemmler, Heldmann, Pauls, & Scherer, 2001), particularly if the panel of physiological responses are not strongly correlated with one another. In addition to looking across a variety of physiological responses, a deep understanding of the individual differences and cultural and contextual factors that influence emotion, along with an appreciation of the developmental, physical, and environmental factors that affect physiology, can enable researchers to augment their understanding of the emotion–physiology relationship.

At the broadest level, relations between peripheral physiology and emotion can be construed in terms of their *sensitivity* and *specificity.* Sensitivity is the extent to which the physiological responses reliably change as a function of shifts in emotion states with the idea that subtle shifts would affect highly *sensitive* measures, but measures that are lower in sensitivity would take more intense emotion states to observe changes. Skin conductance (SC), for example, is highly sensitive because very subtle and low-level changes in emotion can affect SC levels. In contrast, blood pressure (BP) changes are less sensitive given that the emotional experience needs to be fairly intense to alter BP levels (Mendes, 2009).

Specificity refers to how physiological responses are related to discrete mental states, with low specificity indicating that a physiological response is related to many mental states and high specificity indicating that a physiological response is related to fewer or (possibly) a single mental state. Using SC again as an example, though it is highly sensitive, it is not specific. Many affective states, even emotions with different valence like anger and enthusiasm, can engender SC increases (e.g., Kreibig, 2010; Shiota, Neufeld, Yeung, Moser, & Perea, 2011).

The constructs of sensitivity and specificity are crucial to understanding and predicting associations between emotions and peripheral physiological responses, though these relationships can be modified by context. Staying with the example of SC, if the context is constrained such that a smaller array of emotions are likely to be experienced, then one might be on firmer ground to conclude that the physiological response is a reasonable measure of the emotional experience. For example, the threat of experiencing an electric shock reliably increases SC, and while some people might interpret the increased SC as synonymous with the experience of *fear*, others might conclude that SC responses are tracking threat detection, general arousal, or intensity (e.g., LeDoux, 2014). Importantly, it is unlikely that increased SC in the electric shock context indicates an emotion like happiness or disgust. Thus constraining the context can improve the specificity of the emotion–

physiology relationship by limiting the number of likely emotional states that can be experienced.

Autonomic Nervous System

The ANS comprises two major branches: the SNS and the parasympathetic nervous system (PNS), both of which are commonly examined in studies on emotion and physiology, and many measures represent hybrid responses that are influenced by both systems simultaneously. Indeed, the division of the systems is more didactic than functional given the vast number of bodily changes influenced by the *combination* of these systems and the extent to which the SNS and PNS influence each other, which can be reciprocal, coinhibited, coactivated, or orthogonal (Berntson, Cacioppo, & Quigley, 1993).

The SNS functions, in part, to mobilize oxygenated blood from the heart to peripheral sites such as arms, hands, legs, feet, and the brain. The greatest change in SNS responding occurs with physical exertion, like sprinting or intense aerobic exercise. But this system also activates in *nonmetabolically demanding* situations, ones that do not by necessity require an increase in oxygenated blood. Measures that tap aspects of SNS that are commonly used in emotion research include heart rate (HR)/interbeat interval, SC, finger pulse transit time, BP, skin temperature, preejection period (PEP), stroke volume/cardiac output, and local/global blood flow measures (pulse amplitude, total peripheral resistance). Most of these measures tend to be highly correlated with one another, suggesting that studies that examine multiple SNS measures to look at patterns of physiological responses might be unwittingly inflating Type 1 errors if they are not accounting for the common variance in the measures.

The PNS is typically assessed with heart rate variability (HRV) measures such as cardiac vagal responses. Initially, HRV—the time interval between each heart beat—was believed to be a measurement artifact or nuisance, but further exploration into spontaneous changes in the timing of the heart cycle proved to be psychologically and physiologically meaningful. Though there are still disagreements on the specifics related to measurement, quantification, and psychological meaningfulness of HRV, these measures are often used by emotion psychophysiologists, given their putative sensitivity to valence and links to social engagement processes (Larsen, Berntson, Poehlmann, Ito, & Cacioppo, 2008; Porges, 2007).

Porges's (e.g., 2007) polyvagal theory is commonly evoked in studies examining emotional states associated with HRV/vagal changes. Polyvagal theory argues that primates uniquely have vagal nerve modulation (but see Grossman & Taylor, 2007), which has evolved as part of the *social engagement system*. Thus one of the primary postulates of polyvagal theory is that social factors (affiliation, social engagement), personality factors (optimism, bonding, attachment), and emotional states (positive emotions, compassion) can modulate cardiac vagal responses. Thus, higher resting vagal tone is suggested to serve as an index of adaptive regulation and responsiveness to the social environment.

The vast majority of studies examining peripheral physiological responses and emotion focus on one, some, or all of these responses identified above. To a lesser extent emotion researchers have examined responses like electrogastrography (EGG), respiration, or muscle tension. Some of the less commonly examined responses will be reviewed below.

Debate on ANS Specificity of Emotion

Even though peripheral physiological responses are widely integrated in emotion theories, there remain hotly debated theoretical perspectives on how best to conceive of emotions and consequent physiological responses. These arguments include whether there exists a specific identifiable physiological pattern that underlies distinct, "basic" emotions; if physiological patterning maps onto the more dimensional aspects of emotion, like approach–avoid tendencies and positive–negative valence; if subtypes of discrete emotions have patterned physiology; and whether contexts trigger core psychological states (i.e., "ingredients") that engender physiological reactions that are then labeled with emotion words (e.g., Barrett, 2006; Cacioppo, Berntson, Larsen, Poehlmann, & Ito, 2000; Kreibig, 2010; Levenson, 2014; Quigley & Barrett, 2014).

One of the enduring perspectives argues that "basic emotions" have a specific patterning of physiological responses that differentiates anger, fear, disgust, sadness, and happiness (e.g., Ekman, Levenson, & Friesen, 1983). The strong version of this argument suggests that patterned physiological responses related to the experience of discrete emotions occur across human and nonhuman animals, persists across the lifespan, and are unmodified by context (Ekman, 1993). Over the past few decades, much has been written in support of and against this strong version of autonomic specificity of emotions (see Lang, 2014; Levenson, 2014; Norman, Berntson, & Cacioppo, 2014, for recent discussions).

Evidence in favor of the strong view of autonomic specificity of emotions comes from cross-cultural studies and literature reviews (e.g., Levenson, 2003). For example, Levenson (1992) and colleagues traveled to West Sumatra, a large island in Indonesia, and measured a panel of physiological responses from the Minangkabau during the "directed facial action" task. The task requires the movement of facial muscles to create a configuration tied to a discrete emotion while seven peripheral physiological responses were obtained: HR, finger transit time, finger temperature and SC, finger amplitude, respiration period, and respiration depth. They also obtained measures from a U.S. sample using the same paradigm. Although the mean responses for HR, finger temperature, and finger pulse transit time were greater in the U.S. sample than the Minangkabau for all five emotions examined, the patterning of the responses were similar—for example, HR and finger temperature were higher during experiences of anger compared with disgust. The authors concluded that the two cultures "evidenced patterns of emotion-specific ANS activity that were similar," though they followed this with the point that these data did "not [establish] universality" (p. 983).

More recently, Kreibig (2010) identified 134 studies utilizing ANS measures and concluded that there was "considerable ANS response specificity in emotion when considering subtypes of distinct emotions" (p. 394) but also pointed to the need to incorporate ANS measures beyond ones that are the easiest to obtain (e.g., HR and SC). Echoing this point, Levenson identified rarely studied physiological responses in emotion research that might be more reliably related to emotions such as visible changes in coloration, moisture and secretion, protrusions, and appearance of eyes, which are all ANS mediated (Levenson, 2003, 2014). In sum, claims that specific emotions show ANS patterning come from (1) cross-cultural research showing similar patterned responses to basic emotions, and (2) narrative reviews supporting similar directional changes in physiology as a function of the emotion experienced. Finally, it may be the case that emotion psychophysiologists have simply fallen prey to focusing on responses that are the easiest to measure (Levenson, 2003)—akin to looking for lost keys under the light, rather than where they were dropped.

Evidence against the strong view of patterned physiological responses mapping onto discrete emotions comes from meta-analytic approaches that suggest that physiological patterning might relate to more basic *ingredients* of emotions (e.g., Barrett, 2006). For example, in the meta-analyses that appeared in two editions of the *Handbook of Emotion* (Cacioppo, Berntson, et al., 2000; Larsen et al., 2008), the authors concluded that motivational tendencies embedded within emotional states show some consistent ANS patterning. Specifically, approach-oriented emotional states in which there is an expectation for the need to mobilize energy are more likely to activate the SNS than emotional states in which there is no expectation of energy reserves. This is consistent with the biopsychosocial model of challenge and threat, which relies on cardiovascular reactivity to differentiate general *approach* (or challenge) orientation from *avoidance* (or threat) orientation (Blascovich & Mendes, 2010; Mendes & Park, 2014). Also aligned with this perspective is the overlap between fear and defensive/threat responding. LeDoux's (2014) animal work on how the brain detects threats and the consequent identification of neural "fear systems" was called "a mistake that has led to much confusion" by LeDoux himself (p. 2871). Instead, LeDoux argues that animal research shows reflexive motivational responses linked to threat detection more akin to defensive responding than "fear" as an emotional state.

In a more recent meta-analysis of over 300 articles neither traditional meta-analytic techniques nor multivariate pattern classification revealed consistent evidence for autonomic signatures of discrete emotions (Siegel et al., 2016). Based on their results, the authors made two observations about autonomic patterning. First, that there was pervasive variability in autonomic responses during instances of discrete emotions and second, that autonomic patterning was tied to experimental context in which it was induced, though the authors acknowledged that the extant literature was biased in such a way that context and emotion were often confounded. These meta-analytic findings are consistent with the perspective that the *context* in which emotions are examined can alter the physiological responses more than the specific emotion experienced (Lang, Bradley, & Cuthbert, 1997).

Underscoring the heterogeneity of physiological responses that has been observed when examining discrete emotions, some studies have shown different patterns of physiological responses to presumably the same emotion category. Shenhav and Mendes (2014) examined gastrointestinal, SNS, and PNS changes during different types of disgust experiences. Participants were randomly assigned to watch one of three different collections of videos: one condition showed individuals suffering painful injuries and accidents in which legs and arms were contorted beyond natural mobility, but no breaking of the body envelope occurred (e.g., no spilling of bodily fluids or blood); a second condition showed individuals with breaking of the body envelope with emissions of blood, puss, and vomit, and people consuming disgusting things; the third collection consisted of neutral stimuli, landscapes, landmarks, animals, and people in rural and urban areas. Participants in the first two conditions labeled the emotion they were feeling as "disgust" more than any other emotion label provided and showed greater activation of the levator labii (i.e., the muscle region surrounding the nose previously linked to *disgust*) relative to participants viewing neutral stimuli. However, participants watching breaking of the body envelope videos showed decreases in gastrointestinal activity and HR acceleration, whereas viewing painful injuries was associated with no changes in gastrointestinal responses, HR deceleration, and HRV increases. Thus two instantiations of the same emotion, disgust, using the same medium (watching videos) produced similar self-reported and facial expressions, but different physiological patterning of the SNS, PNS, and the enteric nervous system. Together these perspectives suggest greater variability in physiological patterns within the same emotion category, and provide support for a perspective on the "ingredients" of emotions or core motivational properties more likely to share similar physiological patterning—with body envelope breakage engendering more avoidance responses and others' pain experiences engendering more approach-oriented responses (Barrett, 2006; Mendes & Park, 2014).

Emotion researchers often ask "What type of data would be needed to resolve the debate of ANS-specificity of emotional states?" Researchers have suggested organization of peripheral responding along evolved neural circuitry might provide a stronger basis for examining emotion–physiology relations (Lang, 2014). Other researchers have noted the paucity of work examining ANS-mediated changes in bodily expressions that might be more closely tied to emotion experiences that manifest in observable bodily changes. For example, responses like piloerections (goosebumps), blushing, sweating, salivating, tearing, and bulging or twinkling eyes (Levenson, 2014), might reveal distinctions across discrete emotions not previously observed with the typically examined ANS responses, like HR and SCR. Still others have urged researchers to take seriously the social and cultural context, individual differences, and developmental factors that alter how emotions are manifested in the body (Barrett, 2006; Mendes, 2010; Mendes & Park, 2014). Whether any of these approaches resolve this debate remains to be seen, but it is likely that most emotion physiologists would agree that multiple measures—which are not dually regulated—and attention to temporal, contextual, and developmental factors are more likely to lead to better insight into the nature of emotion–physiology relations.

Effects of Emotion on Peripheral Psychophysiology

Previous articles and chapters have reviewed the literature examining physiological responses stemming from emotion states (e.g., Cacioppo, Berntson, et al., 2000; Larsen et al., 2008; Kreibig, 2010). To provide added value here, I use a different organizing principle than what is typically used—where the organizing feature focuses at the level of the emotion category. Instead, the review here is organized by physiological systems. The intention is to show how easy it is to overinfer emotion states as having a distinct physiological signature if the organizing principle is at the level of the specific emotion. Instead, if the organizational structure is sorted by physiological responses, it becomes apparent how multiple mental states—not just emotional states, but also stress, cognition, and motivation—can trigger the same physiological response.

Sympathetic Nervous System

SNS increases have been linked to a variety of emotional states, including ones that differ in valence, and other mental states including effort, motivation, cognition, salience, and stress. Changes in SNS can be assessed in a variety of ways with the most common measures being SC, HR/interbeat interval, pulse transit time, and PEP. These aforementioned responses are not perfect proxies for one another, with each one characterized by different underlying physiological processes (e.g., SC increases are innervated by acetylcholine, whereas cardiac increases by epinephrine). These responses also differ in the extent to which they are dually innervated by the SNS and PNS versus solely influenced by SNS. PEP, for example, is a chronotropic measure based on the time from the left ventricle contracting to the opening of the aortic valve. As such, it is one of the few nondually innervated measures representing solely SNS activation. However, measurement of PEP, most typically assessed using impedance cardiography, tends to be more difficult to obtain than other responses like SC or electrocardiography, and is more costly and requires considerable expertise.

HR and SC changes are the most commonly used peripheral measures in emotion research. As described earlier it is not surprising that these measures are ubiquitous given these responses are sensitive to a variety of internal and external information, and have a predictable, short-lived response that mirrors common emotional reactions. Emotions as varied as fear, amusement, anger, sadness, and disgust reliably bring about HR and SC changes (Kreibig, 2010; Larsen et al., 2008), but so do mental states like effort (Wright & Kirby, 2001), acute stress (Dickerson & Kemeny, 2004; Fredrickson & Matthews, 1990; Jacobs Friedman, Parker, Tofler, Jimenez, et al., 1994), mind wandering (Smallwood, O'Connor, Sudbery, & Obonsawin, 2007), active coping (Obrist, 1976), attention (Pribram & McGuinness, 1975), and rumination (Brosschot, Gerin, & Thayer, 2006; see Figure 9.1). Because these measures are sensitive to many mental states, it is best to conceive of these responses as primarily indicating larger categories of mental states such as mental demand, saliency, general arousal, or effort (Dawson, Schell, & Filion, 2000). This leaves emotion researchers in a difficult position because if the hypothesis is, for example, that an HR response is larger in one discrete emotion than a different emotion, the onus is on the researcher to equate the intensity of the emotion experiences from the different contexts used to induce the emotion. That is, if one wanted to compare HR responses in fear to anger, one would have to resolve the problem of equating the intensity of the emotional stimuli. Would the fear

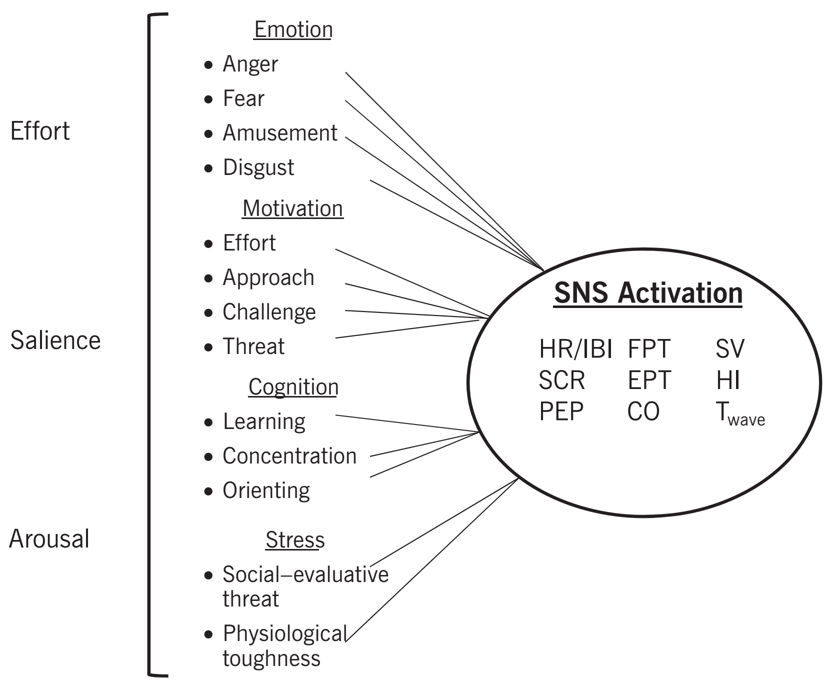

FIGURE 9.1. Sympathetic nervous system (SNS) activation associated with multiple mental states: emotional, motivational, cognitive, and acute stress. HR: heart rate; IBI: interbeat interval; FPT: finger pulse transit time; SV: stroke volume; SCR: skin conductance response; EPT: ear pulse transit time; HI: heather index; PEP: preejection period; CO: cardiac output; Twave: amplitude of T segment.

of a spider presented to someone with arachnophobia be as intense as a derogatory racist insult leveled at a marginalized minority? Because the variety of contexts that engender emotions varies greatly and those contexts differ in many ways, the question of which emotion elicits greater HR or SC can be a frustrating and nonfruitful endeavor.

Does moving to a measure of SNS that is solely innervated solve this problem? Changes in PEP (shorter PEP indicates greater SNS activation) have been observed during anger inductions (Herrald & Tomaka, 2002; Mauss, Cook, Cheng, & Gross, 2007; Mendes, Major, McCoy, & Blascovich, 2008) relative to emotions like shame or motivational states like threat. Though PEP decreases have also been associated with emotions like joy, disgust, and embarrassment (Kreibig, 2010). Considering other mental states, PEP decreases are associated with active coping (Obrist, 1976), and motivational states of threat *and* challenge (Blascovich & Mendes, 2010; Mendes, 2009; Seery, 2013). Much less work includes measurements obtained from impedance cardiography so it is unclear whether this type of measurement will reveal more emotion specificity than measures that are dually innervated (see Norman et al., 2014, for a discussion on why these "purer" measures might reveal more reliable associations).

Though I have treated these SNS measures as separate entities, it is not uncommon to combine these measures to form a composite index (Cole et al., 2001; Murphy, Steele, & Gross, 2007; Roberts, Levenson, & Gross, 2008). The value of doing so is to optimize the common signal across measures and minimize the noise inherent in each measure. On the one hand, this approach can be useful because it might reduce *researcher degrees of freedom* that might be exploited if one collected many measures and then reported just the one(s) that was significant (Simmons, Nelson, & Simonsohn, 2011). On the negative side of the ledger many of the measures have distinct underlying physiological processes, and by combining the measures we might end up learning less about the underlying physiological responses. Composite measures also make it difficult to conduct meaningful meta-analyses since there are not agreed-upon standards of what determines the composite measure.

Parasympathetic Nervous System

There are several measures of the PNS that can be reliably obtained using fairly inexpensive technology and without a lot of experimenter or participant burden (see Allen, 2002). One of the most common measures of PNS used by emotion researchers is high-frequency heart rate variability (HF/HRV), also commonly referred to as respiratory sinus arrhythmia (RSA). It is not surprising that emotion researchers rely on RSA given its putative links to relevant affective states like attachment and social engagement. Cardiac vagal tone (or resting HRV) has been associated with dispositional emotional styles (Demaree & Everhart, 2004; Oveis et al., 2009; Sloan et al., 2001). For example, individuals with greater hostile tendencies have lower cardiac vagal tone at baseline, during an emotional induction task, and at recovery than those lower in hostility (Demaree & Everhart, 2004; Sloan et al., 2001). On the brighter side, Oveis and colleagues (2009) found that those higher in optimism had higher vagal tone. Accumulating evidence suggests that vagal tone might be a reasonable physiological response to index general positive and negative affect with the caveat that particularly high levels of vagal tone might be detrimental; Kogan and colleagues (2014) observed a quadratic relationship between cardiac vagal activity and prosocial behavior such that extremely high levels of vagal tone were associated with fewer prosocial emotions and traits.

A variety of emotions have been associated with HRV decreases and increases that show some valence differences: negative emotions are more likely linked to decreases in HRV, whereas positive emotions might be linked with increases in HRV (Figure 9.2). In support of a valence interpretation of HRV, in a study examining the benefits of implicit goal setting, students were interviewed about their grades while HRV was obtained. Those who exaggerated their obtained grade point average (GPA) during the interview subsequently earned a higher GPA in a later semester. Critical HRV changes mediated the relationship between exaggeration and improvement such that the greater the HRV decreases the *less* students improved and this effect was corroborated by behavioral coding supporting the idea that participants with greater HRV decreases appeared *more* anxious during the interview (Gramzow, Willard, & Mendes, 2008). Evidence showing that HRV increases can be linked with positive outcomes include a recent study that showed that induced compassion, compared with other positive emotion inductions (like pride or inspiration), was associated with higher levels of HRV (Stellar, Cohen, Oveis, & Keltner, 2015). But again, the directional HRV effects associated with valence is far from invariant. For ex-

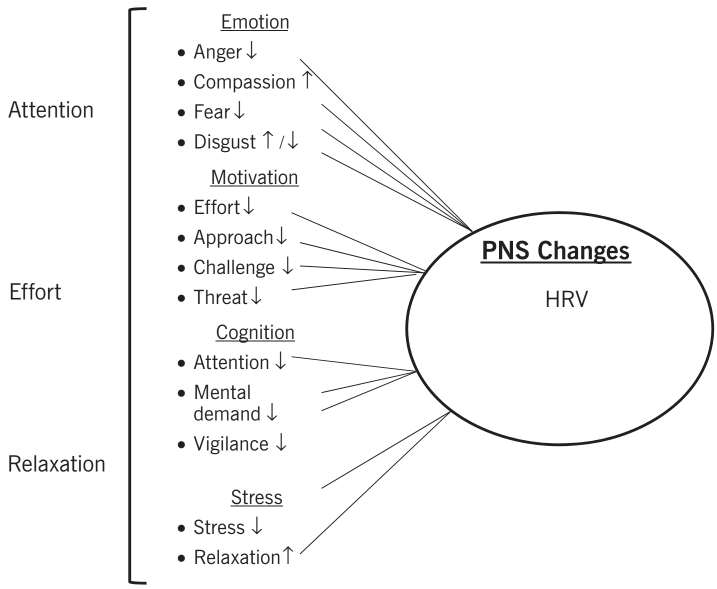

FIGURE 9.2. Parasympathetic nervous system (PNS) changes are associated with multiple mental states: emotional, motivational, cognitive, and acute stress. Arrows indicate the direction of the PNS activation. HRV: heart rate variability.

ample, in the Shenhav and Mendes (2014) study looking at different types of disgust, the condition in which participants watched videos of individuals suffering injuries and experiencing twisted limbs was associated with an *increase* in HRV relative to those watching videos with body envelope breakage. Interestingly, there are commonalities in the stimuli across the "compassion" study and the "disgust" study. In the Stellar et al. (2015) paper, the stimuli included photos of starving children, homeless individuals, and injured animals (Study 2), which shares many features with the disgust condition from Shenhav and Mendes (2014), which used stimuli of people also suffering and potentially experiencing grave and unfortunate outcomes like falling off buildings and extreme sports accidents. Thus HRV reactivity might be associated with fundamental features of the emotion experience that are not best described by the emotion categories (disgust, compassion, anxiety) but instead by interest, attention, and motivational states, like approach and avoid.

Like SNS activation, PNS changes have been linked to mental states that are viewed as part of the stress response or are more cognitive or motivational. Indeed, cognitive psychophysiologists use HRV decreases to index attention and mental effort (Tattersall & Hockey, 1995), and Porges (e.g., 2007) uses the example of target shooting as a reliable task that is associated with HRV decreases. In one study relying on this interpretation, Kassam, Koslov, and Mendes (2009) examined HRV decreases during a judgment and decision-making task and found that greater HRV decreases were associated with more accurate performance, specifically, more accurate responding on an anchoring and adjustment task. Following this logic, HRV on average decreases reliably during a visual tracking task (Cavanagh & Alvarez, 2005), and individual differences in the amount of HRV decreases predicts social perception accuracy and social sensitivity (Muhtadie, Koslov, Akinola, & Mendes, 2015).

Some studies have used emotional and cognitive interpretations to explain the same effect. In a stereotype threat study, Croizet et al. (2004) examined changes in HRV and found that participants primed with threatening stereotypes of their group showed decreases in HRV during a test of "intellectual diagnosticity" and poorer performance than those in the nonstereotyped threat group, and the greater the decrease in HRV, the worse participants performed on the test. However, in the nonstereotyped group, HRV also decreased during the "intellectual test" but the greater the decrease in HRV, the *better* participants performed on the test (though this path was short of significance), which was interpreted as indicated more effort. This work underscores how presumably different mental states (distress compared with mental effort) are associated with a similar physiological response (decrease in HRV) but can have different influences on behavior and performance.

Hemodynamic Responses

BP and precursors of BP, like total peripheral resistance (TPR), have been used by health psychologists for decades given their putative role in disease etiology like essential hypertension and cardiovascular disease. Given this link, BP is probably more closely identified with acute *stress* than emotional states. Hemodynamic changes are slower to respond than SNS activation and can be more challenging to measure continuously, which might also prevent emotion researchers from including these measures in their protocols (Mendes, 2009). Even with less accumulated evidence, reviews report increased BP across a variety of emotions and not necessarily tied to only negative emotional states—such as anger and fear—but also happiness and amusement (Kreibig, 2010; Siegel et al., 2016).

Research stemming from motivational theories often examines changes in BP. Wright and colleagues offer their effort mobilization theory, which relies on BP changes (typically systolic blood pressure [SBP]) and HR increases to index motivational effort (e.g., Wright & Kirby, 2001; Wright et al., 2007). In this perspective, SBP increases linearly with effort, which is consistent with the broader interpretation of SNS activation. Offering a nuanced perspective of motivational states is the *challenge and threat* theory (Blascovich & Tomaka, 1996; Blascovich & Mendes, 2010), which proposes that in active, goal-relevant contexts, appraisals of demands and resources interact to produce either general approach motivation (challenge), or avoidance orientation (threat). One of the physiological changes that best differentiates these psychological states is TPR. In threat states TPR increases, which represents a tightening of the arterioles so blood travel to peripheral sites is impaired, whereas challenge states are associated with increased blood flow to peripheral sites (Mendes, 2009).

In the broader stress literature, there tends to be little nuance in terms of what increases in BP indicates at a psychological level, and instead the broadest, catchall label "stress" is applied to increased BP responses (e.g., Matthews, Woodall, & Allen, 1993; Guyll, Matthews, & Bromberger, 2001). If emotion research can be characterized for forcing too many distinctions between discrete/specific emotions (i.e., *splitting*), stress research suffers from the opposite error of collapsing across possibly distinct mental states (i.e., *lumping*). The differences between emotion and stress research is most obvious when comparing experimental protocols using many of the measures reviewed here from papers claiming to be studying *stress* compared with those studying *emotion*. In many cases the paradigms are similar, even if the interpretations of the mental states are different, likely leading to the common expression "Stress is what is studied in medical schools; emotion is what is studied in psychology departments."

Moderators of the Emotion–Physiology Link

The previous sections may present what seems like an unwieldy literature on ANS responses to emotional states, but a different way to interpret these data is to consider the moderators that may reliably explain the variance in physiological responding across different studies. Thus far, the review of physiological responses associated with emotional states show that these relations are far from invariant. Adopting an approach that relaxes strong essentialist constraints provides a view of emotion that is flexible in terms of how emotions states are manifested in the brain and body. Attending to these moderators may be as important, or even more important, than the emotion category itself. Here, I outline key moderators that can alter the association between emotion and its physiological concomitants. Specifically, moderators such as context; including environment and bodily states (positioning of the body); cognitive states like labeling; developmental factors; and sociocultural factors can affect how emotions are manifested in the body. These factors can influence emotional experience, physiological responses to emotion, and the consequent behavior and feeling states that occur, which underscores the perspective that the emotion–physiology link is flexible and can be altered by top-down *and* bottom-up influences.

Context

Psychological science is replete with examples of how subtle features in the environment or minor tweaks of perspective can alter an emotional state. From holding a pen with one's teeth versus lips leading to more humorous reactions to comic strips (Strack, Martin, & Stepper, 1998) to clutching a warm cup of coffee influencing judgments of others' endearing personalities (Williams & Bargh, 2008), there are many demonstrations that bottom-up influences can alter emotion states, often without conscious awareness.

Bottom-up influences that directly affect the body and/or change the interpretation of the event can alter physiological responses of emotional states. An extensive body of nonhuman animal research work has explored "defensive" responses using rats that were classically conditioned to experience "fear" using acoustic responses and shocks. In one study, Iwata and LeDoux (1988) placed rats in either a cage where they were unrestrained, which allowed free movement, or restrained, which forced immobility. When exposed to an aversive signal, rats that were restrained had a different profile of physiological responses than rats that were unrestrained. Specifically, rats that were unrestrained showed greater HR acceleration relative to restrained rats. This study elegantly demonstrates the influence of context in modulating physiological outcomes to the (presumably) same emotion/affective state. If "fear-conditioned" rats have different physiological responses based on the *context* rather than the specific emotional state, then it is difficult to argue that fear invariably leads to a predictable physiological response. Instead, this finding shows that the context in which an emotion or affective state is experienced can shape the physiological pattern. One interpretation is that when rats' behavioral options are interpreted in terms of their potential to escape or not, the physiological responses provide functional support. When escape is possible, an increase in cardiac responses would allow for more oxygenated blood to innervate peripheral muscles, whereas when no escape is possible a reduction in sympathetic responses facilitates freezing and, in the case of a predator attack, the lower SNS reaction would reduce blood loss if attacked.

Context and body positioning interact in humans as well. In one study using electroencephalographic (EEG) responses, participants were seated either upright or supine while they experienced insults from a confederate, intended to engender an anger state (Harmon-Jones & Peterson, 2009). Those who were upright showed a shift in left-frontal cortical activation that occurs during anger and general *approach-oriented* states, whereas those who were supine did not show a shift in left-frontal cortical activity. Self-reported anger *did not differ* by body position, underscoring that physiological changes are often subtle and may be below conscious awareness. Importantly, like Iwata and LeDoux's (1998) restrained rats, putatively the same emotional state experienced in different contexts—in this example, in different body positions—have a different profile of physiological responses. Because anger is typically conceived as an approach-oriented emotion (Carver & Harmon-Jones, 2009), the conclusion was that an incongruent body position, leaning back when feeling angry, blunts a physiological response that co-occurs with the emotional state.

We recently extended this question by exploring if a body position could *potentiate* an affective state and, as a consequence, influence moral judgments. In a recent study, we examined whether manipulated body positions would interact with experienced affective states to influence moral judgments (Park & Mendes, 2016). Participants were randomly assigned to experience anger or shame and were orthogonally assigned to one of three body positions: leaning forward, leaning away, and upright/control. When participants were induced to experience anger and were in an approach (leaning forward) body position, they were more likely to endorse utilitarian judgments—pushing a person out of a sinking lifeboat to save more lives. Similar to the EEG study above, this study demonstrates that emotional states are malleable and can be altered by body positions.

Cognitive Factors

How one identifies or cognitively interprets an emotion experience provides insight into how top-down influences shape emotion–physiology relations. Self-disclosure or expressive writing has long been suggested to be associated with better health, conceivably due to its ability to make sense of a traumatic event by reducing negative cognitive processes like rumination and preservative thinking (Frattaroli, 2006; Pennebaker, 1997). Following this line of reasoning, *labeling* experienced emotions has been linked to reduced amygdala responding to frightening or aversive stimuli (Lieberman et al., 2007). However, if labeling or disclosure occurs soon after the event, it might cement associations that bond the aversive label with the event. For example, Seery and colleagues (2008) used a nationally representative sample (more than 2,000 respondents) and queried them about their feelings and thoughts regarding September 11, 2001, within 24 hours of the attacks, and then followed them for several years to assess their physical and mental health trajectories (Seery et al., 2008). Those who expressed their thoughts and feeling immediately after the attacks had *worse* health outcomes than those who did not. Thus, reflection and cognitive activity around emotions may create more maladaptive binding of the cognitive components of the emotion and the downstream consequences.

To test the idea that immediate reporting of an emotional experience could change a subsequent physiological response, Kassam and Mendes (2013) randomly assigned participants to an emotion task designed to induce either external negative emotions (anger) or internal negative emotions (shame) and measured cardiovascular reactivity throughout the task (specifically, PEP, cardiac output, and total peripheral resistance). In addition to the emotion manipulation, participants were assigned to either a *reporting* condition or *no-reporting* condition. Quite simply, this manipulation consisted of participants in the reporting condition to self-report their experienced emotion throughout the study. Indeed, this condition mimicked most lab-based emotion studies that rely on self-reported emotions as the primary outcome variable. In contrast, the no-reporting condition did not have participants report on their emotions at any time during the study, and instead used self-reports of technology use as the instruments replacing self-reported emotions. If the act of self-reporting on an emotion state changes the experience of an emotion, then the physiological response might differ between the reporting and no-reporting conditions. Consistent with this prediction, emotion reporting changed physiological reactivity, but only when participants were assigned to the *anger* induction. When reporting on emotions and assigned to the anger induction, participants on average showed greater hemodynamic changes—increased peripheral resistance/increased BP—whereas participants who did not report on their emotional state showed greater cardiac increases and lower hemodynamic responses. Thus, the simple act of reporting on an emotional state changed the pattern of physiological responses even though the emotional induction did not differ. In contrast, among participants in the shame condition, reporting or not on emotional states did not differentially influence physiological reactions—shame was associated with increased cardiac reactivity and increased vascular resistance regardless of the reporting condition. The conclusion of this work was that self-conscious emotions, like shame, are not modified by deliberate and conscious appraisal of the emotional state, but emotions that might be highly contextualized, like anger, might be more modifiable by conscious processes.

Developmental Factors

Much of modern psychophysiological research assumes reliable mind–body connections—changes in emotional states influence bodily responses and the biological milieu can shape experienced emotions. However, connections between mental states and physiological changes are not static across the life course; at different developmental periods processes like *interoception*, *proprioception*, and *reactivity* can alter how emotions are experienced in the body.

As we age cognitive declines such as deterioration in short-term memory, reaction times, and attention occur even in the absence of neurological diseases (e.g., Levy, 1994). In the body, loss of muscle mass, deficiencies of growth hormones, hardening of the vasculature, and blunted activation reduces the flexibility of responding to different environmental demands (e.g., Epel, Burke, & Wolkowitz, 2007; Matthews, 2005). These bodily changes can alter how emotions are experienced. Most critically for understanding the role of the ANS in emotions is that aging bodies have greater difficulty mounting larger SNS increases, which may alter the emotional experience.

Consider the roles of proprioception and interoception in emotion experience and across the lifespan. Proprioception, the awareness of *external* body position during static and dynamic movement, and interoception, the awareness of *internal* bodily changes, both decline with older adulthood. Khalsa and colleagues (2009) examined interoception using a heartbeat detection paradigm with participants ranging in age from 22 to 63; older subjects showed poorer detection of their heart beats than younger and middle-age adults, and the overall bivariate correlation between age and accurate heart beat detection across two time points was approximately $r = -.47$. Similarly, proprioceptive impairments with age occur along varied dimensions of static and dynamic body positions (see Goble et al., 2009, for a review).

Declines in interoception and proprioception are not the only physiological changes that occur in aging that is relevant to emotional states. As people age there is a degrading and loss of flexibility of key physiological systems, like the SNS. For example, Levenson and colleagues found lower HR responses for anger, fear, and sadness in older adults compared with younger adults during a directed facial action task. In some cases younger adults had twice as large SNS increases as older adults (a finding that mirrors physical exercise).

Importantly, in research with older adults, high arousal emotions, like anger, did not engender increases in skin temperature that has been observed in younger adults (Levenson et al., 1991). Changes in the flexibility of the vasculature especially in the peripheral regions—arms and hands, legs and feet—are typically affected by neuropathy that occurs with aging and the extremities tend to be affected first. The lack of skin temperature increase during anger is especially interesting given that anger is characterized as having an approach orientation (Carver & Harmon-Jones, 2009) and has been associated with greater dilation of the arterioles allowing more blood to get to the effector muscles and periphery, which is one of the likely physiological changes that increases skin temperature during anger (Mendes et al., 2008). However, it is important to note that the flexibility of the vasculature is compromised in an asymmetrical manner with age—vessels can still constrict easily but are harder to dilate. Therefore, emotional states that have approach functions may be compromised before states of emotions with withdrawal or avoidance feature, which might become the default response in older age.

Evidence of declines in sensory perception of the body with age and how this decline can interrupt the mind–body connection has been used as evidence of *maturational dualism*, a phenomenon that suggests that the bodily changes that often co-occur with the aging process can influence the experience of affective states in specific ways (Mendes, 2009). Thus, for older adults, intentions, motivations, and emotions may be experienced in the mind (and brain) but not be embodied in the same way as they are in younger adults. The weakening of the mind–body connection in older adulthood is primarily due to a loss of peripheral perception and blunted physiological reactivity and may blunt the ability to use internal states to guide decisions and behavior.

The consequence for this loss in mind–body connections with age has implications for emotion–physiology relations. In a study examining the somatic marker hypothesis, older adults used bodily information to a lesser extent than younger adults (Denburg, Tranel, & Bechara, 2005). In previous papers, the somatic marker hypothesis posited that bodily states outside of conscious awareness can influence behavior (Bechara, Damasio, Tranel, & Damasio, 1997). To test this hypothesis, participants (brain damaged and control) were presented with four decks of cards with various gains and losses associated with the cards. Two of the decks resulted in overall losses—large gains, but large losses as well—whereas the other two decks resulted in smaller gains, but also smaller losses. They found that as participants turned over cards from the various decks, changes in SC co-occurred with choices from the riskier decks. Importantly, these bodily changes *preceded* conscious reporting of which decks were risky by approximately 40 trials. Thus, the somatic marker hypothesis claims that bodily changes can indicate psychological or mental states prior to conscious reporting. In the original article, normal participants were compared with patients with ventral medial lesions. While normal participants consciously reported which decks were risky by about the 40th trial, patients with lesions were not able to learn this pattern.

In the extension of this earlier study, older adults (56–85 years old) did not show preferences for the advantageous decks (Denburg et al., 2005). When examining individual responses, the authors reported that among the younger group, 37 out of 40 participants eventually picked from the advantaged deck; among the older group, only 15 out of 40 showed this same "unimpaired" pattern. The remaining older participants either showed more preference for the disadvantaged deck or no preference. It is unclear whether older participants had blunted physiological responses during the task, which limited their ability to sense internal states, or the physiological response was intact and as strong as that experienced by younger participants, but the ability to sense the bodily changes—interoceptive awareness—was diminished (Khalsa et al., 2009), or there was some neural impairment.

An implication of the loss in mind–body connections is that older individuals might have to rely more on the external environment to determine their internal states, and possibly their emotional experience. This is consistent with Cartensen's socioemotional selectivity theory, which describes a positivity effect in older adults including a shifting away from negative stimuli toward more positive stimuli (Carstensen, 2006). Another implication is that older participants would be more susceptible to suggestions of an emotional state since they might have to rely more on their external world to provide information about their internal states. Although theory and evidence suggest that environmental cues can strongly influence affective states and meaning (Barrett, 2006), the loss of the ability to detect internal states might make older participants more susceptible to environmental cues. Future studies exploring these ideas would be imperative to determine boundary conditions of mind–body relations.

Sociocultural Factors

The shaping of emotion via cultural displays and norms is a vibrant area of inquiry and several thorough reviews highlight critical features in how emotion is experienced and displayed across cultures (see Shweder, Haidt, Horton, & Joseph, 2007). Among many things, culture provides rules of appropriate and inappropriate expression (i.e., display rules) and this cultural context can shape how the body responds to emotional experiences. For example, expressions of anger may have different meanings in different cultures. In a Western culture, anger expression might indicate blocked goals and be aligned with feelings of frustration (e.g., Berkowitz, 1989). In East Asian cultures there is a strong normative prohibition to expressions of anger and tends to be reserved for those in high status or dominant positions (Park, Kitayama, Markus, Coe, Miyamoto, et al., 2013). Recently, Kitayama and colleagues (2015) examined two large related datasets from the United States and from Japan to compare anger expression and consequent physiological and biological health responses with the idea that because anger has different cultural rules around its expression, bodily changes associated with anger expression in the United States would be more detrimental than anger expression in the Japanese context. Relying on more than 1,000 U.S. participants and more than 500 Japanese participants, Kitayama and colleagues found that the interaction between anger expression and culture was significant in predicting physiological outcomes. Specifically, anger expression among Japanese was associated with better biological health, including lower resting BP, whereas in the U.S. context anger expression was associated with poorer health and higher BP.

Summary

The goal of this chapter was to review literature and theory relating to emotion and peripheral psychophysiology. If one adopted an essentialist, natural origin perspective on emotion, emotions would be predictable across the lifespan, resistant to ephemeral changes in the environment, sturdy to differences in language and labeling, and not modifiable by something as subtle as body positioning. However, across different research programs employing multiple methods there is evidence that emotions are manifested in the body in ways that do not respect boundaries around discrete emotions. Taken together, these data suggest that any emotion category for which common language applies—such as *anger*, *sadness*, or *shame*—result in a wide variety of physiological and behavioral consequences. Importantly, one should not conclude that emotion labels at this level of understanding are useless, they certainly are not, but rather that there are critical cognitive, bodily, and developmental moderators that influence the link from emotion to physiological responses. Attending to these moderatos may be as important, or even more important, than the emotion category itself.

CHAPTER 10

Genetic Contributions to Affect and Emotion

Yuliya S. Nikolova, Elena Goetz Davis, and Ahmad R. Hariri

As reviewed elsewhere in this volume, the expression and processing of human emotion relies on highly conserved and increasingly well-characterized biological machinery, which has been incrementally revealed using a variety of experimental methodologies, most notably functional magnetic resonance imaging (fMRI). As our understanding of the shared biological machinery of human emotion has developed, so too has our appreciation of considerable interindividual variability in its operating parameters (Hamann & Canli, 2004). Importantly, this biological variability is reflected in the wide range of expressed dispositional affective traits such as neuroticism and extraversion, which are in turn predictive of psychopathology risk (Bienvenu, Hettema, Neale, Prescott, & Kendler, 2007; Kendler, Kuhn, & Prescott, 2004). These advances and insights have led to growing interest in deepening our mechanistic understanding of individual differences in emotional brain function and related risk for psychopathology. This interest has fueled the development of large-scale neuroimaging studies that afford necessary power to reliably map individual differences in the biological machinery of human emotion (Bogdan, Perlis, Fagerness, & Pizzagalli, 2010; Carre, Hyde, Neumann, Viding, & Hariri, 2013; Stein et al., 2012). Parallel advances in molecular genetics have allowed for the further mapping of this variability onto common genetic variation.

A focus on relatively well-characterized neural circuits and molecular signaling pathways has proven to be particularly useful in the endophenotypic dissection of complex human affective traits, which has in turn provided more tractable substrates for genetic association studies. Thus, drawing on extensive cross-species functional neuroanatomy research, a large portion of the work examining genetic contributions to human emotion has focused on behavioral and neural phenomena pertaining to reward and threat processing. These basic behavioral and neural phenomena are largely subserved by the increasingly well-understood corticostriatal (CSC) and corticolimbic circuitries (CLC), respectively, and represent crucial component processes of more complex human affective and personality traits. Among those, most prominently, various facets of extraversion and positive emotionality have been mapped onto relatively increased signaling within the CSC (Cohen, Young, Baek, Kessler, & Ranganath, 2005; Hermes, Hagemann, Naumann, & Walter, 2011). Similarly, various facets of neuroticism and negative emotionality, including trait anxiety, have been mapped onto relatively higher levels of threat-related reactivity of the CLC (Cunningham, Arbuckle, Jahn, Mowrer, & Abduljalil, 2011; Fakra et al., 2009).

Despite the well-characterized nature of these circuits, the task of mapping the variability in their functioning onto common genetic variation is immensely challenging and, unsurprisingly, as of now, incomplete. The seeming complexity of this endeavor stems from the hypothesized contribution of multiple, perhaps thousands, of genetic variants within a multitude of biological systems, alongside environmental factors, to shaping those circuits as well as the way they give rise to emotion. Nonetheless, initial efforts have yielded promising insights into the basis of individual differences in the functioning of those circuits, and thus also more broadly into the biology of human affect and emotion.

There are currently two major approaches to identifying genetic contributions to variability in these and other phenotypes: (1) the historically older candidate gene approach, which examines the impact of individual genetic variants or biological systems known to be implicated in a particular trait of interest based on prior research; and (2) genomewide association studies (GWAS), which, thanks to recent technological advances, have afforded the examination of variants occurring throughout the genome and their potential contribution to a particular trait without the prioritization of any particular pathway or variant.

Each of these approaches has distinct advantages and disadvantages in an empirical setting. The candidate gene approach is more biologically informed and can successfully be used to explain variability in neural traits of interest even when using relatively small experimental groups. It is, however, limited in its dependence on prior empirical and theoretical work, which may not always be complete or accurate. In addition, it is limited in its relative inability to capture genetic variability occurring across multiple genes and systems, which are likely to simultaneously contribute to the complex neural and psychological traits pertaining to human emotion more broadly, as well as the functioning of the CSC and CLC specifically.

The GWAS approach is better suited to assess polygenic contributions to traits of interest, especially across multiple biological systems. However, GWASs require larger experimental groups (on the order of thousands or tens of thousands of individuals) in order to ensure adequate power to detect significant effects in the context of the multiple statistical tests being conducted. Given the high cost of fMRI, the approach has only been applied in a very limited way to studying the functioning of the CSC and CLC (Ousdal et al., 2012; Stein et al., 2011). In addition, while results from GWAS analyses can serve as powerful hypothesis generators, they are frequently difficult to interpret biologically without mechanistic follow-up by more targeted psychological or neuroscientific investigations, which frequently bear a striking resemblance to candidate gene studies. Thus, ultimately, candidate gene studies and GWAS represent complementary approaches, which can inform and fuel each other.

The current chapter focuses on the candidate gene perspective, not only because it has been adopted by the majority of studies on the genetics of emotion and its underlying circuitry to date, but also because it represents an approach more proximal to the biology of the phenotypes of interest, and thus also a medium through which basic research from the fields of molecular genetics and complex *in vivo* psychology and neuroscience work can be bridged. The biological pathways considered here are largely deemed most representative as regulators of each system or circuit on the basis of the current literature. However, it should be noted that additional pathways not extensively reviewed here may be implicated in the regulation of these and other affect-related phenotypes, and that the reviewed pathways may in turn regulate other non-affect-specific phenotypes as well.

Rather than discussing genetic contributions to behaviorally assessed emotion and affect in humans, this chapter reviews the genetic variants that have been most reliably mapped onto differences in the functioning of the CSC and CLC. The first section discusses genetic contributions to reward-related ventral striatum (VS) reactivity, broadly implicated in positive emotion and impulsivity. Next, we discuss genetic contributions to threat-related amygdala reactivity, broadly implicated in anxiety, neuroticism, and negative affect. The third section focuses on genetic contributions to the cognitive control of emotion. While the chapter focuses on the candidate gene approach, at the ends of the first two sections we also briefly present ways in which this approach has been modified and extended in recent years to incorporate technological and conceptual advances and overcome some of its limitations. Consistent with these recent advances, we also briefly outline future directions for this approach at the end of the chapter.

Genetic Contributions to Reward Processing and Positive Emotion

Reward processing and motivation are crucial for the adaptive engagement in goal-directed behavior and represent a pivotal component of positive affect and emotionality. Imaging genetics studies of positive emotion and reward processing have typically focused on the reactivity of the VS, which serves as a neural hub within the CSC, as well as the neurotransmitter dopamine (DA), because of the central role it plays in regulating reward-related and motivational processing, particularly in the VS.

The blood-oxygenation-level-dependent (BOLD) fMRI signal recorded in the VS during reward processing paradigms is widely thought to reflect increases in phasic DA activity, occurring upon the receipt of unexpected primary rewards or in response to a conditioned stimulus previously paired with reward. Lending support to this notion, multimodal neuroimaging research combining positron emission tomography (PET) and BOLD fMRI has shown that the magnitude of the VS response to monetary reward directly correlates with the amount of DA released in the same region following pharmacological challenge (Buckholtz et al., 2010). Thus, functional polymorphisms within genes involved in regulating each individual step of DA synthesis, signaling, and synaptic clearance are apt to create individual variability in CSC reactivity and reward processing as well as positive emotion on the behavioral level. Several commonly studied functional genetic polymorphisms affecting CSC function by modulating various steps of the DA signaling cascade are reviewed below.

The Dopamine Transporter

The dopamine transporter (DAT), encoded by the gene *SLC6A3*, is a protein with a key role in regulating DA neurotransmission. DAT binds DA after its release into the synaptic cleft and facilitates reuptake of the neurotransmitter into the presynaptic neuron. Thus, DAT helps regulate the duration and intensity of postsynaptic responses to dopaminergic inputs as well as the available presynaptic pool of DA (via recycling). DAT is expressed predominantly in the striatum, including the VS, where it plays a crucial role in modulating dopaminergic inputs from the ventral tegmental area (VTA)—the major source of DA in the CSC (Lewis et al., 2001; Sesack, Hawrylak, Matus, Guido, & Levey, 1998; Wayment, Schenk, & Sorg, 2001).

A variable number tandem repeat (VNTR) polymorphism termed "DAT1" occurs within a regulatory region near *SLC6A3* and results in several different variants (i.e., alleles) of the gene. The alleles range in length and can have anywhere between three and 13 repeats of the same small stretch of DNA, with the 9- and 10-repeat alleles being most frequent in the majority of world populations studied (Doucette-Stamm, Blakely, Tian, Mockus, & Mao, 1995; Kang, Palmatier, & Kidd, 1999; Mitchell et al., 2000). Although not all studies have found an effect of the DAT1 genotype on DAT expression levels (Martinez et al., 2001; Mill, Asherson, Craig, & D'Souza, 2005), several studies have linked the 9-repeat allele to reduced DAT availability (Arinami, Gao, Hamaguchi, & Toru, 1997; Cheon, Ryu, Kim, & Cho, 2005; Heinz et al., 2000; VanNess, Owens, & Kilts, 2005). The presence of the 9-repeat allele would then presumably lead to reduced DAT function, less efficient DA reuptake, and, ultimately, heightened CSC reactivity through increased synaptic levels of DA. Consistent with this notion, individuals carrying at least one copy of the low-expressing 9-repeat allele have been shown to have increased VS reactivity to positive feedback in a number-guessing BOLD fMRI paradigm, relative to individuals homozygous for the 10-repeat allele (Forbes et al., 2009).

Dopamine Receptors

In addition to reuptake mechanisms, DA signaling is also critically dependent on the properties of DA receptors. There are two major classes of DA receptors: D_1-like receptors, which have primarily excitatory functions and include DA receptors D_1 and D_5; and D_2-like receptors, which inhibit DA signaling (via either pre- or postsynaptic mechanisms) and include DA receptors D_2, D_3, and D_4 (Beaulieu & Gainetdinov, 2011).

The D_1 and D_5 DA receptors are encoded by the genes *DRD1* and *DRD5*, respectively. Partially due to the simpler structure and relatively conserved nature of those genes, few association studies have investigated the effects of D_1-like receptor variants on neural function. The molecular, cellular, neural, and behavioral effects of common polymorphisms within the D_2-like family have been studied much more extensively. Thus, the rest of the current DA signaling overview focuses on this class of receptors.

DA D_2 receptors, encoded by the *DRD2* gene, are most densely expressed in the VS, where they are located both pre- and postsynaptically (Beaulieu & Gainetdinov, 2011). Consistent with the inhibitory effect of D_2 receptor signaling on DA neurotransmission, imaging genetics studies have linked polymorphisms resulting in relatively reduced *DRD2* expression to heightened VS reactivity. Specifically, the deletion (Del) allele of a 1-point insertion (Ins)/Del polymorphism (rs1799732) occurring within the 5′ UTR of *DRD2*, frequently termed "*DRD2*-141C Ins/Del," has been associated with up to 78% reduction in striatal *DRD2* expression *in vitro* (Arinami et al., 1997) and increased VS reactivity to positive feedback in a BOLD fMRI number-guessing paradigm (Forbes et al., 2009).

Another commonly studied *DRD2* polymorphic locus is the *DRD2* Taq1A (rs1800497), which is a single nucleotide polymorphism (SNP) located in the adjacent ankyrin repeat and kynase domain containing one (*ANKK1*) gene and probably affects *DRD2* function only indirectly. Its two alleles T (A1) and C (A2) have been linked to relatively decreased and increased D_2 receptor availability, respectively (Jonsson et al., 1999; Pohjalainen et al., 1998). However, the C allele has been associated with increased striatal glucose metabolism (Noble, Gottschalk, Fallon, Ritchie, & Wu, 1997) and reactivity to reward (Stice, Spoor, Bohon, & Small, 2008). This pattern may reflect a specific effect of the *DRD2* Taq1A polymorphism on postsynaptic D_2 receptors localized on inhibitory gamma-aminobutyric acid (GABA) interneurons, which modulate striatal function by in turn inhibiting GABAergic medium spiny neurons, which are the predominant neuronal type in the human striatum. Thus, the C allele may result in increased DA-mediated inhibition of GABAergic interneurons leading to disinhibition of medium spiny neurons and thus, ultimately, increased VS reactivity measured with fMRI.

The DA D_4 receptor, encoded by the *DRD4* gene, mediates postsynaptic inhibition of DA signaling. Unlike *DRD2*, however, *DRD4* exhibits relatively low expression in the striatum (Jaber, Robinson, Missale, & Caron, 1996) and the lowest expression levels in the human brain of all DA receptors (Beaulieu & Gainetdinov, 2011; Rondou, Haegeman, & Van Craenenbroeck, 2010). Nonetheless, preliminary data suggest that the D_4 receptor is expressed at low levels postsynaptically on striatal neurons, as well as presynaptically on glutamatergic afferents from the prefrontal cortex (PFC) to the striatum (Jaber et al., 1996; Missale, Nash, Robinson, Jaber, & Caron, 1998; Tarazi, Campbell, Yeghiayan, & Baldessarini, 1998). Thus, D_4 receptor stimulation can inhibit striatal function either directly or indirectly, via one or both of these independent mechanisms. Based on these localization data, genetic variants associated with higher levels of D_4 function are likely to result in greater DA-mediated inhibition of postsynaptic target neurons and reduced striatal reactivity.

A common VNTR within the coding region of *DRD4* results in alleles of different length (ranging from two to 11 repeats), associated with differential gene transcription and protein function (Asghari et al., 1995). Specifically, the 7-repeat allele has been linked to reduced D_4 receptor sensitivity and reduced postsynaptic inhibition (Asghari et al., 1995). Consistent with the inhibitory role of D_4 receptors on striatal DA, the 7-repeat allele has also been linked to higher VS reactivity to positive feedback (Forbes et al., 2009). Finally, in line with its putative neurochemical effects, the same allele has been associated with increased approach to reward on the behavioral level (Roussos, Giakoumaki, & Bitsios, 2010). Taken together, these findings demonstrate that, despite its relatively low expression levels in the striatum, *DRD4* may play an important role in regulating the reactivity of the CSC and its associated behaviors.

Other Variants

Additional polymorphisms implicated in the regulation of DA signaling in the VS and CSC include the catechol-O-methyltransferase (*COMT*) gene Val158Met (rs4680) SNP (Dreher, Kohn, Kolachana, Weinberger, & Berman, 2009; Yacubian et al., 2007), and the monoamine oxidase A (*MAOA*) rs12843268 SNP (Nymberg et al., 2013). Both of these likely exert their effects on DA signaling through modulating the rate and efficiency of DA enzymatic degradation. In addition, COMT Val158Met may play a role in the cognitive control of emotion, as reviewed in the section "Genetic Contributions to the Cognitive Control of Emotion." Variants that modulate DA signaling more distally have also been implicated in the regulation of VS signaling. Notable examples include the C385A (rs324420) SNP in the fatty amino acid hydroxylase gene (*FAAH*), involved in the enzymatic degradation of endogenous cannabinoid neuromodulators (Hariri et al., 2009), A118G (rs1799971) in the mu-opioid receptor (*OPRM1*; Ramchandani et al., 2011), as well as rs2513281 within the *GAL* gene encoding the hypothalamic neuropeptide galanin (Nikolova, Singhi, Drabant, & Hariri, 2013). The effects and properties of these and other variants (e.g., Ramchandani et al., 2011) found to modulate human CSC function are summarized in Table 10.1.

TABLE 10.1. Genetic Variants Associated with Differences in CSC Reactivity.

Pathway	Molecule	Function	Gene	Polymorphism	Effect on gene/protein function	Neural effect	Seminal report
Dopamine	Dopamine transporter	Synaptic reuptake	*SLC6A3*	3' UTR VNTR	9-repeat allele associated with reduced transcription	Increased VS reactivity in 9-repeat allele carriers	Forbes et al. (2009)
	D2 receptor	Pre- and postsynaptic signaling	*DRD2*	rs1799732	-141C Del allele associated with reduced gene expression	Increased VS reactivity in -141C Del allele carriers	Forbes et al. (2009)
	D4 receptor	Postsynaptic signaling	*DRD4*	3' UTR VNTR	7-repeat allele associated with reduced postsynaptic inhibition	Increased VS reactivity in 7-repeat allele carriers	Forbes et al. (2009)
	Catechol-O-methyltransferase	Synaptic degradation	*COMT*	Val158Met	158Met allele associated with reduced activity of COMT enzyme	Increased VS reactivity during reward anticipation in 158Met allele homozygotes	Yacubian et al. (2007)
Endocannabinoid	Fatty acid amide hydrolase	Enzymatic degradation	*FAAH*	rs324220	A allele associated with decreased degradation of anandamide	Decreased amygdala reactivity in A allele carriers	Hariri et al. (2009)
Galanin, dopamine	Galanin neuropeptide	Intercellular signaling; neuromodulator	*GAL*	GAL 5.1 haplotype: rs2513280, rs2513281	GG haplotype predicts greater GAL expression	Increased VS reactivity in GG haplotype homozygotes	Nikolova et al. (2013)
Opioid	Mu-opioid receptor	Pre- and postsynaptic signaling	*OPRM1*	rs1799971 (A118G)	Unknown	Increased VS response to alcohol in G allele carriers	Ramchandani et al. (2011)

Beyond the Candidate Gene Approach: Multilocus Strategies

Although most genetic studies of reward processing conducted to date and surveyed herein focus on single genes or polymorphisms, like other complex behavioral phenomena, reward processing is shaped by a multitude of genetic influences, which act in concert to create specific neural and, ultimately, behavioral phenotypes. While several studies have investigated interactions between two genetic loci and their effects on reward-related neural processes (Dreher et al., 2009; Yacubian et al., 2007), reward-related brain function is likely to be shaped by the simultaneous impact of many more genetic variants. In support of this notion, a recent study has demonstrated that a biologically founded genetic profile for dopamine signaling based on five of the polymorphic loci reviewed herein (*COMT* Val158Met, DAT1 40-bp VNTR, *DRD4* 48-bp VNTR, *DRD2* -141C Ins/Del, and *DRD2* Taq1A) explains nearly 11% of variability in VS reactivity, while none of the loci taken individually explains any VS reactivity variance, after appropriate correction for multiple testing (Nikolova, Ferrell, Manuck, & Hariri, 2011). This finding underscores the importance of taking the simultaneous impact of multiple loci into account when investigating the genetic correlates of complex neural and behavioral phenotypes. Similar profile scores can be compiled to include additional variants within and beyond the DA system to more extensively capture variability in reward-related neural function and any component of emotion and affect subserved by this circuitry.

Genetic Contributions to Threat Processing and Negative Emotion

As reviewed extensively in other chapters of this volume, the neural system, which plays a pivotal role in the detection and response to threat in the environment, is the brain's CLC. The CLC comprises a distributed network of cortical and subcortical (i.e., limbic) regions, within which the amygdala, a small structure in the anterior medial temporal lobe, serves as a circuit hub. The physiological changes orchestrated by the amygdala in response to both conditioned and unconditioned stimuli are primarily associated with increased vigilance and arousal and are neither directly equivalent to the conscious experience of fear, nor in fact sufficient to produce this affective state in humans (LeDoux, 2014) . Nonetheless, they are a necessary and indispensable part of the biological basis of fear and negative affect (Ochsner et al., 2004; Schaefer et al., 2002). Consistent with this notion, variability in the functioning of the amygdala has been associated with pathological, as well as normal-range, negative affective states and traits in humans (Etkin & Wager, 2007; Hariri, 2009).

While DA clearly plays a central role in reward processing and learning, there is not a single neurotransmitter molecule that plays a similar role in the context of threat processing and fear conditioning in the amygdala and the CLC. Instead, multiple systems and neuromodulators contribute to variability in the functioning of the circuit. Signaling within and by the amygdala relies primarily on the brain's major excitatory and inhibitory neurotransmitters glutamate and GABA, respectively. However, the relative sensitivity of the amygdala to glutamatergic and GABAergic inputs from additional nodes of the CLC can be modulated by monoaminergic projections originating in the brainstem.

Monoaminergic modulation of amygdala function is mediated by serotonin (5-hydroxytryptamine [5-HT]), DA, and norepinephrine (NE), which are synthesized and secreted by neurons residing in the dorsal raphe nucleus (DRN), VTA, and locus ceruleus (LC), respectively. Functional neuroanatomy research in animal models and human pharmacological challenge studies converge to suggest all three monoamines are involved in regulating the activity of the amygdala (Bigos et al., 2008; Hariri, Mattay, Tessitore, Fera, et al., 2002; Hurlemann et al., 2010; Sadikot & Parent, 1990). However, the modulator whose contribution appears most prominent is 5-HT (Sadikot & Parent, 1990). Thus, the vast majority of studies that have identified genetic markers of CLC function have focused on genes involved in the regulation of 5-HT signaling.

The Serotonin Transporter

The serotonin transporter (5-HTT) is a presynaptic transmembrane protein, which is instrumental in the reuptake of 5-HT following its release into the synaptic cleft. Similarly to DAT for DA, 5-HTT is an important regulator of both the duration and the intensity of the postsynaptic responses elicited by 5-HT signaling in the CLC. A common VNTR polymorphism occurs in the promoter region of the 5-HTT gene (*SLC6A4*). This polymorphism, referred to as the serotonin transporter-linked polymorphic region (5-HTTLPR), results in a short (S) and a long (L) allele of the gene, which have divergent functional properties. Critically, the S allele has been associated with reduced *SLC6A4* transcription and reduced capacity for 5-HT reuptake *in vitro* (Lesch et al., 1996). Consistent with these early findings, numerous imaging genetics studies have also linked the S allele to relatively heightened amygdala reactivity *in vivo* (Hariri, Mattay, Tessitore, Kolachana, et al., 2002; Munafo, Brown, & Hariri, 2008; Murphy et al., 2013). Notably, the latter finding constitutes the most widely replicated association in imaging genetics. The link between reduced 5-HT reuptake capacity and amygdala hyperresponsivity is also corroborated by studies demonstrating that threat-related amygdala response is potentiated in individuals with lower DRN 5-HTT binding (Rhodes, Murthy, Dresner, Selvaraj, Stavrakakis, et al., 2007) or following the acute administration of a selective serotonin reuptake inhibitor (SSRI; Bigos et al., 2008).

Consistent with animal studies demonstrating that stress results in local increases in amygdala 5-HT signaling (Amat, Matus-Amat, Watkins, & Maier, 1998), additional BOLD fMRI research in humans indicates that the relationship between 5-HT reuptake capacity and amygdala reactivity may be potentiated by environmental adversity. Specifically, carriers of the S allele show larger increases in amygdala reactivity under acute threat (Drabant et al., 2012), as well as stronger fear conditioning, particularly in the context of recently experienced stressful life events (Klucken et al., 2013). This synergistic effect of exposure to environmental challenge and genetically driven variability in 5-HT reuptake capacity is also consistent with extensive epidemiological evidence linking the S allele to increased vulnerability to major depressive disorder (MDD), particularly in the wake of life adversity (Caspi et al., 2003; Karg, Burmeister, Shedden, & Sen, 2011).

The 5-HT$_{1A}$ Receptor

The 5-HT$_{1A}$ receptor, encoded by the *HTR1A* gene, is another key element in the regulation of 5-HT signaling in the CLC. 5-HT$_{1A}$ receptors are found in DRN projection target areas, where they mediate postsynaptic inhibition, as well as on DRN neurons, where they function as autoreceptors mediating negative feedback inhibition of 5-HT release. Multimodal PET–fMRI imaging studies have shown that there is an inverse correlation between DRN 5-HT$_{1A}$ receptor binding and threat-related amygdala reactivity, consistent with a reduced capacity for autoreceptor regulation of 5-HT signaling in this region (Fisher et al., 2006).

A common functional SNP (rs6295) resulting in a C / G substitution, occurs in the promoter region of the human *HTR1A* gene. The G allele is associated with impaired transcriptional repression and consequently relatively increased levels of 5-HT$_{1A}$ receptor as well as enhanced capacity for autoreceptor-mediated negative feedback (Lemonde et al., 2003). Consistent with these *in vitro* findings, the same allele has been associated with relatively decreased threat-related amygdala reactivity *in vivo* as well as reduced levels of trait anxiety (Fakra et al., 2009).

Other Variants

Additional variants impacting 5-HT signaling through divergent biochemical mechanisms have also been associated with individual differences in amygdala reactivity. Those include the tryptophan hydroxylase 2 (*TPH2*) rs4570625 SNP (Brown et al., 2005; Canli, Congdon, Gutknecht, Constable, & Lesch, 2005), which likely modulates 5-HT synthesis; and the *MAOA* upstream VNTR (u-VNTR; Buckholtz et al., 2008), which impacts 5-HT enzymatic degradation. Additional genetic variants in systems more distally involved in the regulation of neurotransmission within the amygdala include the brain-derived neurotrophic factor (*BDNF*) rs6265 (Montag, Reuter, Newport, Elger, & Weber, 2008), and haplotypes in neuropeptide Y (*NPY*; Zhou, Xu, & Jiang, 2008), as well as rs1064448 within the adenylate cyclase 7 (*ADCY7*; Joeyen-Waldorf et al., 2012). In recent years, small genomewide association studies of amygdala reactivity (Brown et al., 2012; Ousdal et al., 2012) have identified additional candidates of unknown functionality, whose relevance has yet to be verified through replication in independent samples. A summary of variants found to modulate human CLC function (e.g., Bogdan, Williamson, & Hariri, 2012; Brown et al., 2005; Lohoff et al., 2014; Meyer-Lindenberg et al., 2006; White et al., 2012; Zhou et al., 2008) is provided in Table 10.2.

Beyond the Candidate Gene Approach: Multilocus Strategies and Epigenetic Effects on Threat Processing

As with VS reactivity, each individual polymorphic locus is likely to account for only a relatively small fraction of variability in amygdala reactivity. While no study to date has investigated the effects of a multilocus genetic profile for 5-HT signaling on amygdala reactivity, a profile score comprising 5-HTTLPR and variants in the 5-HT_{1A} and $_{2A}$ receptor genes has been found to moderate the effects of mood reactivity on attentional bias—a process likely mediated at least in part by differences in amygdala reactivity (Disner, McGeary, Wells, Ellis, & Beevers, 2014). Thus, multilocus genetic profiles reflecting 5-HT and other monoaminergic signaling are likely to enhance statistical power to account for genetically driven variability in CLC function.

While genetic factors are apt to account for a large proportion of the measurable variability in brain function, especially when cumulative effects across genes and systems are considered, they are nevertheless unlikely to account for all such variability for two interrelated reasons: (1) there are multiple intervening steps between the assembly of a DNA sequence and its expression as a functional protein, all of which are subject to intricate non-DNA-sequence-based regulation; and (2) environmental factors may moderate the effects on genetic variation on many behaviorally relevant neural phenotypes (Klucken et al., 2013). Epigenetic modifications of DNA and chromatin may help account for both sources of variability, as these modifications are not only involved in regulating gene expression without altering the basic DNA sequence, but are also heritable and subject to environmental modulation (Goldberg, Allis, & Bernstein, 2007). Thus, the study of the epigenetic landscape may yield much needed insight into the mechanisms that link genetic variation to complex phenotypes.

In strong support of this notion, it has recently been demonstrated that relatively high levels of methylation in the proximal promoter region of *SLC6A4* predict greater amygdala reactivity in two independent samples. Providing additional cues as to the molecular mechanisms underlying this effect, methylation in the same region was associated with reduced gene expression in postmortem amygdala tissue. Critically, all of these effects persist even after accounting for the 5-HTTLPR genotype (Nikolova et al., 2014).

These findings critically implicate epigenetic modifications in the regulation of brain function and suggest their effects may in fact override those of functional DNA-sequence-based variation. Thus, epigenetics should ideally be considered in all studies aiming to identify genetic influences on neural functioning, particularly in cases of suspected or established environmental moderation. With the increasing availability of methods for assaying the human epigenome in its entirety and reasonable, though far from perfect, convergence between methylation patterns in the brain and in peripheral tissues (Tylee, Kawaguchi, & Glatt, 2013), such considerations would hopefully become increasingly easy to meet.

Genetic Contributions to the Cognitive Control of Emotion

While the first two sections of this chapter focused primarily on genetic influences modulating bottom-up processes pertaining to emotion processing and reactivity, in this section we discuss genetic contributions to the top-down control of affect and emotion. Specifically, this section focuses on a common functional polymorphism that influences the efficiency of the PFC in responding to positive and negative stimuli in the environment, and thus has effects on emotional experience, reactions to stress, and vulnerability to psychopathology. Due to reciprocal interactions with subcortical systems, variation in this gene also indirectly impacts bottom-up signaling and can therefore impact the demand on prefrontal regulatory resources.

The relationship between prefrontal functioning and DA has been hypothesized to have the shape of an inverted-*U*, where peak PFC functioning occurs at intermediate levels of prefrontal DA availability and D_1 receptor activation (Goldman-Rakic, Muly, & Williams, 2000). Dopaminergic tone and signaling in the PFC is primarily regulated by the catabolic action of the COMT enzyme (Karoum, Chrapusta, & Egan, 1994; Lundstrom et al., 1995; Mannisto & Kaakkola, 1999). A common functional polymorphism in the gene that encodes COMT, referred to as *COMT* Val158Met or rs4680, affects the thermostability of the COMT enzyme and thus its functionality. Met/Met homozygotes have a 40% reduction in enzymatic activity compared with Val/Val homozygotes (Chen et al., 2004), and therefore, there is a relative increase in DA availability with an increasing number of Met alleles. At baseline, Met/Met homozygotes are hypothesized to have close to an optimal level of prefrontal DA and thus their cognitive functioning is at a peak (Mattay et al., 2003). Consistent with this theory, several studies have found cognitive advantages associated with the Met/Met genotype, including both performance indices and evidence of prefrontal efficiency (e.g., Blasi et al., 2005; Bruder et al., 2005; Egan et al., 2001; Farrell, Tunbridge, Braeutigam, & Harrison, 2012; Fossella et al., 2002; Goldberg et al., 2003; Green, Kraemer,

TABLE 10.2. Genetic Variants Associated in the Differences in CLC Reactivity

Pathway	Molecule	Function	Gene	Polymorphism	Effect on gene/protein function	Neural effect	Seminal report
Serotonin	Tryptophan hydroxylase 2	Serotonin biosynthesis	*TPH2*	rs4570625	Unknown	Increased amygdala reactivity in T allele carriers	Brown et al. (2005)
	Serotonin transporter	Synaptic reuptake	*SLC6A4*	5-HTTLPR	Short allele associated with decreased transcription	Increased amygdala reactivity in short allele carriers	Hariri et al. (2002)
	5-HT_{1A} autoreceptor	Negative feedback	*HTR1A*	rs6296	G allele associated with more efficient transcription	Increased amygdala reactivity in G allele homozygotes	Fakra et al. (2009)
	Monoamine oxidase A	Enzymatic degradation	*MAOA*	u-VNTR	3- and 5-repeat alleles associated with decreased transcription	Increased amygdala reactivity in 3- and 5-repeat allele carriers	Meyer-Lindenberg et al. (2006)
Neuropeptide Y	Neuropeptide Y	Intercellular signaling; neuromodulator	*NPY*	Haplotypes at rs17149106, rs3037354, rs16147, rs16139, rs5573, rs5574, rs16475	rs16147 in promoter region alters NPY expression *in vitro*	Increased amygdala reactivity in lower NPY expression diplotypes	Zhou et al. (2008)
Monoamines	Vesicular monoamine transporter	Presynaptic signaling	*VMAT1 SLC18A1*	rs1390938	Ile allele leads to increased monoamine transport into presynaptic vesicles	Increased amygdala reactivity in Ile allele carriers	Lohoff et al. (2014)

Endocannabinoid	Fatty acid amide hydrolase	Enzymatic degradation	*FAAH*	rs324220	A allele associated with decreased degradation of anandamide	Decreased amygdala reactivity in A allele carriers	Hariri et al. (2009)
Serotonin	Adenylate cyclase 7 enzyme	Intracellular signaling	*ADCY7*	rs1064448	Unknown	Increased amygdala reactivity in T allele carriers	Joeyen-Waldorf et al. (2012)
Glucocorticoid	FK506 binding protein 5	Transcriptional regulation of HPA axis	*FKBP5*	Haplotypes at rs7748266, rs1360780, rs9296158, rs3800373, rs9470080, rs9394309	Unknown	Increased amygdala reactivity in the context of emotional neglect in haplotypes with risk alleles	White et al. (2012)
	Mineralocorticoid receptor	HPA axis response onset regulation	*NR3C2*	rs5522	Val allele associated with decreased cortisol-related transactivation *in vitro*	Increased amygdala reactivity in val allele carriers	Bogdan et al. (2012)
Testosterone	Androgen receptor	Postsynaptic signaling	*AR*	Trinucleotide (CAG) repeat polymorphism	Unknown	CAG length inversely correlated with amygdala reactivity to angry and fearful faces when controlling for variation in testosterone	Manuck et al. (2010)
Acetylcholine	Choline transporter	Acetylcholine reuptake	*SLC5A7*	rs333229	GG presumed to have impaired choline transport and subsequent reduced acetylcholine availability for neurotransmission	Increased amygdala reactivity in GG allele homozygotes	Neumann et al. (2006)

Deyoung, Fossella, & Gray, 2013; Malhotra et al., 2002; Mattay et al., 2003; see also Mier, Kirsch, & Meyer-Lindenberg, 2010).

In positive or low-stress emotional contexts, Met/Met individuals thrive and succeed. For example, real-life pleasant experiences elicit a greater positive affective response for individuals with increasing numbers of Met alleles. Wichers et al. (2008) used an experience sampling method to capture affective responses in the moment. They found that events rated as equally pleasant across *COMT* genotype groups produced higher positive affective ratings in Met carriers, and the same number of pleasant events elicited a greater mood increase with more Met alleles. Another example comes from a gene-by-environment study that investigated the impact of socioeconomic adversity and educational attainment on cognitive performance (Enoch, Waheed, Harris, Albaugh, & Goldman, 2009). Under favorable conditions, Met/Met individuals exhibited superior performance on subtests of the Wechsler Adult Intelligence Scale—Revised (WAIS-R) (Wechsler, 1981).

However, the Met-allele cognitive advantage has been shown to be reversed under conditions of stress or negative stimuli. With more socioeconomic adversity, fewer years of education, and presumably more emotionally difficult circumstances, the Met/Met individuals' WAIS-R performance was significantly worse than that of Val/Val individuals (Enoch et al., 2009). Consistent evidence was found in a laboratory study where Met/Met individuals exhibited poorer working memory task performance after an acute psychosocial stress manipulation (Buckert, Kudielka, Reuter, & Fiebach, 2012). Several researchers have hypothesized that the effects of stress result in an increase in dopamine availability that pushes Met/Met homozygotes past the peak point of the inverted-*U* curve and into a position of supraoptimal DA and worse cognitive performance (Bishop, Cohen, Fossella, Casey, & Farah, 2006; Buckert et al., 2012; Mattay et al., 2003).

The Met-associated cognitive advantages have been couched as a tradeoff coupled with affective vulnerability. Termed the "warrior/worrier model" (Goldman, Oroszi, & Ducci, 2005; Mier et al., 2010; Stein, Newman, Savitz, & Ramesar, 2006), this theory states that the Met variant, or "worrier," is advantageous for cognitive tasks requiring memory and attention, but is susceptible to affective dysregulation under stress. Stress not only shifts the Met/Met position on the inverted-*U* curve beyond the optimal range, but the effects of negative stimuli and negative affect are more potentiated in Met/Met individuals. By contrast, the Val variant provides an advantage in processing aversive stimuli and adapting under stressful circumstances—the "warrior strategy." The cognitive inefficiency seen in Val/Val homozygotes becomes protective when the environmental context is stressful or stimuli are aversive.

The advantages associated with the superior maintenance of information in working memory in Met/Met individuals is coupled with a disadvantage in that working memory cannot easily be reset or shifted away from processing a particular stimulus. This pattern of working memory maintenance occurs at a D_1-receptor-dominated state, as described by the dual-state theory of prefrontal DA function (Durstewitz & Seamans, 2008). The D_1 state allows for mental representations to be sustained over delay periods, supporting working memory and protecting from distractors. However, because of the high threshold to change the signaling pattern, this stability is associated with inflexible information processing and perseveration. By contrast, Val/Val individuals are characterized by a preferential activation of D_2 receptors within the synaptic cleft, due to the rapid clearance of extrasynaptic DA by the high-functioning COMT enzyme. The D_2 state facilitates switching between different activity patterns, which supports flexible problem solving and the incorporation of new information. However, this flexibility is associated with increased distractibility and failure to maintain working memory processes (Durstewitz & Seamans, 2008).

In summary, the Met-related DA signaling profile favors D_1 receptor activation, maintenance of a current working memory representation, tonic DA signaling, and resistance to distractors, while the Val-related DA signaling profile favors D_2 receptor activation, set shifting, phasic DA signaling, and responsiveness to distractors (Bilder, Volavka, Lachman, & Grace, 2004). When it comes to processing affectively laden, and particularly, negative information, the more flexible information processing style seen in Val/Val homozygotes is actually advantageous. There is evidence that Val carriers can more readily disengage from processing negative information, reallocate attentional resources away, and thus show attenuated neural and self-reported responsiveness to negative emotional stimuli. Val carriers thus show more "efficient" neural processing of affective stimuli, manifest as decreased ventrolateral PFC activation on emotion processing tasks (Mier et al., 2010). By contrast, Met carriers show relatively greater prefrontal activation in response to emotional stimuli, particularly those that are negative.

Met-carriers' increased reactivity to negative stimuli may contribute to affective vulnerability, possibly due to a persisting attentional bias toward negative stimuli and therefore a heightened demand on regulatory resources. Several research groups have found evidence of increased amygdala activation in Met carriers during processing of negative pictures or negative emotional faces (Lonsdorf et al., 2011; Rasch et al., 2010; Williams et al., 2010). Consistent event-related potential (ERP) evidence shows Met carriers' heightened neural responsiveness to negative stimuli (Herrmann et al., 2009), and they have higher fear-potentiated startle responses after being primed with aversive pictures (Montag, Buckholtz, et al., 2008). Met/Met individuals also have increased pain responsiveness and higher pain sensitivity (Diatchenko et al., 2005; Zubieta et al., 2003), and report more negative affect in response to pain. They are also more sensitive to stress (Hernaus et al., 2013), including stressful life events that can lead to psychopathology such as PTSD (Kolassa, Kolassa, Ertl, Papassotiropoulos, & De Quervain, 2010; Valente et al., 2011). Although not all results are consistent with this pattern (e.g., Domschke et al., 2008, 2012; Kempton et al., 2009; Lelli-Chiesa et al., 2011), the majority are consistent with the theory that increased DA in the limbic system can lead to disinhibition of the amygdala and potentiation of amygdala responsiveness (Hariri, Mattay, Tessitore, Fera, et al., 2002; Rosenkranz & Grace, 2001; Tessitore et al., 2002). Catecholamine release triggered by negative stimuli could result in potentiated signaling in Met carriers, whose lower COMT activity results in a slower return to baseline (Bishop et al., 2006; Canli, Ferri, & Duman, 2009).

The relatively stronger (and possibly more persisting) bottom-up signal seen in Met carriers triggers a greater need for top-down regulation. In healthy individuals, increased prefrontal activation in response to negative stimuli is likely effective in mitigating the negativity bias. However, excessive activation of those regulatory pathways could lead to susceptibility to anxiety and dysphoria over time and/or under emotionally demanding conditions (Heinz & Smolka, 2006). Met/Met homozygotes may show perseveration on negative stimuli and impaired regulation of negative emotionality, for example, as evidenced by a deficit in extinguishing conditioned fear (Lonsdorf et al., 2009). The connectivity between prefrontal regulatory regions and limbic regions during the processing of emotional stimuli has been shown to be increased in Met carriers and associated with inflexible personality traits and more negative ratings of stimulus images (Drabant et al., 2006; Rasch et al., 2010).

The Met-related vulnerability for inflexible processing of affective information could manifest as increased or potentiated negative affect, rumination, and even difficulty disengaging from ineffective behavioral strategies or maladaptive personal goals. These tendencies may lead to dysfunctional self-regulation and psychopathology (Baumeister & Heatherton, 1996; Bilder et al., 2004; Davis & Nolen-Hoeksema, 2000; Nolen-Hoeksema, 2000). However, in many instances Met carriers' superior attentional control may be effectively applied to reduce perseveration on negative emotional content, as the behavioral differences across genotype groups are often subtle. Environmental context, stress, and history of negative experiences are all relevant to whether these underlying tendencies will impact behavior and mood and how persistent those effects will be, thus further underscoring the role of the environment in modulating genetic effects on emotion processing.

Conclusions

In summary, advances in human neuroimaging and molecular genetics over the past two decades have allowed for some of the interindividual variability that occurs in complex affective traits and states to be mapped onto variability in neural function, which has in turn been at least partially explained by differences in genetic and epigenetic background. This mapping has been particularly successful when focusing on well-characterized circuits mediating the processing of reward and threat, their adaptive integration, and their associated affective traits. While variants impacting neurotransmission in multiple systems and pathways have been implicated in regulating neural phenotypes pertaining to these processes, the main emerging themes in the literature indicate that genetic variants leading to relatively increased DA signaling are associated with a relative increase in reward-related VS reactivity, along with its affective and behavioral consequences. Similarly, those associated with relatively increased 5-HT signaling are generally predictive of increased amygdala reactivity and relatively heightened sensitivity to threat. A genetic variant modulating DA signaling in the PFC has been implicated in differences in the cognitive control of emotion processing in a more complex, context-dependent manner. Future studies integrating multilocus genetic and epigenetic data with current and novel neuroimaging approaches to these and other increasingly well-understood circuits of emotion processing are particularly likely to yield further insight into the origins of the vast interindividual variability characterizing human emotion processing and complex affective traits.

CHAPTER 11

OLFACTION

Explicit and Implicit Emotional Processing

Jeannette M. Haviland-Jones, Patricia Wilson,
and Robin Freyberg

We are surrounded by chemosignals (airborne chemicals with information value, including odors) at all times in our lives. Some like to say that we live in a "chemical soup"—not referring to factory wastes, but to the everyday chemical information that our own bodies, plants, storms, books, foods, and so forth produce. Some of this "soup" cues us about the moods and other motivational information in the air, but not in such a way that we are usually aware of it. In spite of the ubiquity of chemicals in the air, and in spite of a common acceptance that smell has an emotional component, in the past, smells have been considered unimportant by the scientific community, even for emotion (see Classen, Howes, & Synott, 1994, for a review of the dismissal history). However, emotion research in olfaction is now an area of rapid change, ripe for innovation.

As this review demonstrates, much of the new information on emotion and olfaction is related to the investigation of implicit processes in olfaction. We begin the chapter with some background on the methods in olfactory research to show how they have had an impact on changes in this area. Next we review background on the olfactory system with particular emphasis on how research questions arise related to different parts of the olfactory system. We then move to areas of research, much of it emerging only in this century. Human chemosensory mood communication is reviewed, and then the effects of nonhuman chemosignals on emotion and social behavior. The last research section examines how natural odors in the environment affect emotion. This includes a brief introduction to malodors. Finally, we provide some perspective on conceptual and theoretical advances.

Ends Not Independent of Means: The Influence of Methods

We begin with an introduction to methods commonly used in emotion and olfaction research because many of the controversies about the significance of olfaction for emotion rest upon differences between the results of research that emerged from more explicit methods and those beginning to emerge from more implicit methods (see Sela & Sobel, 2010, for a discussion of subconscious odor effects, or Haviland-Jones & Wilson, 2008, for related issues). To demonstrate, we review the traditional use of self-report, then the more recent use of narrative process as a semantic, but more implicit, approach to emotion reporting. Behavioral and attitudinal measures are becoming more used as well. Finally, we provide a brief introduction to the physiological and neurological approaches current in olfaction research pertinent to emotion.

Not long ago at a meeting of chemosensory scientists, the phrase "gold standard" for testing emotion meant that any effect of an olfactory stimulus on emotion had to live up to the standard that a person asked to smell a scent would report a change in emotion. This measure often produced rather small effects, difficult to replicate. Of course, the conclusion then was that any emotional responses to odors, scents, or chemosensory stimuli were likely to be highly individual and, with few exceptions, produced by past associations that could be difficult to verify or replicate.

The Self-Report Problem

Most often the self-report in olfaction research is completely explicit. In the research laboratory, a research participant knows the questions pertain to odor. He or she is asked to smell something. Usually the first self-report questions are the identity, hedonic, and intensity questions—the participant is first asked what the odor is, then how pleasant it is and how intense. Obviously, this explicitly brings the attention to the odor and provides a framework for associations to the odor and to two continua: hedonics and intensity. This method in itself may skew the results with expectations that there are continua, not categories, and that hedonics and intensity have primacy. Often, there is then a list of descriptives to rate including "woody," "musty," and so forth. Finally, the person is asked to rate his or her mood. Not surprisingly, under these conditions, ratings of hedonics and emotion are highly correlated, somewhat tempered by the associations revealed in the descriptives. The problem apparent to the consumer marketers, most directly, but also to experimental sensory scientists, broadly, is that ratings of pleasantness, liking, and mood state obtained using this explicit self-report method do not reliably predict behavior or physiological responses. In social psychology, we have known for some time that explicit and implicit processes (e.g., Nisbett & Wilson, 1977) do not always reveal the same types of results.

It is true that self-reports have a number of advantages, including an intuitive persuasiveness, but most important is their ease of use. However, they also come with a number of familiar drawbacks even if an explicit description is needed. Most notably, participants are not always reliable documenters of their emotions (note again Nisbett & Wilson, 1977). Questionnaires often lack precision in their assessment of complex and transitional emotions. Different people often interpret questions differently (Sheatsley, 1983), a reality more likely the more complex the assessment.

Given the caveats pertaining to explicit methods, it should be no surprise that alternative approaches are gaining in use. Alternative methods in the tradition of emotion research that do a better job of capturing nonconscious emotional experience in response to olfaction exposure include narrative, behavioral, psychophysiological, and neuroimaging methods.

Narrative Methods

One of the more interesting methods to capture nonconscious emotions is that of the narrative method. Typically, the participant is asked to write about a recent event. It is akin to self-report in that the participant is personally offering information about the self but it is implicit in two ways. First, the participants are not asked for an emotion report on their current state though they may be asked to include feelings in their event report. Second, this procedure is not necessarily linked to any odor. In many cases a perithreshold odor is used, meaning that people cannot discriminate rooms with the chemosensory input from rooms without this input. People can be asked to participate in sensory studies and told they may be in an olfactory, visual, temperature, auditory, or similar type of condition and then they can give consent to details in all conditions and in fact may be enrolled in a study with many dimensions. This further takes away any focus on olfaction. Yet our research demonstrates that such perithreshold odors influence not the content of a narrative necessarily, but categories that we call *search* categories. For example, a perithreshold floral odor is not likely to lead to writing a narrative about flowers or gardens, but instead to almost any content that includes more positive emotion words and more intimate words such as "loving" and "liking." This reflects an underlying socioemotional state in which the floral odors may prompt a search for happy and affiliative information (Haviland-Jones, Hudson, Wilson, Freyberg, & McGuire, 2013).

This use of narrative method is derived from Pennebaker's research (e.g., Pennebaker & Seagel, 1999). Generally, ordinary dialogue or text reveals underlying emotional states. This is confirmed by the Magai and Haviland-Jones (2002) finding that frequently used emotion words in writing are part of an emotional dynamic system including frequently used facial emotional signals—that is, emotion is revealed both in words and in expression. This method is a powerful tool for research on implicit process related both to fluctuating states and relatively stable ones. The use of narrative methods within olfactory research is growing as its many uses are becoming increasingly apparent (Castellanos, Hudson, Haviland-Jones, & Wilson, 2010; Freyberg & Ahren, 2011; Haviland-Jones et al., 2013; Kiecolt-Glaseret al., 2008).

Behavioral Methods

Behavioral methods have long been useful when fragrances are presented at explicit levels of detection, as well as at implicit levels. For example, Baron (1997) observed that participants exposed to pleasant odors in a shopping mall were more likely to help a confederate when their help was solicited. While the pleasant odors could easily have been detected, it is unlikely that people were aware of using them as cues. More recent extensions of this work have shown that pleasant ambient odors also encouraged spontaneous helping behaviors (Guéguen, 2012b) as well as social approach behaviors (defined as providing a phone number to a potential suitor; Guéguen, 2012a). Similarly, Haviland-Jones et al. (2013) showed that after being in a room with a perithreshold floral odor, people approached a stranger, sometimes touching him or her, to engage in a task. In this study, the behavioral method showed that scents differed in their impact on social and emotional behavior but the explicit self-report on moods used in the study showed no significant differences.

Facial movements indicative of emotion have also been used successfully in recent studies. As will be seen below in studies of human mood odors, such implicit odors can affect emotion expressions (de Groot, Smeets, Kaldewaij, Duijndam, & Semin, 2012; de Groot, Smeets, Rowson, Bulsing, Blonk, Wilkinson, & Semin, 2015).

Physiological and Neuroimaging Methods

Given that emotion involves a physiological component, it is expected that investigation of the effects of odors on emotion would seek support via physiological measures including cardiac or galvanic skin responses, or from indices of neural activity. Physiological measures may demonstrate significant effects even when a chemosignal is not detected and presumably separated from explicit associations.

Physiological indices and self-report indices sometimes support each other, but not in all instances. For example, the undetected chemosignal androstadienone (AND) has a modulating effect such that reported negative mood and heart rate response and/or galvanic skin response all decrease (Jacob & McClintock, 2000); these methods support one another. On the other hand, a study of jasmine tea and lavender odors at the lowest detectable concentration, found both significantly decreased heart rate and increased parasympathetic nerve activity, attesting to their calming and relaxing qualities (Kuroda et al., 2005) but only jasmine tea showed decreases on self-reported anxiety and tension. In a third study (Kiecolt-Glaser et al., 2008), participants reported increased positive mood for lemon oil compared with lavender on a variety of mood measures both direct (self-report) and indirect (see Kiecolt-Glaser et al., 2008); however, there were no observed changes in heart rate, blood pressure, or salivary cortisol. Findings of studies such as these, with their variability in terms of methods supporting or not supporting one another, complicate interpretation. However, the greater danger lies in equating inconsistent results with dismissal of any effects at all.

Advances in neuroimaging techniques have enabled access to brain structures that are involved in the nonconscious emotional processing of olfactory stimuli (e.g., Lundström, Boyle, Zatorre, & Jones-Gotman, 2008; see Lubke & Pause, 2015; Pause, 2012; Soudry, Lemogne, Malinvaud, Consoli, & Bonfils, 2011, for reviews). Positron emission topography (PET) or functional magnetic resonance imagery (fMRI) demonstrates that an olfactory stimulus impacts not only areas specifically dedicated to olfactory processing but other brain areas as well showing the embeddedness of the ancient olfactory system (Lubke & Pause, 2012). Jacob, Kinnunen, Metz, Cooper, and McClintock (2001) used PET following nonconscious exposure to AND and found activation in brain areas associated with mood and attention. Additionally, using commercially available fragrance, Herz, Eliassen, Beland, and Souza (2004) found that a pleasant memory odor cue was significantly more likely to activate the amygdala and hippocampus, suggesting that personally meaningful cues had demonstrable effects on the brain areas associated with emotion and memory (Panksepp, 2011).

The Biology of Olfaction

The methods of assessing the effects of airborne chemical signals rarely address the three different parts of the olfactory system separately but it is important to be aware of the different potential functions of the system as future researchers are likely to be more inclusive of this (e.g., Delplanque et al., 2008). The olfactory system involves odor detection and discrimination. The trigeminal system, in terms of olfaction, is principally concerned with somatic arousal, and detection of irritants. The vomeronasal organ (VNO) is considered vestigial in humans by most researchers but is responsible for detection of pheromones and clearly is present in a wide variety of nonhuman species. We review each system briefly, illustrating aspects of each system pertinent to emotion research.

The Olfactory System

The primary olfactory system involves detection of odor molecules by the olfactory epithelium, transmission of the information to the main olfactory bulb and then to the primary olfactory cortex (Brand, 2006). A link between olfaction and emotion is widely acknowledged, both in terms of popular wisdom and neuroscience. For example, the history of fragrances detected by the olfactory system shows usage of pleasant fragrances for love and attraction from ancient times to the present day (Classen et al., 1994; Jelinek, 1996; Stoddart, 1990). We adorn ourselves with fragrance to attract others as well as to affect our own emotions (e.g., Schiffman, Suggs, & Sattely-Miller, 1995). Detecting and reacting to these scents is the domain of the olfactory system.

The processing of both olfactory and emotional signals involves common pathways in the limbic system and related brain areas. For example, both the amygdala and the orbitofrontal cortex receive input via the olfactory tract. Emotion processing implicates both of these areas (Baas, Aleman, & Kahn, 2004; Britton et al., 2006; Rolls, 1996; Zald, 2003). Savic (2005) has noted that olfactory information, like other sensory systems, is processed both in parallel and hierarchically. However, she notes that the most primary level of odor perception involves the amygdala and an immediate emotional response.

Unlike every other sensory system, olfactory information projects directly to the central nervous system, rather than first traveling to the thalamus (Stockhorst & Pietrowsky, 2004). The olfactory epithelium is composed of exposed neurons that are replaced on a regular basis (Carleton, Petreanu, Lansford, Alvarez-Buylla, & Lledo, 2003). Further, humans have a generative capacity to "learn" to smell odors to which they had been anosmic, often after few exposures (Sela & Sobel, 2010).

A particularly interesting feature of the olfactory system is that organisms may respond physiologically and emotionally in the presence of chemical signals even when they are not aware of and cannot consciously detect any odor (see Sela & Sobel, 2010). In effect, odors may potentiate emotional and behavioral responses even when there is no attentional focus on the odor or if it is below the threshold for detection (e.g., Bensafi et al., 2003; Haviland-Jones, Wilson, & Freyberg, 2015; Lubke & Pause, 2015).

People often seem unaware of the motivational and emotional effects governed by the olfactory system and even less aware that they, themselves, produce chemical communications. Of course, we are aware of many kinds of odors from the foul odors of decay on the one hand, to the pleasant smell of infants on the other. But there is still a very large number of chemosignals, especially motivational signals that are revealed to have significant input in careful research, ones that we commonly ignore (see the section "Mood Odors").

The Trigeminal System

The trigeminal system serves a somatosensory (e.g., temperature or pain) and motor (e.g., biting and chewing) function for the face and head (see Brand, 2006, for a review). In contrast to the olfactory system, the trigeminal system first projects to the thalamus and then to the cortex. The three branches of the trigeminal nerve enervate different parts of the face with the mandibular branch only carrying motor information. The ophthalmic and the maxillary branches extend into the nasal lining resulting in complex interactions between the two systems, with most odor perception involving both systems (Hummel & Livermore, 2002).

A particular function of the trigeminal system is detection of chemical irritants, for example, recoiling from the smell of ammonia. This may lead to negative judgments, but some stimulants to the trigeminal system provide information that is judged to be exciting, generating interest. For example, the crisp and energizing smell of peppermint stimulates the trigeminal system and has several psychological effects (see Raudenbush, 2004, for a review).

The Vomeronasal System

The vomeronasal system (VNS) is a third system present in many species specifically responding to airborne chemical cues that have been termed "pheromones." The VNO, situated in the nose, responds to chemical signals, sending information via the vomeronasal nerve to the accessory olfactory bulb (Halpern, 1987). While the VNO can be detected in the human fetus and also in many adults, it may be vestigial; it may not be universal; and even when present, it may not be functional (see Meredith, 2001, for a review).

The controversy concerning the VNO in humans supports controversy concerning pheromone communication in humans. Pheromones are defined as chemical messages emitted by a member of a species and detected by another member of that species resulting in physical and/or behavioral changes (Karlson & Luscher, 1959). In addition to their connection with sexual attraction among many nonhuman species, pheromones provide other information, including information about food and predators. Emerging research has found that humans can be affected by chemical messages from other humans, a topic we return to later. Whether these messages can be considered pheromones is controversial (see Wysocki & Preti, 2004); however, these controversies need not impact a discussion of the human chemical signals (see Sela & Sobel, 2010).

Whether or not detected by the VNO, human chemical signals have been shown to elicit a range of responses from other humans. For example, both male (Preti, Wysocki, Barnhart, Sondheimer, & Leyden, 2003) and female (Stern & McClintock, 1998) axillary compounds can cause changes in a woman's menstrual cycle. There is also support for a mood effect associated with AND (Jacob & McClintock, 2000), one of this category of steroids.

A more nuanced appreciation for the olfactory system and its role in human experience has replaced a very limited early understanding (Haviland-Jones, Wilson, & Freyberg, 2015). This expanded insight interconnects with a long history of popular wisdom and naïve psychology, a history that often dismisses odor's importance while basking in its delights and distancing from its "other side." Odors do impact mood and emotional behavior. However, the exact mechanism has yet to be fully elucidated.

Recent Discoveries

There is new information from genetics, sensory perception, and psychobiology that affects our changing appreciation for the scope of olfaction in human experience and emotion. Not only are new methods opening new research territory for emotion and olfaction, there are exciting discoveries about the basic system. Buck and Axel's (1991) work revealed that fully 1% of the human genome is assigned to the genes that govern olfaction, a dedication exceeded only by those assigned to the immune system. This work earned them the 2004 Nobel Prize and played a large role in energizing research on olfaction.

New analyses unexpectedly show the exceptional acuity for odors among humans, rivaling and surpassing most mammals (Laska & Seibt, 2002). The olfactory system uses some 1,000 odor receptors in different patterns of activation to detect many hundreds of odors at concentrations as low as one part per trillion (Yeshurun & Sobel, 2010). The problematic issue is that this acuity does not link to semantic differentiation. In other words, we do not easily recognize and label the vast numbers of odors that we can discriminate. This supports our premise that approaches to research that capitalize on nonconscious processes are important.

Another significant discovery about the olfactory system may lead to our understanding of whether or not olfaction operates differently from other senses—particularly in how it regulates emotion. Kass, Rosenthal, Pottackal, and McGann (2013) found that the synaptic output of the olfactory sensory neurons, the first cells that physically contact odor molecules in the nose and project the information to the olfactory bulb, changes when an odor is paired with shock. This challenges the view that the emotional associations occur only in the cortical limbic brain regions. The synaptic changes may be related to the observation that people exposed to chemical compounds traumatically, later may have serious reactions to chemosignal levels thought to be below threshold. This finding has interesting implications for specialized olfactory system functions.

Mood Odors

Probably of most significance to the study of olfaction and emotion is the accumulating evidence demonstrating that humans communicate emotions with body chemosignals and odors. In this domain it is almost startling how much "mood odors" affect human behavior and how little credence is given to this phenomenon. This research area particularly illustrates our premise that many social–emotional cues are processed subconsciously. Our knowledge of the socioemotional effects of mood odors comes from the variety of more recently applied methods outlined above. This includes narrative "word slips" (Pennebaker & Seagel, 1999), dream memories (Castellanos et al., 2010), attributions toward others (Freyberg & Ahren, 2011), movements (Haviland-Jones et al., 2013), and changes in social patterns showing trust (Liljenquist, Zhong, & Galinsky, 2010).

Chen and Haviland-Jones (1999) were one of the first to reveal the connection between body odor and mood. Specifically, young children and both young and senior adults, male and female, wore underarm pads that allowed for the collection of axillary odors while they were wearing nightshirts for several days. In a second session, evaluators were exposed to these odors from an open glass jar while doing other tasks, though they were not asked to sniff the jars, nor was their attention drawn to them during the first part of the study. Later they would be asked to rate and identify the chemosignal. Participants reported more negative mood when exposed to the odors from the young men, whereas they reported more positive mood when exposed to the odors from the older women. Further, participants incorporated more aggressive dream content in narratives when exposed to the young men's odors, whereas they incorporated more affiliative content in dream narratives when exposed to those from the older women. Because the odors of young men and older women were not discriminated in the later task and both were considered relatively intense and unpleasant, it is unlikely that associations to gender or age led to the associations detected both in self-report and in narrative report.

The results of the Chen and Haviland-Jones (1999) study prompted additional research to explore how mood might be communicated by human body odors. We hypothesized that what was communicated was the mood of the young men or older women rather than just associations with age and gender—that the older women were actually at a happier time in their lives than the younger men who were likely in a competitive and uncertain time of their lives. In the next studies, directed at discovering mood odor, we therefore used axillary odors collected from people while they watched mood-induction videos to induce fear or happiness—the same people donated both mood odors (Chen & Haviland-Jones, 2000; Haviland-Jones & McGuire, 1999). Using forced choice procedures (detectors sometimes complained there was nothing to detect or that the task was impossible), we learned that detectors were able to identify which mood induction a group of people was exposed to at significantly above chance levels just from the odor pads.

More recently, some researchers have produced human mood odors in a variety of different settings including anxiety-producing exams (Pause, Lübke, Laudien, & Ferstl, 2010), sky-diving (Mujica-Parodi, & Strey, 2006), or a high rope course (Zernecke et al., 2011). Although similar effects are found with these different collection strategies, it is still not known what the chemical composition of these mood odors may be and how differences in components may result in either individual or in behavioral differences.

Aside from showing that the mood odors can be discriminated, recent research by de Groot and colleagues (2015) has demonstrated that happy, fear, and disgust odors produced facial expressions in perceivers that matched the odors. In other words, sensing a fearful mood odor from an unseen fearful person is likely to lead to a fear expression—that is, a motor response—in the perceiver. Such findings extend research on mirror neurons (Aglioti & Pazzaglia, 2011; Tubaldi et al., 2011). In the original mirror neuron research, the sensory system is visual: seeing a disgust face led to making a disgust face. Here, smelling disgust led to making a disgust face (and, as yet untested, possibly producing another disgust odor). This suggests that olfactory stimuli affect the motor system via different neural pathways than visual stimuli. This is an exciting new research area.

Additional studies have expanded our understanding of the effects that body odors have on those exposed to them. For example, exposure to human odors can affect decisions about the emotional qualities of pictures and faces (Pause, Ohrt, Prehn, & Ferstl, 2004; Zhou & Chen, 2009) and even affect something as automatic as a startle response (Prehn, Ohrt, Sojka, Ferstl, & Pause, 2006). Pause and colleagues (2004) showed how exposure to an anxiety chemosignal impacted how participants perceived a neutral face. In their study, participants were primed with happy, fearful, and sad faces before rating the emotion on a neutral face. Results showed that although priming with the happy face usually prompts seeing happy in a neutral face, an anxiety chemosignal disrupted this pattern. Mujica-Parodi et al. (2009), Zhou and Chen (2009), and Zernecke et al. (2011) have extended these results to other paradigms such as the morphing of faces. Taken together, this body of research suggests that the anxiety chemosignals significantly affect attributions of emotion and that they exert most of their influence on ambiguous stimuli.

There is a suggestion that communication for emotion may operate differently in the olfactory system than in other sensory systems. For example, Chen, Katdare, and Lucas(2006) expected that exposure to fear mood odors would decrease reaction times in identifying threatening words, as would exposure to a frightening visual cue. While there were no differences for threatening stimuli, the reaction times were slower for the ambiguous stimuli—the opposite of what was expected. Such findings relate to work by Sela and Sobel (2010), who presented evidence that perception in olfaction generally operates differently from visual or auditory perception. They argue that the olfactory system is not organized optimally to locate objects, even frightening ones, but instead works subconsciously and rapidly to scan environments for motivationally congruent information. In this sense, it is possible that the olfactory cue did not give definitive spatial/object information. Instead, it set a broad scope scanning for relevant types of information to be gleaned from other sensory systems. In setting up such a search for other systems, it slowed the reaction to ambiguous cues. This suggests that different sensory systems may serve different functions so that what leads to faster reactions for the visual system may lead to slower reactions for the olfactory system.

The moods that can be identified are not only negative. Positive mood odors such as happiness, calmness/relaxation, and safety can also be identified (e.g., Chen & Haviland-Jones, 2000; Haviland-Jones & McGuire, 1999; Haviland-Jones & Wilson, 2008). However, further research is needed to fully explore this phenomenon. We suggest that positive mood odors could be just as important and as discriminable as positive emotion cues in the visual domain. A smile is a cue that is discrete, easily recognized, emerges early in life, and has considerable social significance; perhaps positive mood odors have a similar impact. The fact that people seem to have no confidence that this is the case is not sufficient evidence that they have negligible impact. There is little confidence for signs of alarm yet alarm signals are now known to have important effects.

Clinical Implications

There are several approaches to the emotional saliency of odors in clinical fields that serve to indicate that this area has potential for future work. We mention two: the effect of human odor in communicating personality and the effect of anosmia on emotional health.

Personality and Body Chemosignals

Two studies show that human body odor gives cues for personality types such as neuroticism and, possibly, dominance. Body odor was collected via cotton pads from a group of donors who also rated themselves on personality traits. In two studies, one with child participants and one with young adult participants, neuroticism was identified from body odor. The young adults, but not the children, could also identify dominance. Neither group could identify extraversion. Sorokowska (2013; Sorokowska, Sorokowski, & Szmajke, 2012) explains why personality might be discernible via body odor by focusing on the production of hormones in relation to stress and anxiety. Particularly noteworthy, given the work on fear body odor, is that neuroticism can be defined as a pervasive feeling of anxiety, stress, and fear.

Using measures of brain processing and focusing on reactions to human mood odors, Pause and colleagues (Pause et al., 2010) found that socially anxious people, in comparison with those low in social anxiety, had an amplified startle response when also exposed to fear mood chemosignals. In other words, socially anxious people were especially sensitive to the chemosignals.

Anosmia and Related Problems with Olfactory Acuity

It is quite common for people who lose olfactory sensitivity to become depressed. Beyond that, a wide range of studies have demonstrated the extent of olfactory deficits in clinical populations (see Atanasova et al., 2008, for an extensive review). The most heavily researched areas include patients suffering from schizophrenia, depression, and Alzheimer's disease (e.g., Cumming, Matthews, & Park, 2011; Kästner et al., 2013; Rahayel, Frasnelli, & Joubert, 2012). However, this research needs to be considered critically as methods of assessment are not standardized and medications may affect responses as well.

Socioemotional Effects of Nonhuman Chemosignals

Nonhuman chemosignals both above and below conscious detection, tapping into explicit and implicit processes, have been demonstrated to impact both emotional and social functioning. In this section we present examples of the effects of processed or manufactured scents on human emotions and social interaction. Later in this section we turn to the effects of odors on emotional memories, and finally their use in commerce. There are a range of other studies not clearly related to emotion but still demonstrating the influence of odor on a variety of attributions (e.g., Holland, Hendriks, & Aarts, 2005) but we do not have space to review them.

Fragrance Effects on Emotion

Nearly two decades ago, Schiffman and colleagues (Schiffman, Sattely-Miller, Suggs, & Graham, 1995; Schiffman, Suggs, et al., 1995) found that using cologne improved moods for both men and women in midlife. Participants used the colognes for several weeks, reporting moods on a standard self-report. Compared with baselines or with nontreated groups, both men and women were less depressed, anxious, and irritated when using colognes.

There is some evidence that specific fragrances may have different effects for different people. Hämmerli, Schweisgut, and Kaegi (2012) found fragrance choices are likely to be influenced by genetic information. There is also evidence that different fragrances may have different social and emotional effects. Freyberg and Ahren (2011) demonstrated that when adolescent girls were asked to use a new fragrance and it was perceived as less pleasant than their own, they had lower levels of social enjoyment while using it. They also used fewer words indicative of intimacy in written narratives. Taken as a whole, such research findings confirm that man-made fragrances may affect moods and social relationships and begin to unravel the many individual differences.

Fragrance Effects on Social Interaction

Studies of the effects of nonhuman chemosignals in social interactions often show complex social context effects. For example, in a study of the impact of a college woman's fragrance on college men, it was found that the women who wore a pleasant and potent fragrance were rated as warm and romantic but only if the women were dressed informally (and appropriately for the college environment). Women who were dressed formally wearing the same fragrance were not rated favorably (Baron, 1981).

Another example of explicit effects on social behaviors involves the scent of baking pastry (cookies) or roasting coffee. Baron (1997) had experimenter confederates ask shoppers at a mall for change of a dollar while standing in front of a shop where cookies were baking, coffee was roasting, or in front of a nonscented store in another part of the mall. Shoppers who were asked for assistance in front of the baking or coffee shops were significantly more likely to help the confederate. Apparently, a pleasant, homey scent can affect social behavior. This finding has been supported recently by Guéguen (2012b) who found that spontaneous helping behavior (retrieving and returning a dropped glove in a shopping mall) was facilitated by a pleasant odor.

The studies of perfume or baking show the effects of explicit chemosignals and suggest the influence of context as well. However, even implicit nonhuman chemosignals, below conscious awareness, may have significant effects, sometimes even more potent. In a study of the impact of odor on social preferences (Li, Moallem, Patter, & Gottfried, 2007), the rating of neutral faces was primed with pleasant, neutral, or unpleasant odors presented below the threshold for conscious detection. Conscious detection thresholds are highly variable, however, so the participants also engaged in a signal detection task to determine their individual thresholds. Li and colleagues found that the subconscious detection group was influenced by the odor prime, rating a neutral face as more likable in the presence of a pleasant odor and less likable in the presence of an unpleasant odor. The conscious detection group was not affected by the primes. Similarly, Liljenquist et al. (2010) placed participants in either a room sprayed with Windex cleaner at a level near threshold or in a nonscented room. Those in the low-level clean-scented rooms were more likely to share a monetary windfall and in a second study to volunteer their services and to donate money to a cause. The researchers conclude that undetected "clean" scent can instigate social behaviors related to moral virtues. One may question, then, to what extent our everyday moods and actions are influenced by natural and/or artificial odorants.

Explicit processes can also be demonstrated by the research on the effect of odor on memory. Again summoning folk wisdom, most would acknowledge that a particular odor can conjure up a particular memory. This is the "it smells like summer at the beach when I was a kid . . . such happy times" experience. Such experiences are emotional and idiosyncratic (Wysocki & Gilbert, 1989). They have also been immortalized in literature, most prominently by Marcel Proust in *Swann's Way* (1913/1957). A passage from the novel recounts the protagonist's experience of sipping tea and eating Madeleine biscuits and then being swept away in a sea of emotion and memory back to his childhood.

Research on memory processes has shown that odor-induced memories are reported to be more emotionally laden than those induced via other sensory modalities (Herz, 2000). Other work has shown that odors associated with particular experiences evoke more memories for the experience than do random odors or no odor at all (Aggleton & Waskett, 1999). Such associations are explicit and learned, tapping into cognitive and semantic processes, and argue for the power of odor to influence autobiographical memory and its attendant emotional components.

There is substantial evidence that chemosignals provided in commercial spaces have an effect on the desirability of goods and affect consumer behavior. Marketing researchers have found that a pleasant ambient odor will heighten a consumer "shopping experience," making it more likely that the consumer will visit the store again (e.g., Douce & Janssens, 2013). Odors have been found to exert this effect even for online shopping (Vinitzky & Mazursky, 2011). In a study investigating multiple sensory experiences and shopping (Morrison, Gan, Dubelaar, & Oppewal, 2011), music and a pleasant odor (vanilla) were both found to create arousal in shoppers, directly affecting their perception of their shopping experience as pleasurable. This in turn led to behaviors desirable from the retailers' perspective, such as increasing the time spent shopping. The scent of lavender in a florist shop showed similar effects. When lavender was used (as an additive scent, not by presentation of lavender plants) more consumers were attracted and purchases increased (Jacob, Sefan, & Guéguen, 2014).

Pleasant scent seems to motivate the purchase of items through the enhancement of socioemotional behaviors. They may also affect other behaviors. Intending to counteract malodors in clubs, odors of orange, seawater, and peppermint were piped into three separate clubs (Schifferstein, Talke, & Oudshoorn, 2011). Not only was mood affected positively by all three scents compared with a no odor control, but so was dance activity, judgments of the music, and ratings of the overall experience. Adding the research on memory to the marketing domain, Morrin and Ratneshwar (2003) confirm that fragrance may provide long-term, detailed memory of products. This long-term memory effect warrants further investigation.

This selection of research on the effects of nonhuman, manufactured chemosignals clearly demonstrates that their presence can affect human mood and social behavior, quite possibly also attention and a variety of cognitive processes. Not all chemosignals will be effective and their effectiveness varies with the context in which they are used. Nevertheless, this shows the potential for future research in several areas.

Emotional Reactions to Natural Odors in the Environment

Of course, humans leaving mood messages in the air is an environmental event of a sort, as are our manufactured perfumes and scented products. There is also evidence for the effects of chemicals in the air from a "nature" less manufactured on mood, attention, and behavior related to health or well-being. Attention to this has increased with the increasing concern about industrialization, climate change, urbanization, and related problems (for more general approaches to natural environments including parks, see Jaffe, 2010) leading to the development of a new field within environmental psychology that merges psychology, architecture, urban planning, and horticulture (Sternberg, 2009). In this next section, we give a few examples of naturally occurring chemosignals in our environments that also affect our emotions and often our social behaviors. First, we review some chemosignals that have positive emotional effects and then turn to those with more negative emotional effects.

Positive Emotion Effects from Olfactory Stimuli in the Environment

In a series of studies investigating the effects of flowers, we (Haviland-Jones, Rosario, Wilson, & McGuire, 2005) studied how flowers—which are, of course, naturally occurring chemosignal producers—evoke positive emotional and social responses in humans. The first study riveted our attention because all of the participants exposed to a mixed flower bouquet responded with the Duchenne (zygomatic/orbicularis orbis) smile and significantly more reported more positive emotion over a 3-day period compared with participants who received fruit baskets or a pillar candle. In the second study, participants (older adults in retirement communities) received "doses" of floral bouquets. Those who received more than one over several weeks had lower reports of depression. Possibly related to the improved mood, they scored higher on an episodic memory task. Finally, in a third study, a single gerbera daisy—but less so, a pen—given to a person in an elevator led not only to the Duchenne smile but also movement toward a stranger and initiation of conversation. Unexpectedly, this was equally the case for men as well as women.

Our original research has been extended. For example, Weber and Heuberger (2008), using varieties of blooming plants, showed that participants reported an increase in positive mood, calmness, and alertness when in the natural odor condition as compared with the control condition. The effects of pleasant odors tended to be long-lasting. Another recent study demonstrated that simple exposure to flowers increased women's favorable perceptions of a man, and increased the likelihood of accepting a date (Guéguen, 2011). In other words, simple exposure to flowers affected mood. Showing a similar pattern to certain other chemosignals, the mood effects extend to other social interactions.

After noting the effects of multisensory florals, we started to examine just the effects of floral odors, focusing on odors from plants that have "co-evolved" with people, such as roses. We found that exposure to a floral odor that was not intense enough to be detected (i.e., at perithreshold level) led to increased uses of positive emotion words in narratives and to a greater likelihood of approaching a stranger (Haviland-Jones et al., 2013). In this case, we were comparing a cultivated "natural" fragrance to fresh air as well as to classic perfumes. Also using floral scents, Cupchik extended the research on floral odors to social memory. He and his colleagues reported that exposure to the odor of gardenias while reading a passage from literature resulted in better memories for social referents (Cupchik & Phillips, 2005; Phillips & Cupchik, 2004).

The effects of some floral odors are potent enough to rival pharmacological products. For example, exposure to floral odors reduced symptoms in depressive patients (Komori, Fujiwara, Tanida, Nomura, & Yokoyama, 1995). The fragrances affected neuroendocrine hormone levels and immune function and were "more effective than antidepressants." The physiological and behavioral effects resulting from exposure to floral odors even can be demonstrated in mice. The odor of roses reduced anxiety (de Almeida, Motta, Faturi, Catallani, & Leite, 2004; Bradley, Starkey, Brown, & Lea, 2007); similar effects were found for *Gardenia jasminoides* (Sergeeva et al., 2010) and sweet orange (Faturi, Leite, Alves, Canton, & Teixeira-Silva, 2010). These studies find the effects comparable to treatment with diazepam (Valium) but without the sedative effects—that is, without motor and attention deficits. In these additional examples, the fact that the research participants were not human makes the case for the effects even more strongly. There was no previous exposure to cultivated plant odors that would account for learning or association. The significance of the studies seems to be that some naturally occurring fragrances such as floral scents affect emotion; they at least lessen anxiety or depression, sometimes rather dramatically.

Natural odors from plants or animals affecting human motivation and behavior are not unique. Interspecies communications through chemosensory signals is not uncommon in the insect phyla (Weller, Jacobson, & Conner, 2000) and are even noted in mammals (Von Helversen, Winkler, & Bestmann, 2000). Some flowers give off an odor that brings large gatherings of bats to "party," as the researchers report (Von Helversen et al., 2000). The bats come in response to a chemosensory, airborne signal that mimics bat odors used for gathering. So it is known that plants and mammals may have coevolved systems that require chemosensory information.

We (Haviland-Jones et al., 2005) suggested that flowering plants have found a positive "mood niche" to exploit in a system coevolved with humans. Humans provide propagation and care for these special flowering plants that in turn improve human moods. There may be some places in the world or some plants or animals that evoke or provide more happiness for people than other places, plants, or animals. This may result in places with an overall better mood environment for people.

Negative Emotion Effects from Olfactory Stimuli in the Environment

As the review of positive emotions elicited by natural environmental plants above shows, chemosignals in the air from natural sources such as flowers are at least as effective in moderating mood and social behavior as fragrances produced from manufactured products. These are effects on positive emotions and moods, and social behavior. However, chemosignals, even ones that occur naturally in the environment, as well as manufactured ones, can have negative effects. It is beyond the purview of this chapter to review the large area of research that addresses odorous chemicals harmful to health that result from human activities (e.g., see Yu, Tsunoda, & Tsunoda, 2011, for a review); instead, we focus on those affecting moods or stress.

The argument that the unpleasantness of odors is in "the nose of the beholder" often leads to the conclusion that one may "adapt to" or even "learn to like" unpleasant odors. Work by Delplanque and colleagues (2008) casts doubt on this simple "familiarity" assumption. In two carefully controlled studies, participants rated odors that were similar in intensity. The expected correlation between familiarity and pleasantness occurred only for pleasant odors, not for unpleasant odors. Additionally, only the unpleasant odors were correlated with a physiological stress measure. They infer that the effects of unpleasant odors are not susceptible to familiarity and that odors do not lie on a single pleasantness continuum. This is supported by brain activity as well as autonomic changes (see Rouby & Bensafi, 2002).

Additional research implicates unpleasant odorants to stress within the laboratory context. For example, when people inhale unpleasant odors, there is an increase in blood pressure and a change in blood sugar levels (Martin, 1996; Nimmermark, 2004). Asmus and Bell (1999) demonstrated that exposure to unpleasant odors not only increases negative affect and avoidance behaviors, but that these increase as the odor becomes more unpleasant. As with the more positive effects of floral odors, there are effects on mood reports and effects on social perception as well as changes in other sensory sensations such as pain (e.g., Marchand & Arsenault, 2002; Demattè, Osterbauer, & Spence, 2007).

Another aspect of malodor in the environment is more specific to the space inside buildings and may result in "sick building syndrome" (SBS). Although the symptoms associated with SBS include physical distress such as eye irritation or nausea, recent research also documents effects with emotional components. For example, Redman, Hamilton, Malloch, and Kleymann (2011) observed that SBS had long-term associations with emotional burnout, job stress, and a variety of stress-related outcomes including diminished job satisfaction.

Regarding naturally occurring malodors, Rotton (1983) found that exposure to ethyl mercaptan adversely affected both judgments and performance. Research since that noteworthy early study has generally corroborated and extended this work, particularly to naturalistic settings. Ethyl mercaptan is a naturally occurring odor coming from many sources ranging from marshes to sewage treatment areas to industries manufacturing jet fuel. People are extremely sensitive to this odor and because of that sensitivity, it is added to natural gas used in homes so that gas leaks will be detected and promptly reported.

Another type of relatively natural malodor is associated with industrial farming (see Nimmermark, 2004, for a review). These are of particular note because they are associated with depression. They tend to impact a subset of the population generally located in poor, rural areas. For example, studies have shown that living near hog farms increases negative emotion while decreasing positive emotion (Schiffman, Bennett, & Raymer, 2001), increases depression (Bullers, 2005), and decreases quality of life (Wing & Wolf, 2000). Effects have been confirmed using a longitudinal model (Horton, Wing, Marshall, & Brownley, 2009).

Summary

In this chapter, we first provided an overview of methods needed for emerging research on emotion and olfaction and emphasized the importance of methods useful for implicit processes in recent research (see Freyberg, Wilson, & Haviland-Jones, 2015, for more detail). We then provided an overview of the three parts of the olfactory system and took particular note of recent discoveries. Future research is likely to attend to the separable functions of this complex system. The main part of the chapter reviewed examples from several areas of current research. These included human mood body odors, nonhuman chemosignals that have emotional and social significance, and, finally, naturally occurring environmental chemosignals that affect moods and health.

As we make progress in olfaction and emotion we are learning that the olfactory system does not provide much focus on the direction or identification of objects and may be constructed so that it is relatively "blind," as Sela and Sobel (2010) propose. We proposed that the olfactory system is designed more as a subconscious, parallel, rapid processor that prompts searches to be carried out often by the other senses (Haviland-Jones & Wilson, 2008). This system is probably an ongoing, not-quite-conscious, match/mismatch process that is correlating bits of information between olfaction and the other sensory systems. It is our hypothesis that the olfactory system is actively and continuously searching for existing communicative background information, especially related to emotional and motivational issues. The subtle orientation or perhaps bias provided by chemosignals can shift behavior or attention slightly to accommodate the search without interfering with ongoing behavior. That the brain responds without awareness to odors was first clearly demonstrated by Pause (2012). Her research has been the impetus for and has continued to support the position that awareness of body odor in particular is not necessary for responses; that there are different brain processes for body odor than for common odors. This has raised the question of whether there are dual roles for implicit and explicit processes in human odor communication.

We had first proposed the subconscious, parallel, rapid processor in our previous review of olfaction and emotion (Haviland-Jones & Wilson, 2008), somewhat tentatively. We called it the *search engine hypothesis*. Since then, there has been some support, both evidential and theoretical. For example, the potential emotional impact of mood chemosignals is established by several researchers. Even when not identified, one person's body chemistry affects another's facial movements and attributions, and alters the semantic web so that words related to the mood odor become more frequent in use and more quickly identified (for discussion of communicative aspects, see Haviland-Jones, Wilson, & Freyberg, 2015; Lubke & Pause, 2015). A similar process has been found for a few other nonhuman odors including "floral." Much work remains to be done before we can be confident about the extent of the possible discrete cues and the constraints on their effects.

A "Gedanken experiment" may help illustrate the functions of the putative search engine. This shows how we search for a target or event or even memory that is congruent with the olfactory cue. In the process, we are very likely to believe that the origin of the search was in the seen or heard or touched target or event that was identified later in the search, skipping the subconscious olfactory cue. If there is a lingering fear chemosignal in a room and someone enters, we would predict that it would prompt a rapid subconscious search of the environment for related contextual cues, as well as cues from an internal memory network. The mere presence of a fear chemosignal may affect arousal as the olfactory system is attentive to the cue. Whether it prompts fear behavior beyond the behavior attendant on a search such as visual scanning (head and eye movements) is not determined, but depends on other available information gathered in the memory or environmental scan. For example, if the persons greeting each other in this room continue to be relaxed, finding no other cues for fear, the incongruent fear signal will not change their behavior. If there is some other ambiguous cue, such as lights blinking, then the fear chemosignal leads to a sense of threat. If the lingering chemosensory cue had been from happiness, the same blinking lights might have been interpreted as something amusing. From a more personological position, the person in the room might be characteristically anxious (see Magai & Haviland-Jones, 2002; Pause et al., 2010) and any prompt to search for threat might initiate a well-learned set of anxious behaviors and attributions. In none of these cases would it be likely that the fear chemosignal would be identified as the source of the search.

The *search engine* also can be called into operation even by scents of which we are aware. In these instances it is the process that is not acknowledged. In the examples of perfumes and floral fragrances, it is often the case that there is an easily detectable odor; these scents influence mood, intimate behavior, attributions, and the semantic network. We expect, however, that most people attribute their better moods and friendly behavior to discernible objects and people, not to something in the air, though that is a well-worn and apt metaphor.

Future research on the search engine hypothesis will profit both from extending the research into new areas, including developmental and cross-cultural, and making it more inclusive of research in other areas. For example, in a variety of sensory fields there are parallel theories such as the automaticity theory (e.g., Bargh, Schwader, Hailey, Dyer, & Boothby, 2012; Bargh, Gollwitzer, Lee-Chai, Barndollar, & Trötschel, 2001). For a limited example, Bargh and colleagues (2012) found that there is an "embodiment" of sensory processes in which there are metaphoric associations for sensory inputs. Warm air is associated with warm feelings and heavy weights with seriousness. In olfaction, we find many examples to bolster the embodiment concept such as that floral scent is associated with happiness (Haviland-Jones et al., 2005), or fishy odors with untrustworthiness (Lee & Schwarz, 2012), or cleanliness with virtue

(Liljenquist et al., 2010). In the case of odors, however, more attention is needed to the adaptive origins of the connections (e.g., see Haviland-Jones et al., 2005, on the coevolution of flowers and people, or Schiffman et al. 2001, on malodors).

A critical factor to consider in olfaction and emotion is that chemosignals—whether from people, processed or synthetic scents, or the environment—can encode valuable emotional information and affect changes. In this new century alone we have discovered that people can communicate emotions with body chemicals. In addition, some scents affect wide categories of behavior, from approach to attribution to semantic networks and to effects on the immune and cardiovascular systems. In other words, chemosignals have been shown to have wide-ranging effects on mood, attention, behavior, and attribution. It remains part of the challenge to understand why much of the influence of chemosignals on emotion is out of ordinary awareness. In spite of the many recent advances and intriguing pockets of discovery, emotion research in the area of olfaction remains open—a fast, growing, exciting field for both theoretical and applied research.

CHAPTER 12

Interoception and Emotion

A Neuroanatomical Perspective

A. D. (Bud) Craig

When someone asks you "How do you feel?," your answer includes your bodily feelings as well as your emotional feelings. The embodiment of emotions is fundamental for many observers (Barrett, Quigley, Bliss-Moreau, & Aronson, 2004; James, 1890/2007; Wiens, 2005). This chapter presents evidence indicating that bodily awareness, or more accurately interoceptive awareness, has a crucial role in emotional awareness—in other words, that the neural substrates responsible for subjective awareness of your emotional state are based on the neural representation of your body's physiological state.

Interoception Redefined

The word "interoception" originally meant sensory input from the "interior" of the body (Sherrington, 1900), but modern neuroanatomical evidence shows that primates have a phylogenetically novel sensory pathway, which represents the ongoing status of all tissues and organs of the body, including viscera, muscle, bone, and skin; thus, it makes sense to redefine the term "interoception" to mean the sense of the physiological condition of the entire body (Craig, 2002). In all mammals, this sensory information provides the continuous input required for ongoing control of blood flow and respiration—that is, control of smooth muscle—whereas the exteroceptive and proprioceptive sensory inputs that underlie discriminative touch and limb position sense, respectively, are used to control skeletal (or striated) muscle. This conceptual distinction differs from the conventional view, which holds that the discriminative cutaneous feelings of temperature and pain are processed along with discriminative touch in the well-recognized body map ("homunculus") in the Rolandic cortex, while the less distinct visceral feelings are processed in more archaic regions. That categorization obscures the fact that neither stimulation nor damage of somatosensory cortices produces or alters feelings of temperature and pain, and it ignores both the inherent emotional (i.e., affective and motivational) qualities and the reflexive autonomic effects that characterize such bodily feelings. Modern evidence shows that the neural systems for interoception and exteroception are morphologically and genetically distinct, and accordingly, textbooks are beginning to incorporate this conceptual distinction. The interoceptive pathway to the cortex has deep significance, because it is most highly developed in hominids, and in humans it underlies not only all bodily feelings but also subjective awareness of "the material me."

We are all familiar with the feelings that come from our bodies, such as warm, cool, hungry, thirsty, or the feeling that something hurts, and whether that something is skin, muscle, or a tooth. Yet, we all experience these interoceptive feelings differently. Individual interoceptive awareness scores vary widely, as measured with a heartbeat perception task (e.g., the accuracy of heartbeat counts over intervals of 30–60 seconds). Interoceptive awareness correlates with sensitivity to and tolerance for a painful stimulus, with gastric sensitivity, and with self-reports of bodily awareness (Herbert & Pollatos, 2012; Pollatos, Fustos, & Critchley, 2012). An individual's heartbeat awareness score also correlates with autonomic reactivity, and with self-rated intensity of emotional feelings, whether positive or negative. Further, better heartbeat perceivers are better at reading their own emotional feelings, as well as others' emotional feelings; they also function better cognitively in tasks of selective and divided attention, and in decision-making tasks based on environmental cues or intuitive choices (Dunn, Evans, Makarova, White, & Clark, 2012). They even have a more accurate subjective sense of the passage of time in the range of 8–20 seconds (Meissner & Wittmann, 2011). Importantly, better heartbeat perceivers display better self-regulation of energy expenditure. In fact, optimal behavioral performance in elite athletes and military special operations warriors is crucially dependent on activity in the interoceptive pathway that is described in this chapter (Paulus, Flagan, Simmons, Gillis, Kotturi, et al., 2012).

Interoceptive Feelings and Homeostatic Emotions

The interoceptive pathway originates in sensory fibers that represent the condition of the body for the purpose of homeostasis, that is, the ongoing, hierarchically organized neurobiological process that maintains an optimal, energy-efficient balance across all aspects of the physiological condition of the body. Homeostasis in mammals comprises autonomic, neuroendocrine, and behavioral mechanisms that support many integrated functions. In humans, homeostatic behavioral motivations are accompanied by distinct interoceptive feelings; the interoceptive modalities include all feelings from the body, such as temperature, pain, itch, hunger, thirst, muscle ache, visceral urgency, "air hunger," and so on. Consistent with the view that an emotion in humans consists of a sensation and a motivation with direct autonomic sequelae (Rolls, 1999), I regard these feelings and the associated behavioral motivations as homeostatic emotions. This concept is directly implied by the neuroanatomical organization described below, and it emphasizes the essential autonomic role of the affectively charged feelings from the body and explains why they have strong autonomic sequelae.

Thermoregulation provides a good example of a homeostatic emotion. The salient purpose of thermoregulation, as of homeostasis, is optimal energy management in support of life. All animals thermoregulate, even amoeba, and the primordial means of thermoregulation is motivated behavior. We normally think of temperature sensation as a discriminative cutaneous (exteroceptive) sensory capacity. However, the obligatory hedonic affect (pleasantness or unpleasantness) we feel with each temperature stimulus is the perceptual concomitant of behavioral thermoregulatory motivation. This affect highlights the overarching importance of temperature sensation for homeostasis, because its valence depends directly on your body's thermoregulatory needs (Mower, 1976). Thus, the cool glass of water that feels wonderful if you are overheated feels gnawingly unpleasant if you are chilled. Conversely, if you are chilled, then a hot shower feels wonderful, even if it is stinging and prickly, but it would be called painful if you were too warm. Similarly, if you remain in a room that is too chilly (or too warm) for energy-efficient thermoneutrality (or if you place your hand on an object that is too cold or too hot), then you feel a growing discomfort (which as it increases is called painful) until you respond in a behaviorally appropriate manner. In the same way, eating salt or sugar is pleasant (and thus motivated) if the body needs it, but it becomes unpleasant and distasteful after you have eaten enough (i.e., "stimulus-specific satiety"). These affective feelings reflect behavioral motivations that are driven by the homeostatic needs of the body, and in humans this combination of a feeling and a motivation is a homeostatic emotion. Note that homeostatically motivated behaviors occur in all animals and require no awareness of accompanying feelings. In fact, the structural absence in subprimates of the pathways described below implies that they cannot experience feelings from the body of the same kind or in the same way that humans do.

Thus I concur with the idea that emotional behaviors evolved as energy-efficient means of producing goal-directed actions that fulfill homeostatic and social needs (Darwin, 1872/1965). I believe that our capacity for awareness—of our emotional behaviors and of our concomitant subjectively experienced feelings—evolved because it afforded enormous enhancement of the efficiency, complexity, and purview of emotional communication. Modern research shows that our emotions guide our decisions and our behaviors, and that interoceptive signals and interoceptive awareness are crucial (Montague, 2006). Some authors regard emotions as episodes, because they focus on measurements of strong emotions like rage or fear, but from an evolutionary neurobiological perspective, emotions are not simply occasional events, rather they are continuously ongoing. Emotional behaviors can occur without subjective awareness and feelings, as they do sometimes in humans and constantly in animals other than hominins, elephants, cetaceans, and corvids, all of which can recognize themselves in a mirror (and make music; see below). From this perspective, all of our behaviors are emotional behaviors.

Interoceptive Awareness from the Bottom Up

As a functional neuroanatomist, I have studied the organization of the brain with anatomical and physiological methods (e.g., tract-tracing, microelectrode recordings) in comparative animals, and with psychophysical and functional imaging methods (e.g., functional magnetic resonance imaging [fMRI]) in humans. My research is based on the knowledge that the brain is not a mystical structure, but rather is reproducibly and evolutionarily well organized for the purpose of maintaining and advancing both the individual and the species. The brain is not color-coded, its internal connections are not readily visible, its physiological operations are ephemeral, and it is organized in serial processing streams and hierarchical networks that are difficult to analyze. Early studies identified the sensory regions (e.g., for vision, touch) and motor regions (skeletal or visceral activation) of the human cerebral cortex with lesions and electrical stimulation. Modern functional imaging studies, which produce color-coded maps of brain activation based on changes in local blood flow, have validated the early insights and are now used in experimental psychology to reveal brain regions that are active during different cognitive and emotional tasks. Such studies are constrained by inherent limitations in temporal, spatial, and statistical resolution, and most importantly by the fact that a top-down phenomenological approach (sometimes referred to as "blob-ology"; see Sternberg, 2000) generally does not reveal the underlying neural organization. By contrast, the findings described in this chapter are built on a bottom-up view of the ascending sensory pathway that represents the physiological condition of the body.

I describe first the functional neuroanatomical characteristics of the interoceptive (homeostatic sensory) pathway in primates, beginning at the spinal level and proceeding up the neuraxis to the brainstem and thalamo-cortical levels in monkeys and in humans. Then, I highlight functional imaging experiments that demonstrate activation by cool stimuli, studies that validate the identification of the ascending interoceptive pathway and support the concept of homeostatic emotions. One of these experiments revealed the progression of interoceptive integration that underlies our subjective awareness of bodily feelings. Next, I summarize a wealth of convergent evidence indicating that the same regions are involved in all subjective emotional feelings, which substantiates the interoceptive basis of emotional awareness. Finally, I describe evidence for a left–right emotional asymmetry in forebrain processing. These insights identify interoceptive processing regions that can serve as treatment targets for emotional disorders.

The Ascending Interoceptive Pathway in the Macaque Monkey

Modality-selective peripheral sensory nerve fibers that represent all homeostatic sensory activity generate the distinct affective bodily feelings by way of discrete ascending sensory channels that originate in lamina I of the superficial dorsal horn. Activity is conveyed specifically first to the autonomic cell columns in the spinal cord, then to the cardiorespiratory and homeostatic sensorimotor regions in the brainstem. Forebrain connections that evolved in primates surmount the ancient homeostatic system and provide a dual projection to the limbic sensory cortex (in the insula) and limbic motor cortex (in the cingulate region; Figure 12.1; see Craig, 2002, 2004, 2014, for detailed descriptions).

The Interoceptive Dorsal Horn

Small-diameter (A-delta and C) primary sensory fibers (which include nociceptors, thermoreceptors, osmoreceptors, and metaboreceptors) innervate every tissue of the body (including bone) and report all aspects of the physiological status by signaling temperature, hypoxia, hypoglycemia, hypo-osmolarity, acidity, interleukin-1-beta, muscle metabolic products that uniquely signify muscular work, and so on. They conduct slowly and have low rates of ongoing activity, which is energy efficient. They terminate monosynaptically on projection neurons in lamina I (or the marginal zone) at the top of the superficial spinal (and trigeminal) dorsal horn. In contrast, the exteroceptive large-diameter A fibers that innervate mechanoreceptors and proprioceptors terminate on large neurons in the deep dorsal horn.

These two regions (i.e., the superficial [or interoceptive] dorsal horn and the deep [or exteroceptive] dorsal horn) are morphologically and genetically distinct. During development, these two regions arise differentially from apical and axial neuroepithelium, respectively, in a remarkably coordinated ontogenetic sequence. The lamina I neurons originate embryologically from cells in the lateral horn of the intermediate zone—that is, from progenitors of the autonomic cell columns—and they migrate to the top of the dorsal horn at precisely the right time to meet the ingrowing small-diameter fibers. Their migration is facilitated by a substantive rotation of the entire dorsal horn that simultaneously leads the large-diameter sensory fibers in the classic recurrent trajectory to the large neurons in the deep dorsal horn, which originate from the alar plate and serve as interneurons for skeletal motoneurons. This pattern is guided by two ancient and distinct gene regulatory networks in all vertebrates. Interestingly, in half of the families of birds, the interoceptive and exteroceptive regions end up in a side-by-side arrangement, instead of the top-and-bottom arrangement that is present in all mammals.

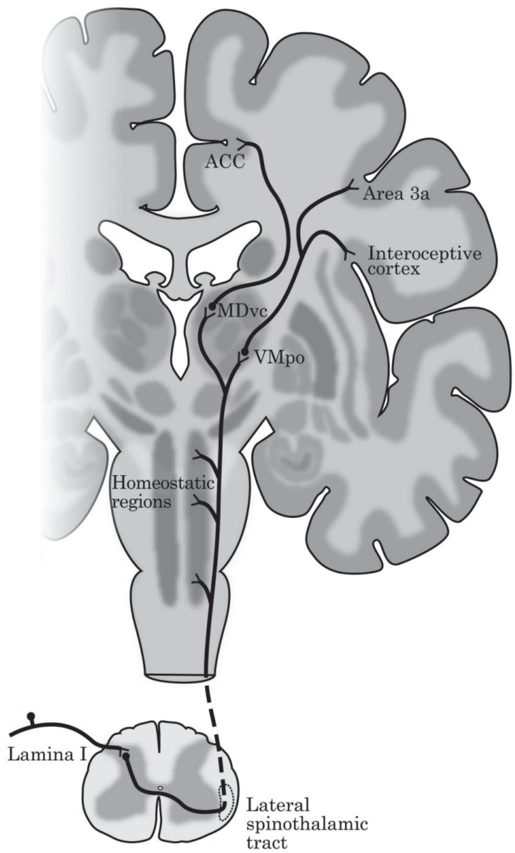

FIGURE 12.1. A schematic representation of the homeostatic (interoceptive) afferent pathway in primates that represents the physiological condition of the body. The main forebrain projections are to the dorsal posterior insula (interoceptive cortex) and to the medial prefrontal region (the anterior cingulate cortex, or ACC). The pathway that ascends from lamina I of the spinal cord via the lateral spinothalamic tract represents the sympathetic half of the homeostatic afferent system, and a parallel pathway via the nucleus of the solitary tract and the basal portion of the ventromedial nucleus in the thalamus represents its parasympathetic half (not depicted). From Craig (2003). Reprinted, with permission, from the *Annual Review of Neuroscience*, Volume 26. Copyright 2003 by Annual Reviews (*www.annualreviews.org*).

Thus, together the small-diameter sensory fibers and the lamina I neurons constitute a coherent homeostatic sensory system that is the sensory complement of the visceral motoric outputs of the sympathetic division of the autonomic nervous system. Small-diameter sensory fibers in the cranial parasympathetic nerves (e.g., vagus and glossopharyngeal) that innervate all cranial and internal organs similarly terminate in a specialized region of the medulla (the nucleus of the solitary tract [NTS]) that drives motoric outputs in the same nerves. Projection neurons in the NTS and in lamina I lead in parallel to all brainstem homeostatic regions and, in primates, also to relay nuclei in the thalamus. Together the NTS and lamina I pathways convey homeostatic sensory input from the entire body.

Lamina I Neurons

Lamina I neurons in cats and monkeys comprise several modality-selective classes that can be regarded as virtual "labeled lines," or discrete sensory channels, that engender distinct feelings from the body, such as first (sharp) pain, second (burning) pain, cool, warm, itch, affective (sensual) touch, muscle ache and cramp, and so on, upon integration in the forebrain. Each class consists of a morphologically distinct type of neuron that receives input selectively from a particular subset of small-diameter sensory fibers. These classes can be differentiated on the basis of stimulus responses, axonal projections, descending modulation, and electrophysiological, pharmacological, and immunohistochemcal properties.

For example, the cool-sensitive thermoreceptive-specific (COOL) lamina I neurons respond linearly to graded innocuous cool stimuli (Figure 12.2A) and plateau at noxious cold temperatures, just as human cool sensitivity does. In contrast, the polymodal nociceptive (heat, pinch, and cold [HPC]) lamina I neurons respond selectively to noxious *heat*, *pinch*, and noxious *cold*, and their responses correspond with the psychophysical characteristics of the human sensation of burning pain. Whereas the COOL neurons are pyramidal-shaped cells, the HPC neurons have multipolar shapes (Figure 12.2B); similarly, the HPC neurons are inhibited by morphine (both systemic and local), while the COOL neurons are facilitated.

These characteristics fit with the conventional view of lamina I neurons as "pain and temperature" cells, but certain anomalies fit better with a broader role and signify a role in homeostasis. For example, the HPC cells evince an accelerating discharge to noxious cold stimuli of increasing intensity, consistent with the feeling of burning cold that we report for thermal stimuli below approximately 59°F (15°C). However, the HPC cells are also sensitive to innocuous cool stimuli below a mean threshold of approximately 75°F (24°C)—that is, at cool temperatures that normally do not evoke a feeling of burning cold pain. Such activity is "anomalous" for a "pain cell," but it is entirely consistent with the fact that ambient temperatures below approximately 75°F become progressively uncomfortable and can ultimately be fatal. The evidence indicates that generation in the forebrain of the feeling of burning pain by HPC cells is normally inhibited by the activity of COOL cells. The COOL cells respond to temperatures cooler than neutral skin temperature (approximately 90°F [32°C]), and they are strongly activated by temperatures below 75°F. But, if COOL activity is suppressed by a blockade of A-delta fiber activity (using pressure applied to a peripheral nerve) or by simultaneous warming in the "thermal grill illusion of pain" (which does not inhibit HPC activity), then a feeling of burning pain is unmasked with cool stimuli at such temperatures. Thus, the cool activation of HPC cells below 75°F is consistent with a role in thermoregulatory behavioral motivation, because such temperatures, if maintained for only a few hours, can produce tissue necrosis (called "trench foot" during World War I) and morbid hypothermia.

The role of lamina I neurons in homeostasis is most clearly revealed by the neurons that respond selectively to small-diameter sensory fibers from muscle. While some of these sensory fibers cause feelings of muscle burn, pain, and cramping when strongly activated, many signal muscular work, or energy usage, and some are sensitive to mild vascular distension and signal blood flow; these neurons provide crucial sensory feedback to cardiovascular and respiratory control networks in the brainstem.

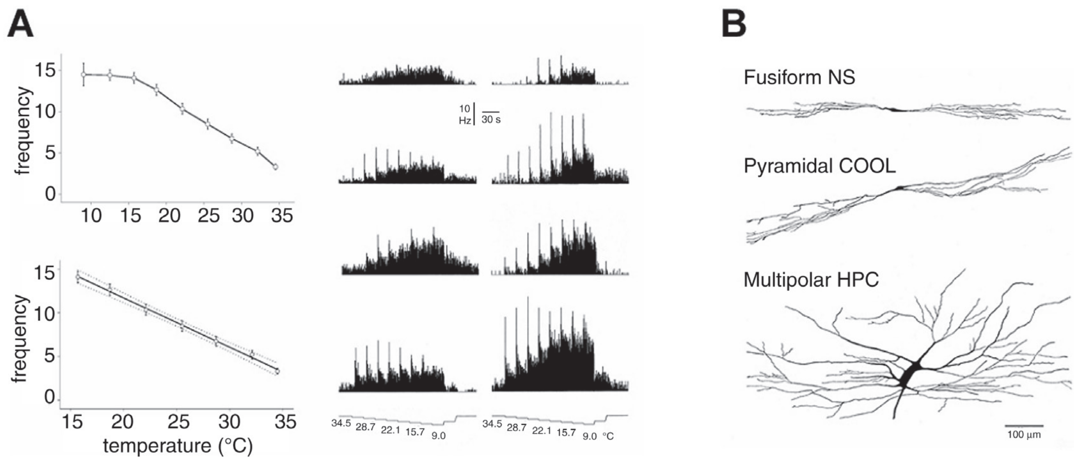

FIGURE 12.2. (A) Original data showing that thermoreceptive-specific lamina I spinothalamic neurons linearly encode skin temperature. The graphs on the left show the ensemble mean, and the graphs on the right show the responses of individual neurons to the characterizing staircase stimulus. From Craig, Krout, and Andrew (2001). Similarly, respiration rate and depth is modulated linearly by the temperature of inhaled air, a signal that only lamina I neurons can provide. Thus, lamina I neurons do not simply act as emergency signals, rather, they are engaged in homeostasis continuously. Furthermore, they represent all physiological conditions—for example, small-diameter sensory fibers can also respond to cytokines, steroids, hormones, and other immune modulators, consistent with the roles of sympathetic and parasympathetic autonomic motor neurons in regulating immune and neuroendocrine functions.

The anatomical projections of the axons of lamina I neurons convey small-diameter homeostatic sensory activity directly to the homeostatic integration and control regions in the spinal cord and brainstem, thereby providing the substrate for the modality-selective somatoautonomic reflexes that are of fundamental significance for homeostatic function (Sato & Schmidt, 1973). In the spinal cord, their *only* major projection is to the autonomic cell columns in thoracolumbar segments, where sympathetic preganglionic output neurons are located. In the brainstem, they project *exclusively* to homeostatic integration sites, such as the ventrolateral medulla, the catecholamine cell groups A1–A2 and A5–A7, the parabrachial nucleus (PB), and the periaqueductal gray (PAG). These sites also receive sensory activity associated with the parasympathetic system by way of the NTS. These sites are all heavily interconnected with the hypothalamus and amygdala in the forebrain. The key role of lamina I in homeostasis is highlighted by the fact that the autonomic cell columns and lamina I are the only spinal sites that receive descending modulation directly from hypothalamic control sources.

Lamina I Projections to the Primate Forebrain

High-resolution anatomical tracing experiments revealed that the axons of lamina I spinothalamic neurons ascend in the lateral spinothalamic tract at the location where spinal lesions in humans interrupt contralateral feelings of pain, temperature, itch, and sensual touch (Figure 12.1). In subprimates, ascending lamina I activity is processed mainly in brainstem sites (e.g., A1, PB, and PAG), which then provide a more integrated signal to emotional behavioral control regions in the forebrain. In primates, modality-selective lamina I spinothalamic neurons terminate densely and somatotopically in a specific thalamo-cortical relay nucleus (VMpo). A parallel pathway, also unique to primates, conveys homeostatic sensory input from the vagal and glossopharyngeal nerves by way of the NTS (and PB) to a rostrally contiguous thalamo-cortical relay nucleus (VMb). These thalamic nuclei in turn project topographically to a discrete area of dorsal posterior insular cortex that is centered in the superior limiting (peri-insular) sulcus (Craig, 2014).[1]

Together, these projections provide a direct cortical image of all homeostatic sensory activity from the body. Notably, this *interoceptive cortex* is delimited by labeling for the receptors of corticotropin-releasing factor, which many investigators regard as a definitive marker for homeostatic processing (Sanchez, Young, Plotsky, & Insel, 1999). The interoceptive cortex may be the tensile anchor that is responsible for the sharp cortical fold of the lateral sulcus; this fold improves energy efficiency by minimizing the separation of interoceptive cortex from other homeostatic processing regions (e.g., in the cingulate sulcus). Our recent analyses in the macaque monkey suggest that interoceptive cortical activity is integrated topographically in the middle insula first with exteroceptive (i.e., cutaneous mechanoreceptive and proprioceptive) and other activity important for emotionally salient object-related movements, and also with multimodal amygdalar and ventral striatal inputs important for other-directed emotional behaviors (e.g., face and hand movements or vocalizations used for social communication and identification; Evrard, Logothetis, & Craig, 2014).

Lamina I neurons in primates also provide a direct thalamo-cortical pathway that activates the cingulate motor area in the anterior cingulate cortex (ACC; or the anterior middle cingulate) by way of a medial thalamic relay (MDvc) and VMpo, as well as integrated homeostatic sensory inputs from the brainstem (both PB and PAG). By contrast, in subprimates the medial thalamic sources of input to the ACC receive only the integrated inputs from the brainstem. This cingulate cortical area can be regarded as limbic motor cortex in all mammals, because of its association with homeostatic (autonomic and behavioral) output activity and its descending projections to the PAG in the brainstem; it is also a major source of descending cortico-spinal motoric activity. The insular cortex can be regarded as the complementary limbic sensory cortex, because of its association with homeostatic sensory activity via inputs from lamina I, NTS, and PB, and its descending projections to PB. This homeostatic sensory-motor concept fits well with the hierarchical organization of homeostatic sensory-motor integration and with the modern view that the frontal cortex is organized globally in a sensory and a motor network.

The Ascending Interoceptive Pathway in Humans

Thermosensory Activation of the Posterior Insula

Temperature, like pain and itch, is a feeling from our bodies that we normally externalize. We readily ascribe temperature to an object or the environment. Temperature sensation has always been regarded as a discriminative exteroceptive cutaneous sensory capacity allied with the sense of discriminative touch (i.e., mechanoreception). However, the thermoreceptors in our skin, muscles, and viscera actually report local tissue temperatures, which are needed for the energy-efficient control of body temperature (i.e., thermoregulation). The functional neuroanatomy of temperature sensation in humans reflects the primordial importance of temperature sensibility for autonomic control and homeostasis.

Our quantitative positron emission tomography (PET) study of cool stimulation of the palmar hand demonstrated that the location of discriminative thermosensory cortex in humans fits precisely with the location of interoceptive cortex identified by functional and tracing studies in the monkey described above (Craig, Chen, Bandy, & Reiman, 2000; Hua, Strigo, Baxter, Johnson, & Craig, 2005). Plate 12.1 (see color insert for plates) shows three different analyses of brain activation during the application of six different steady cool temperatures at both a low (yellow) and a high (red) statistical criterion. The first row is a simple contrast between the highest and lowest temperatures, which served as a mask for subsequent analyses. The second row shows a regression analysis against thermode temperature; it reveals that only one activation site in the contralateral cortex was linearly correlated with objective stimulus temperature (i.e., the red blob on the left side at level 24). That matches the linear response of COOL lamina I spinothalamic neurons shown in Figure 12.2, and therefore that evidence identifies primary thermosensory cortex.

That location also fits with clinical reports of patients with stroke damage that produced thermanesthesia (Schmahmann & Leifer, 1992; Greenspan, Lee, & Lenz, 1999). Strikingly, this region is not part of the somatosensory cortices that represent touch sensation, which are in the postcentral gyrus (S1) and in the parietal operculum (S2). Rather, the association of insular cortex with visceral sensation and autonomic function as limbic sensory cortex fits neatly with the view that temperature sensation is important first of all for homeostasis. These findings provided the first evidence for interoceptive cortex in humans.

Characteristics of Human Interoceptive Cortex

Consistent with our PET thermosensory study, modern functional imaging, lesion, and stimulation studies in humans confirm the crucial role of the dorsal posterior insula for sensations of graded pain, graded temperature, graded itch, dynamic or painful muscle sensation, affective (sensual) touch, hunger, thirst, taste, stomach distension, cardiorespiratory activity, "air hunger," and so on (e.g., Olausson et al., 2002; Cechetto & Shoemaker, 2009; see Craig, 2014, for additional references). The activation associated with sensory input from the cranial (parasympathetic) nerves (e.g., during stomach distension) are represented just anterior to activation by cutaneous temperature or pain (i.e., input from sympathetic innervation), though in some studies, the interoceptive activation seems to have merged with activation in the mid-insula (see Craig, 2014). Overall, the evidence supports the presence in humans of a coherent interoceptive cortex that engenders the cortical image of the physiological condition of the body and constitutes the primary sensory cortex for all affective bodily feelings. It is important to recognize that this pathway emerged evolutionarily as an extension of the hierarchical homeostatic system; thus, affective feelings from the body in humans reflect its homeostatic condition.

The findings in the macaque monkey indicate that VMpo + VMb and interoceptive cortex are topographically organized in the anterior-to-posterior (face-to-foot) direction. The available imaging evidence in humans demonstrates the same somatotopic gradient in the dorsal posterior insula for sensations of heat pain, innocuous cool, muscle pain, and affective touch (e.g., Brooks, Zambreanu, Godinez, Craig, & Tracey, 2005; Hua et al., 2005; Henderson, Gandevia, & Macefield, 2007; see Craig, 2014, for additional references). Significantly, this gradient is orthogonal to (i.e., independent of) the medial-to-lateral (face-to-foot) organizational gradient of the main somatosensory regions in the thalamus and cortex. This contrast substantiates the morphological distinctness of the interoceptive cortex. Unfortunately, its location had previously been assigned to the second somatosensory cortical area (S2), and most atlases today still contain that error.

Notably, VMpo is greatly enlarged and more complex in humans than in the macaque monkey, and so is the insula. Interoceptive cortex in the monkey extends the entire antero-posterior length of the insula (approximately 6–8 millimeters), but in humans the insula is much larger (approximately 50–60 millimeters), and interoceptive cortex occupies only the posterior third. Whereas almost all of VMpo and interoceptive cortex in the monkey is devoted to discriminative temperature, pain, and taste activity, in humans this pathway seems to represent all aspects of homeostatic sensory activity. For instance, in humans the many small-diameter sensory fibers from muscle that are activated by ongoing vascular distension are apparently included, because even mild cardiovascular maneuvers (e.g., passive cycling) activate the dorsal posterior insula; most trenchantly, the human participants in one study reportedly described a mild intramuscular vascular distension as a feeling of deep, innocuous, localized "pressure" (Haouzi, Chenuel, & Huszczuk, 2004; Cechetto & Shoemaker, 2009; Cui, McQuillan, Blaha, Kunselman, & Sinoway, 2012).

Interoceptive Activation of Human Cingulate Cortex

Activation is reported in the cingulate region in nearly all functional imaging studies of pain (referred to here simply as ACC, but including the anterior mid-cingulate cortex), as well as in studies of muscle and visceral sensation. Functional imaging studies that examined the thermal grill illusion of pain and hypnotically modulated pain unpleasantness associate ACC activation with the affective motivation of pain (i.e., negatively valenced urgency; see Craig, 2014); that interpretation is consistent with the view that pain is a homeostatic emotion, which simultaneously generates both a feeling and a motivation. That interpretation is also consistent with the association of the ACC and medial prefrontal cortex with behavioral agency, including measures of motivation (e.g., outcome value; Kennerley & Wallis, 2009) and performance (e.g., error or outcome likelihood; Brown & Braver, 2005; Alexander & Brown, 2011).

Activation in the ACC was not observed in our PET thermosensory study. However, in a subsequent fMRI study, we observed that dynamic cooling stimuli applied to the hand produced graded activation both in the dorsal posterior insular cortex and at a site in the cingulate region comparable to the site where we had previously observed activation during a painful cold (or hot) stimulus (Hua et al., 2005). Since a rapidly dropping temperature presents a homeostatic challenge, it makes sense that it would produce a stronger behavioral motivation signal than a steady innocuous cool stimulus. Together, these findings support the view that temperature produces both a feeling and a behavioral motivation in humans—that is, a homeostatic emotion.

In functional imaging studies, interoceptive stimuli usually activate both insular and cingulate regions. Just as for temperature, stimuli that cause feelings of itch, muscle ache, hunger, and thirst are also homeostatic emotions that drive behavior, and they also activate both regions. The condition of our bodies directly affects our feelings and our motivations continuously.

The Anterior Insula and Subjective Feelings from the Body

Activation during Subjective Awareness of Thermosensory Feelings

In our PET thermosensory study, we had the opportunity to ask each participant to rate the intensity of his or her subjective feeling for each cool stimulus, and thus to ask, "How do we feel temperature?" Our subjective sense of innocuous temperature is fairly linear, but it is not as linear as the ascending COOL lamina I sensory channel. The deviation is sufficient to provide a robust statistical difference between cortical activation associated with subjective rather than objective temperature. The third row in Plate 12.1 (see color insert for plates) shows a regression analysis of the same PET dataset against the participants' subjective ratings of the cool intensity. A large area of activation in the anterior insula and orbitofrontal cortex on the right side is conspicuous in these data. Close comparison of the activation blobs at level 24 in rows 2 and 3 reveals that in the subjective regression analysis, a new activation site appears just anterior to the main site activated in the objective temperature regression analysis.

These data indicate that there is an immediate rerepresentation of thermosensory activation in the middle insula on the homolateral side, just anterior to the interoceptive cortex. This rerepresentation must be an abstracted or integrated re-representation, because its activity is significantly more closely related to subjective ratings than to objective temperatures. The data show activation in the mid-insula on the other side, too, indicating a commissural transfer; that leads to a lateralized region of activation in the anterior insula and orbitofrontal cortex on the right side that appears large enough to contain a series of rerepresentations, which are strongly correlated with subjective feeling.

This is a neurobiologically parsimonious pattern of activation, because progressive rerepresentations that combine feature extraction and cross-modality integration are present in the serial processing streams observed in the visual, auditory, and (parietal) somatosensory cortical regions; serial rerepresentations are also consistent with the pattern of evolutionary emergence of new processing regions in the primate cortex (Krubitzer & Kaas, 2005). The posterior-to-anterior gradient of increasingly complex integration fits also with the gradient present in dorsal prefrontal cortex (Koechlin & Jubault, 2006).

These PET thermosensory findings demonstrated for the first time that subjective bodily feelings are based directly on interoceptive integration in insular cortex. These results suggest that the activation in the anterior insula substantializes (provides the basis for) our human experience of bodily feelings. The strong lateralization is clear evidence of hemispheric specialization (see the section "Bivalent Asymmetry in the Bicameral Forebrain").

Activation during Subjective Awareness of Other Bodily Feelings

Thus our PET imaging data on temperature sensation illuminate an anatomical model in which human subjective awareness of feelings from the body is generated directly from rerepresentations in the insular cortex of the interoceptive image of the body's homeostatic condition. Imaging and lesion data for other bodily feelings (e.g., heat pain, affective touch and taste) show a similar progression of activity from the dorsal posterior insula first to the middle insula bilaterally and then to the anterior insula (predominantly on the left or right side; e.g., Brooks, Nurmikko, Bimson, Singh, & Roberts, 2002; Olausson et al., 2002). (Note that activation peaks in the primary taste cortex and mid-insula have not yet been dissociated; see Craig, 2014.) This progression is supported by modern meta-analyses of the functional associations, functional connectivity, and structural covariance of the insular cortex, which indicate distinct differences between the posterior, middle, and anterior portions of the insular cortex (e.g., Deen, Pitskel, & Pelphrey, 2010), with greatest complexity in the anterior insula (Cauda, Costa, Torta, Sacco, D'Agata, et al., 2012).

Whereas subjective bodily feelings and emotional feelings alike associate most strongly with activation in the anterior insula (see the section "The Anterior Insula and Subjective Emotional Feelings"), the evidence suggests that bodily feelings emerge first in the middle insula, as revealed in our PET thermosensory study. Activation in the middle insula also occurs during cutaneous mechanical stimulation or hand movement (which first activates the somatosensory and motor cortices); complementary clinical reports suggest that this represents a "feeling," because a lesion of the mid-insula (especially on the right side) can produce loss of the subjective feeling of (deficits in) touch or limb movement on the entire opposite side of the body (called "anosognosia for hemianesthesia or hemiplegia"; Karnath & Baier, 2010). The subjective feeling of limb ownership also correlates with activation in the mid-insula, based on studies of the "rubber hand illusion" (see Craig, 2009, 2015).

Similarly, the affective bodily feeling of craving cigarettes (or cocaine or food; i.e., hunger) correlates with mid-insula activation, and this is complemented by the observation that a lesion of the middle and anterior insula enabled heavy smokers to quit immediately, saying that the feeling of craving cigarettes was gone (Naqvi & Bechara, 2010). Last, a PET study of a maintained feeling of unpleasantness due to a painful cutaneous or intramuscular stimulus showed maintained activation exclusively in the bilateral mid-insula (Schreckenberger, Siessmeier, Viertmann, Landvogt, Buchholz, et al., 2005). Nevertheless, subjective awareness of bodily feelings correlates most strongly with activation in the anterior insula, as clearly demonstrated (for the first time) in our PET thermosensory study. Similarly, the anterior insula is the region most strongly activated during subjective bodily feelings of lust and intumescence in men or orgasmic quality in women (Bianchi-Demicheli & Ortigue, 2009). Affective touch activates contralateral dorsal posterior insula, then bilateral mid-insula, then left anterior insula in association with a subjective feeling of pleasure (Olausson et al., 2002). The same pattern has also been shown in studies of heat pain (see Craig, 2015, for additional references).

The location of taste cortex in humans was initially assigned to the anterior insula, analogous to the monkey. Subjective ratings of flavors and tastes correlate most strongly with activation in the anterior insula (predominantly left); in contrast, gustatory activation in the posterior/mid-insula is modulated by attention (i.e., primary representation) and homeostatic bodily needs (i.e., overlapping mid-insula integration). Notably, responses to brief tastes of high-quality wines in professional sommeliers were observed in posterior/mid-insula and bilateral mid-insula, and the strongest activation associated with the subjective ratings was to aftertaste in the left anterior insula (which they called "OFC"; Castriota-Scanderbeg, Hagberg, Cerasa, Committeri, Galati, et al., 2005). Thus, this pattern is the same as for other bodily feelings. Last, an individual's subjective interoceptive awareness (measured with a heartbeat perception task and a bodily awareness questionnaire) is most strongly correlated with activation in the right anterior insula, and remarkably, with the physical volume of that area only (Critchley, Weins, Rotshtein, Öhman, & Dolan, 2004).

The Anterior Insula and Subjective Emotional Feelings

Activation in the anterior insula is associated with subjective feelings of each of the six emotional feelings regarded by many as primary: anger, sadness, happiness, surprise, disgust, and fear. Evidence has been obtained by using movie clips or sound tracks lasting 2–3 minutes or by showing a standardized set of photographs depicting emotional scenes. Feelings associated with secondary emotions (e.g., empathic happiness or empathic pain) are also characterized by activation of the anterior insula. Individuals listening to music they enjoy display activation in the anterior insula (L > R; Koelsch et al., 2006). Feelings of romantic love or maternal love in individuals viewing a photograph of their romantic partner or their baby display strong activation in the anterior insula (also L > R). Feelings of unfairness, uncertainty, joy, trust or distrust, and social exclusion are all associated most strongly with activation in the anterior insula (see Craig, 2002, 2009, 2015, for references).

Convergent functional imaging findings reveal that the anterior insula and the anterior cingulate cortices are conjointly activated during all human emotions (Lindquist, Wager, Kober, Bliss-Moreau, & Barrett, 2012). To my mind, that fits with the idea that the limbic sensory representation of subjective "feelings" (in the anterior insula) and the limbic motor representation of motivations (agency, in the anterior cingulate) together form the fundamental neuroanatomical basis for all human emotions (Craig, 2009, 2015). These two regions are the sites most commonly activated across all functional imaging studies.

These findings are complemented by clinical observations; most of the available evidence suggests that the anterior insula is crucial for experiencing feelings, because insular damage disrupts subjective feelings. For instance, a study of patients who had a stroke with restricted insular damage reported "loss of awareness to external stimuli" (Ibanez, Gleichgerrcht, & Manes, 2010). Damage specifically to the anterior insula interrupts emotional awareness and self-conscious behaviors in patients with a neurodegenerative syndrome known as fronto-temporal dementia (Seeley et al., 2007), or patients with depersonalization disorder (Medford, 2012). In one study, three patients were examined who had focal damage in the anterior insula on one side (two left, one right) that specifically included the site that is activated normally during behavioral tests for pain empathy; the authors reported that all three patients had markedly reduced emotional awareness. In rigorous tests, the patients identified pain in others significantly less often and more slowly than normal subjects, and they all failed an interference test of empathic pain feelings (in contrast to patients with damage in the cingulate region; Gu, Gao, Wang, Liu, Knight, et al., 2012).

Contradictory evidence was described in two patients with encephalitis who reportedly retained self-awareness even though the insular cortex of their brains was "completely" destroyed bilaterally (Feinstein, Rudrauf, Khalsa, Cassell, Bruss, et al., 2009; Damasio, Damasio, & Tranel, 2013). However, close examination of the published magnetic resonance imagings (MRIs) reveals that a significant amount of the dorsal anterior insula remains intact in one case on the right side (patient B; see figure 4, row II, left side of image in Damasio et al., 2013), and in the other case on the left (patient R or Roger; see figure 1, 4c, 5c, right side of image in Feinstein et al., 2009), as addressed earlier (see Craig, 2011, 2015). Furthermore, a study by a team that included investigators at the same institution as the prior authors described seven patients who had a stroke with damage to more than half of one insula (four right, three left); they found significantly reduced affect to both pleasant and unpleasant stimuli, along with a "marked attenuation of valence ratings" in response to emotional images, consistent with a crucial role of insular cortex in subjective emotional awareness (Berntson, Norman, Bechara, Bruss, Tranel, et al., 2011). Similarly, more recent clinical lesion studies concluded that the insula is a key structure for emotional embodiment or "the feeling of self" (Grossi, Di Vita, Palermo, Sabatini, Trojano, et al., 2014; Besharati, Forkel, Kopelman, Solms, Jenkinson, et al., 2014).

Intersection of Interoceptive Awareness and Emotional Awareness in the Anterior Insular Cortex

Evidence of several different kinds has accumulated supporting the interoceptive basis (or the embodiment) of emotional feelings. Studies showed that thermal stimulation of the hand can alter interpersonal feelings of closeness or of trust (see Craig, 2009, 2015, for references). A close correspondence was demonstrated between vasoconstriction on the hand and the intensity of feelings of limb ownership during the "rubber hand illusion," and the investigators concluded that "awareness of our physical self and the physiological regulation of self are closely linked in a top-down manner" (Moseley, Olthof, Venema, Don, Wijers, et al., 2008, p. 13169). Others found that emotional intensity and insular activation varied cyclically following each heartbeat (Gray, Beacher, Minati, Nagai, Kemp, et al., 2012), and that pain-related autonomic responses were correlated with the personality traits of neuroticism and introversion (Paine, Kishor, Worthen, Gregory, & Aziz, 2009).

More directly, several fMRI studies reported that the neural activation associated with subjective interoceptive feelings and the activation associated with emotional feelings overlap uniquely in the anterior insula, consistent with psychological evidence that interoceptive (heartbeat) awareness and self-reports of emotional experience are directly correlated (Barrett et al., 2004). One early study (with low spatial resolution) demonstrated synergistic activation of the anterior insula when interoceptive feelings (non-noxious esophageal distension) and graded emotions (viewing graded facial expressions of disgust) occurred simultaneously (Phillips et al., 2003). A more recent study directly compared activation during a heartbeat interoceptive awareness task with activation during emotional feelings evoked by watching a movie; the investigators found a unique region of overlap in the right anterior insula, and critically, the activation at that site was correlated with the intensity of the emotional feelings reported by the participants. The authors interpreted their findings as evidence for the "functional convergence" of emotional and bodily feeling experiences (Zaki, Davis, & Ochsner, 2012).

Studies by another group compared activation while participants attended either to their own internal bodily state or to their own emotional state (Terasawa et al., 2013a, 2013b). In the first study, they found activation during both tasks in the right anterior insula (and the left ventromedial prefrontal cortex); in the second, they identified overlapping activation in the bilateral anterior insular cortex (AIC; and areas in the bilateral temporoparietal junction, lingual gyrus, and medial frontal cortex, and portions of the brainstem). They also reported that the emotional activation in the right anterior insula was positively correlated with neuroticism, while the interoceptive activation there was negatively correlated with "extraversion, agreeableness, and openness to experience," which resembles other results cited above (p. 264). Together, these findings provide strong support for the concept that subjective awareness of both feelings from the body and emotional feelings is engendered in the AIC. In other words, the evidence suggests that all of our feelings are based on the integration of interoceptive activity in the insular cortex that enables us to experience feelings from our bodies. This conclusion was validated by a recent study showing that happiness, or "momentary subjective well-being," is directly correlated with activation in the ventral striatum and the ventral AIC during a series of simple choices with monetary rewards (Rutledge, Skandali, Dayan, & Dolan, 2014).

On the other hand, one paper described a region activated by taste stimuli (while simply held in the mouth) in the left mid-insula and another in the left anterior insula; both regions had also responded to food images in a preceding food discrimination task, but only the food image responses in the posterior region were modulated (selectively) by blood glucose levels. The authors concluded provocatively that their observations contradicted the pattern of interoceptive integration described above (Simmons, Rapuano, Kallman, Ingeholm, Miller, et al., 2013). In fact, their results fit well with these ideas. The posterior region likely included both the primary gustatory cortex (which is modulated by attention to food) and the mid-insular region (which is modulated by homeostatic integration of energy needs); by contrast, the activation in the anterior region corresponds with the activation that occurs during a cognitive task of any kind. That activation was not modulated by blood glucose levels during either the food image discrimination task or the subsequent passive tastant stimulation because in both situations they were irrelevant to the task.

In summary, there is overwhelming evidence that the integrative homeostatic processing mechanisms in the anterior insula (both right and left) provide a crucial substrate for all subjective feelings. This is a major conclusion that has now received convincing support from many convergent lines of inquiry, and in my opinion, deserves to be described in textbooks.

A Homeostatic Model of the Subjective Awareness of Feelings

Thus a refined and integrated image of the state of the body in the AIC seems to provide the basis for the "feeling self." In the homeostatic model I have proposed (Craig, 2009, 2015), the homeostatic sensory (interoceptive) activity that represents the physiological condition of the body is integrated first in the mid-insula—with emotionally salient inputs from all sensory modalities, from subcortical homeostatic control regions (hypothalamus and amygdala) and regions with bivalent hedonic signals of incentive and motivation (ventral striatum, orbitofrontal cortex),—and next in the anterior insula—with emotionally and socially salient activity from other limbic cortical regions (ACC, ventromedial prefrontal cortex), as well as cognitive/planning regions (e.g., dorsolateral prefrontal cortex). This posterior-to-anterior progression of increasingly complex interoceptive rerepresentation and integration in the human insula provides a foundation for the sequential integration of the homeostatic condition of the body with all activity in the body and in the brain representing; the sensory environment; internal autonomic/homeostatic motor state; affective motivational conditions; and finally, emotional, social, cognitive, and intentional conditions (see Figure 12.3).

In this model, the progressive integration of all neural activity—for the purpose of attaining optimal energy efficiency in the control of emotion and behavior—culminates in a complete representation of homeostatic salience as vivid feelings that are continuously changing in the immediate moment (the ongoing *global emotional moment* of

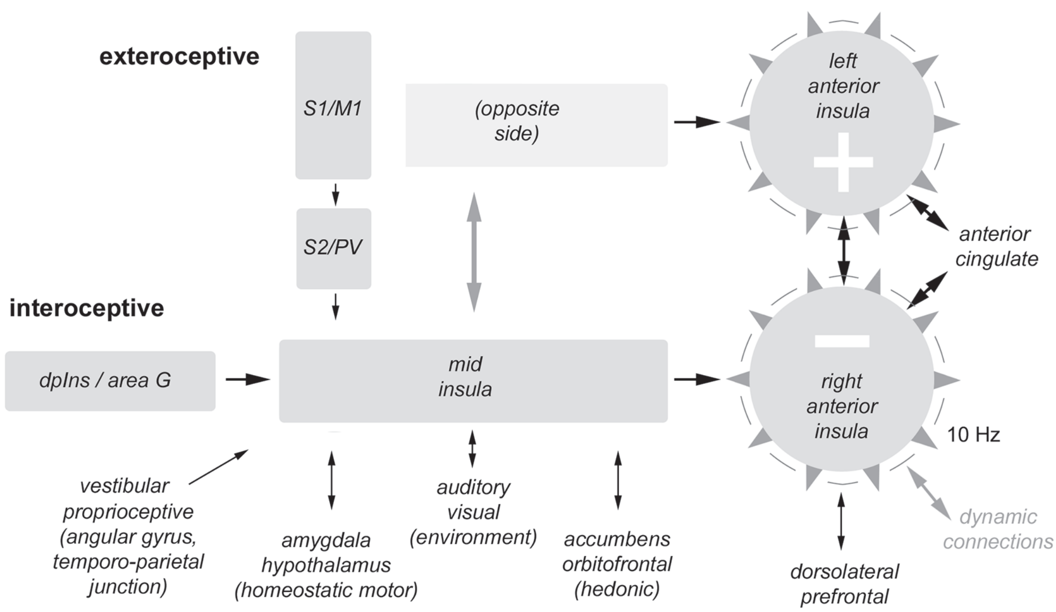

FIGURE 12.3. A conceptual diagram of the progressive integration in the posterior, middle, and anterior insula of interoceptive state with the sensory, autonomic, motivational, and contextual conditions of the body and the brain to produce a finite set of global emotional representations. In this homeostatic model, the right anterior insula represents the energy-consuming (sympathetic) conditions, and the left anterior insula represents the energy-enriching (parasympathetic) conditions.

"now"). The passage of time is incorporated with the generation of quantal storage units that can represent all feelings during a discrete period of present time; in particular, they store the feelings that accumulate in the ongoing global emotional moment during the current discrete time period (or moment). The frame rate of moments is synchronized with a global oscillation frequency (e.g., the alpha waves associated with alert attention; Sadaghiani, Scheeringa, Lehongre, Morillon, Giraud, et al., 2010), consistent with evidence showing that recurrent updating of awareness is synchronized with the alpha rhythm (Chakravarthi & VanRullen, 2012). The array of quantal storage units underpins a cinemascopic representation of the sentient self, or the "material me" across time. This construct has remarkable emergent characteristics, and it offers sensible explanations for a variety of psychological phenomena (e.g., the perceptual moment, emotional time dilation), philosophical concepts (e.g., subjectivity), and clinical syndromes (e.g., anxiety disorders and postraumatic stress disorder [PTSD]). The finite set of quantal storage units constrains the extent of the "specious present"; it provides a flexible mental resource for storing and comparing any neural activity patterns, and it manifests anticipated feelings based on internal models learned by experience. Future expectations and surprises can be described by a temporal-difference reinforcement model or a Bayesian predictive coding model (Seymour et al., 2005; Seth & Critchley, 2013) that is sensitive to negative value prediction errors with the goal of maximizing energy efficiency in the control of emotional behavior (see below; Vidal, Perrone-Bertolotti, Kahane, & Lachaux, 2014).

As I summarized earlier (Craig, 2009, 2015), activation in the AIC is also associated with subjective time perception, directed or maintained attention, perceptual decision making, self-performance monitoring, perception of visual images of one's own face or body, and cognitive functions and mental operations (e.g., during the "feeling-of-knowing"); essentially, the AIC is active during all feelings and all tasks. Accordingly, in the model, the ongoing global emotional moment includes feelings about motivations, intentions, plans, and thoughts, and it can be modified by expectations and motivations based on interconnections between the anterior insula and the ACC and other sites. This perspective mitigates a main criticism of the James–Lange theory (i.e., that it did not allow for feelings of internally generated emotion). It also affords ready explanations of the bidirectional interactions between homeostatic functions and emotional states—for example, in anxiety, somatization, and psychosomatic illness. The model's predictions of the key role of the AIC in subjective time perception are rapidly being confirmed (e.g., Wittmann, 2013; Pfeuty, Dilharreguy, Gerlier, & Allard, 2015; Tomasi, Wang, Studentsova, & Vokow, 2014)

No other region of the brain is activated during all feelings and all tasks. Hence, I proposed that the AIC engenders awareness. To my mind, awareness means knowing that I exist, being able to feel (perceive) that I am feeling (experiencing) the feeling of being alive. As detailed elsewhere, I suggest that the feelings that we experience from our bodies emerge from the integration of the high-resolution interoceptive image with homeostatic and emotional motor signals; in particular, the beat-by-beat sensory activity of small-diameter receptors sensitive to vascular flow and energy utilization throughout the body enables us to feel the ongoing process of homeostasis in the living body. In my view, that generates homeostatic sentience; I feel that I am (alive). This homeostatic motor–sensory–motor paradigm differentiates self from other, automatically valuates any sensory stimulus by its autonomic reflex activation pattern, and provides the basis for the perception of emotional feelings as if they were feelings from the body, actualized by their central and peripheral homeostatic motor pattern. This proposal is supported by evidence from studies of perceptual recognition, attentional blink, error awareness, inspection time, and so on (see Craig, 2009, 2015). Quantitative evidence that the emotional "vividness" of a visual stimulus (and importantly, of the memory of that event) is mediated by activation in the mid-insula strongly corroborates this model (Todd, Talmi, Schmitz, Susskind, & Anderson, 2012). A recent electroencephalogram (EEG) study of visual perceptual suppression concluded that the timing of alpha and gamma oscillations in the anterior insula "could reflect the first emergence of conscious visual perception from the top of the cortical hierarchy" (Vidal et al., 2015).

In this model, whatever comes into awareness is a "feeling." Being able to "feel" every thought, perception, emotion, or potential behavior provides a powerful "common currency" for the evaluation of physical energy costs and benefits in support of optimizing behavior. The optimization of energy utilization compelled the evolutionary development of a common valuation system for energy cost–benefit analysis (for a similar viewpoint, see

Cabanac, Cabanac, & Parent, 2009). In hominids, the brain consumes 25% of the entire energy budget, and the enlargement of the hominid brain during evolution required an enormous increase in dietary energy, perhaps afforded by fish and cooked meat. The complete interoceptive integration of all salient activity in the insular cortex fulfills the overarching need to optimize energy utilization in the control of the emotional behavior of each individual, which includes the cooperative behavior within each social group. This model fits with the observation that the most anterior portion of the insular cortex grew more rapidly ("hyperallometrically") than the rest of the brain during hominid evolution (Bauernfeind et al., 2013). This model is also supported by recent fMRI evidence indicating that the anterior insula is crucially involved in computing the anticipated and actual effort needed to obtain a desired goal (Fitzgerald, Friston, & Dolan, 2012; Skvortsova, Palminteri, & Pessiglione, 2014; Engström, Karlsson, Landtblom, & Craig, 2014).

The anterior insula does not function independently; it is interconnected with the central autonomic network at the brainstem and forebrain levels, all distributed cortical networks, its complement on the other side of the brain (via the anterior commissure), and with the bilateral ACC. In order to represent all feelings, it must have dynamic connectivity throughout the cortex, which recent findings support (Cauda, Costa, Torta, Sacco, D'Agata, et al., 2012; Sepulcre, Sabuncu, Yeo, Liu, Johnson, et al., 2012; see Craig, 2009, 2015). It is also organized into numerous partitions that are being analyzed (e.g., Touroutoglou, Hollenbeck, Dickerson, & Feldman, 2012; Cauda et al., 2012; Power, Schlaggar, Lessov-Schlaggar, & Petersen, 2013). The bilateral anterior insula and anterior cingulate constitute key hubs that can function as a "core control network" that issues coordination signals and conveys information that guide network interactions in the multiplex "microstate" activity of the brain, thereby guiding all behavior (e.g., Cole & Schneider, 2007; Britz, Van, & Michel, 2010; Menon & Uddin, 2010). This network may not be present in monkeys (Mantini et al., 2013). The most recent network analyses of attentional control and fluid intelligence are consistent with this model (Uddin, Supekar, Ryali, & Menon, 2011; Cole, Yarkoni, Repovs, Anticevic, & Braver, 2012; Duncan, 2013; Power et al., 2013; Müller, Langner, Cieslik, Rottschy, & Eickhoff, 2014; Crittendon & Duncan, 2014; Dixon, Fox, & Christoff, 2014). Finally, this model can explain why the bilateral AIC and ACC are uniquely disrupted in all forms of Axis I mental illness (including anxiety, bipolar, depressive, obsessive–compulsive, schizoaffective, and substance use disorders; Goodkind et al., 2015). They orchestrate energy utilization in the body and brain alike.

If the anterior insula engenders feelings and controls network activity in the human brain, then that might seem to imply that feelings drive behavior. Nevertheless, literally hundreds of studies in the psychology literature support the hypothesis that feelings do not propel behavior, but rather are the consequence or concomitant of behavior (e.g., Laird, 2014; Wegner, 2014). In this model, the limbic motor system generates behavior, while the anterior insula guides and coordinates its agency.

Bivalent Asymmetry in the Bicameral Forebrain

In the established psychophysiological model that many authors espouse, emotion is more strongly associated with the right forebrain than the left. However, psychophysiological evidence has accumulated indicating that the left and right halves of the human forebrain are differentially associated with emotion. Based on studies of EEG activity, cortisol secretion, and cardiac and immune function, the left or right forebrain respectively associated with positive or negative valence, approach or avoidance (withdrawal) behavior, and affiliative or personal relevance, albeit with possible underlying circuits that are specialized for particular emotions (Davidson, 2004; Allen & Kline, 2004). Similarly, ethological evidence indicates that the right forebrain participates in arousal and predator avoidance, and the left forebrain in feeding and routine behaviors, in all vertebrates (MacNeilage, Rogers, & Vallortigara, 2009; Rogers, 2014). Clinical evidence from studies of the Wada (amobarbital) test, depression, heart rate variability, and cortisol release generally support the same asymmetry (Heilman, 2000; Conway et al., 2013). It seems likely that this pattern of forebrain emotional asymmetry is anatomically based on an asymmetrical representation of homeostatic and emotional motor activity that originates from asymmetries in the peripheral autonomic nervous system, and which first the descending motor pathways and later the substrates for our feelings evolved to match (see Craig, 2005, 2009, 2015).

In autonomic terms, in this proposal emotions are organized according to the fundamental principle of autonomic opponency for the management of physical and mental energy. In this homeostatic model, the left forebrain is associated predominantly with parasympathetic activity, and thus with nourishment, safety, positive affect, approach (appetitive) behavior, and group-oriented (affiliative) emotions; the right forebrain is associated predominantly with sympathetic activity, and thus with arousal, danger, negative affect, withdrawal (aversive) behavior, and individual-oriented (survival) emotions. In this model, management of physical and mental (meaning neural and representational) energy is the salient organizational motif (as for homeostasis), such that energy enrichment is associated with the left forebrain and energy expenditure is associated with the right forebrain, consistent with the general respective roles of the parasympathetic and sympathetic efferent systems. The homeostatic sensory representations evolved to match the preexisting autonomic and emotional asymmetries in the vertebrate forebrain, which provided a substantial improvement in the energy efficiency of the control of emotional behavior and communication, and thus facilitated increasingly complex (and cooperative) social interaction. In this model, for example, the homeostatically parsimonious role of the left insula in positive (parasympathetic) emotional affiliation grounds its association with verbal emotional communication (the left anterior insula is included in Broca's area) and the predominant use of the contralateral (right) hand for deictic pointing among humanoid primates (De Waal, 2003).

Thus, in this model coordinated opponent interactions between the two hemispheres, mirroring the autonomic principle of coordinated opponency, can provide an energy-efficient means for precise representation, control, and regulation, as it does for antagonistic muscles across a joint and for hormones that regulate water and salt (i.e., angiotensin and atrial natriuretic peptide). To explain the efficiency of an opponent regulatory system, the analogy of driving a car is useful: Rather than using only one hand to move the steering wheel in opposite directions, it is more efficient if you place your two hands on opposite sides (e.g., at the 9:00 and 3:00 positions), because then you can control it more easily by exerting a steady downward pressure with one hand and simply varying the downward pressure applied with the other hand. This is exactly how the coordinated opponent autonomic control of the heart functions; tonic excitatory sympathetic drive is modulated by rapid variations in inhibitory parasympathetic drive. Note that in an opponent control system the sensors and the controller outputs are optimally tuned to the balance between the antagonist effectors (e.g., Dimitriou, 2014).

In this model, the forebrain coordinates emotional control in the same manner. This model instantiates neurobiologically the psychological proposal that a hypothetical "calm and connection system" opposes the arousal–stress system (Uvnas-Moberg, Arn, & Magnusson, 2005). It substantializes the bivalent concept of emotion, in which positive and negative affects are different psychological dimensions, yet it is consistent with an aspect of the core affect concept, in which energization is a key dimension (Russell & Barrett, 1999). It also fits with imaging evidence that pleasure and pain are opposed hedonically within the limbic reward–punishment circuitry (Seymour et al., 2005; Ellingsen et al., 2014; Baliki et al., 2013).

Thus, the model provides a structural basis for the idea that coordinated opponent interactions between the left and right insula and cingulate are fundamentally significant for emotional balance and regulation. Positive and negative affect interact in an opponent fashion—for example, social engagement (and oxytocin) can suppress arousal, stress, depression, and cortisol release, whereas the latter factors can reduce mood, sociability, and immune function (Heinrichs, Baumgartner, Kirschbaum, & Ehlert, 2003). This model is directly supported by evidence that increased vagal sensory activity caused by breathing slowly inhibits pain affect, but only in individuals who have a supply of positive energy to utilize (Zautra, Fasman, Davis, & Craig, 2010). Similarly, listening to emotionally pleasing music activates the left anterior insula more strongly than the right (Koelsch et al., 2006), and damage in the left anterior insula can produce a selective loss of musical enjoyment (see Craig, 2009, 2015; Griffiths, Warren, Dean, & Howard, 2004). A strikingly clear asymmetry in anterior insula activation is produced using auditory clicks, which activate the left anterior insula more strongly if faster than 3 Hz but the right if slower (Ackermann & Riecker, 2004). These temporal effects are consistent with the actions of parasympathetic and sympathetic activity on heart rate, respectively. Finally, these considerations provide a solid neurobiological foundation for explaining how increased parasympathetic sensory activity can synergistically enhance positive emotion and reduce negative emotion—for example, by electrical stimulation of the vagus nerve in patients who are treatment-resistant chronically depressed (Conway et al., 2013; see Craig, 2009, 2015).

Two quantitative meta-analyses of functional imaging studies that used emotional tasks (88 in one, 143 in the other) revealed asymmetric activation in both the amygdala and the AIC: During positive feelings, there was strong activation almost exclusively in the left amygdala and left AIC; during negative feelings, there was bilateral activation in the amygdala and the anterior insula (Stevens & Hamann, 2012; Duerden, Arsalidou, Lee, & Taylor, 2013). These findings fit the pattern of forebrain asymmetry described above, given that it makes sense for both sides of the brain (and thus, both sides of the body) to be immediately responsive to dangerous conditions. The fact that opponent control usually involves coordinate activation of both sides can explain why this pattern is difficult to observe because predominant activation of one side or the other will be observed only under strongly polarized conditions and because opponent activation is also required for regulation. Both studies also reported that this pattern is partially obscured by subtle differences between males and females; that finding could explain why a different meta-analysis and an imaging study of sympathetic nerve activity found consonant asymmetric activation in the amygdala but not in the insular cortex (Kühn & Gallinat, 2012; Henderson et al., 2012). Confirmation is provided by a more recent study of feedback evaluation that found responses to losses in the right anterior insula and to both losses and wins in the left anterior insula, which the authors interpreted to mean that "the right anterior insula is mainly involved in processing the salience of the outcome, whereas the left is . . . important for subsequent behavioral adaptations" (Späti et al., 2014, pp. 4428–4429). Transcription of an immediate early gene associated with emotional memory formation in the basolateral amygdala also shows consonant asymmetry, with left positive and right negative (Young & Williams, 2013). A high-resolution magnetoencephalographic study of participants who passively viewed standard emotional images similarly reported that the right basolateral amygdala was activated by negative (unpleasant) images (along with the right insula if they were also arousing), while the left centromedial amygdala was activated by pleasant images (if they were arousing; Styliadis, Ioannides, Bamidis, & Papadelis, 2014).

The largest hurdle for the acceptance of these ideas has been the lack of clear neuroanatomical evidence. However, the critical experiments needed to demonstrate asymmetric connections in the emotional motor system and the reward–punishment system are difficult to perform; that would require, for example, complete bilateral double-labeling of descending pallidal and amygdalar projections to the upper brainstem, or of interconnections between the left and right habenular nuclei and the serotoninergic and dopaminergic neurons in the upper brainstem. A stark morphological example of such asymmetry has been available in the size of the habenular nuclei of the zebrafish, but similar anatomical differences have not been observed in mammals. Nevertheless, two landmark studies in humans were recently published (Tomer, Slagter, Christian, Fox, King, et al., 2013, 2014); the authors used PET imaging to measure binding density of a dopamine D_2 receptor ligand, and they found that asymmetric binding in the striatum and medial prefrontal cortex was highly correlated with the trait-like behavioral orientation bias and the approach–avoidance behavior of individual human participants, and thus with affective asymmetry. Their work provides convincing neuroanatomical evidence for the forebrain asymmetry of emotion in humans.

Acknowledgments

I thank Lisa Feldman Barrett for her editorial suggestions, and Ian Kleckner and Alexandra Touroutoglou for suggestions on updating this chapter. I am grateful to the Barrow Neurological Foundation for support.

Note

1. The insula is a cortical "island" buried within the lateral sulcus that is interconnected with amygdala, hypothalamus, ventral striatum, and cingulate and orbitofrontal cortices. It is a well-developed but hidden, operculated fifth lobe of the brain only in anthropoid primates. The primordial role of the insular cortex is integration of olfactory, gustatory, and viscerosensory activity with emotional behavior, primarily ingestion.

CHAPTER 13

THE AFFECT OF TASTE AND OLFACTION

The Key to Survival

Linda Bartoshuk and Derek J. Snyder

The notion that affect (pleasure and pain) are linked to well-being and survival is an old one. Jeremy Bentham (1789) is widely quoted: "Nature has placed mankind under the governance of two sovereign masters, pain and pleasure. It is for them alone to point out what we ought to do, as well as to determine what we shall do."

Pain is, of course, innately negative, but taste is both innately negative (bitter, sour) and positive (sweet, salty). The dislike of pain lets us escape physical damage. Dislike of bitter lets us avoid poisons. Dislike of sour is less clear; some have argued that sour taste might warn of unripe fruit, but it certainly warns of acid. Love of the sweetness of mother's milk leads a newborn to nurse right after birth; love of the saltiness of dilute sodium allows rapid replacement of the sodium necessary for nerves to fire and muscles to contract after losses of sodium and water (e.g., sweating during exercise; loss of fluid with birth). Where hard-wired affect fails to protect us, learning steps in. Learning attaches pleasure to stimuli that do us good and displeasure to stimuli that do us harm.

This chapter discusses how nature uses the affect of taste and olfaction to help us survive. We begin with the innate affect of taste, then move on to the learned affect of olfaction. In essence, the olfactory system identifies objects for us; the olfactory sensations acquire affect based on the consequences of our interactions with those objects. Early studies focused on the biological motivations that fueled the acquisition of olfactory affect associated with foods (e.g., ingestion of calories endows associated olfactory sensations with positive affect; nausea endows them with negative affect). However, olfaction not only helps us identify foods but also helps us identify important objects in our environments (predators, prey). Thus, studies of the acquisition of affect associated with environmental stimuli have also been targets of innovative studies.

Measurement of affect is essential to the study of affect. We have made great progress in quantification of our experiences including quantification of affect. However, attempts to compare sensory and hedonic experiences across groups have been flawed. We discuss the flaw and a solution in the final section of this chapter.

Studies of taste and olfaction have broader significance as well. Our experience of affect guides our philosophical views of good and bad. If the insights gained from taste and olfaction generalize to broader domains, those insights may help us make the world a better place.

Taste and Innate Affect

Taste Affect Is Hard-Wired in the Brain

Taste Senses Certain Nutrients

Nature uses taste to solve nutritional problems that must be solved rapidly. However, this kind of solution only works for nutrients that produce a clear sensory cue (we thus must have receptors that signal that nutrient) and stimulate parts of our brains that are hard-wired to recognize them. This kind of hard-wired solution is viable for nutrients that are commonly present in our environments. Table 13.1 shows the nutrient sensed by each of the "four basic tastes."

Salty, sour, sweet, and bitter were identified in the 19th century as the basic taste qualities. Attempts to add other categories (e.g., metallic) were dismissed in that era, but more recent attempts to add umami and fat taste are still under discussion. We prefer not to include these sensations as basic taste sensations since the affect associated with them is not innate but rather is learned (to be discussed later); we see the innate affect associated with taste qualities as one of the most important characteristics that dissociate taste from other sensations.

Facial Expressions Reflect Hard-Wired Affect

Some of the best-known evidence for the hard-wired affect of taste comes from the work of Jacob Steiner (1977) on facial expressions in the newborn. "The sweet stimulus leads to a marked relaxation of the face, resembling an expression of 'satisfaction.' This expression is often accompanied by a slight smile and was almost always followed by an eager licking of the upper lip, and sucking movements." Sour leads to lip pursing. "Stimulation with the bitter fluid leads to a typical arch form opening of the mouth with the upper lip elevated, the mouth angles depressed, and the tongue protruded in a flat position. . . . It was often followed by spitting or even by the preparatory movements of vomiting." Facial expressions have been studied by other investigators (Rosenstein & Oster, 1988) and in other species as well (Ganchrow, Oppenheimer, & Steiner, 1979; Jacobs, Smutz, & DuBose, 1977), most recently, the horse (Jankunis & Whishaw, 2013).

Incidentally, sweet affect is apparently present prior to birth. De Snoo (1937), a pediatrician, sought to medicate the fetus by inducing it to drink amniotic fluid to which a medication could be added. He induced drinking by injecting saccharin into amniotic fluid. The willingness of the fetus to drink the sweetened amniotic fluid demonstrated sweet affect prior to birth.

Human neonatal responses to NaCl are ambiguous. However, developmental work with sheep (Mistretta, 1981) led to the insight that in some species the salt receptors develop after birth.

TABLE 13.1. Four Basic Tastes: Nutrient and Mechanism

Nutrient	Taste	Mechanism
Sodium	Salty	Na^+ channels in certain taste cell membranes allows Na^+ ions to enter salty receptor cells and initiate events that lead to a neural signal.
Acid	Sour	H^+ channels in certain taste cell membranes allow H^+ ions to enter sour receptor cells; in addition, undissociated acid molecules can enter in other ways and dissociate intracellularly; the signal for sour is the total H^+ concentration within the sour receptor cell (DeSimone & Lyall, 2006).
Glucose	Sweet	Glucose is the fuel of the brain. In addition to glucose alone, the sucrose molecule is broken down into its constituent glucose and fructose by digestion. Fructose is converted to glucose in the liver. Sweet receptors are G-protein-coupled receptors (GPCRs). The major receptor (called a heterodimer) is constructed of two proteins. The taste (TA) genes expressing these proteins are *TA1R2* and *TA1R3*; the heterodimer has binding sites for glucose, fructose, sucrose, and a variety of other molecules. The biological purpose of the sites for those other molecules is unknown, but their existence is responsible for what we call "artificial sweeteners." In addition to the heterodimer, one of the proteins (expressed by *TA1R3*) can act as a receptor for high concentrations of sugar (Zhao et al., 2003).
Poison	Bitter	Most poisons taste bitter. Bitter receptors, like sweet receptors, are GPCRs. There are 25 different genes that express bitter receptors (Meyerhof et al., 2010). Some of those receptors are highly specific for a given compound (specialists), while others can bind multiple compounds (generalists). Multiple bitter receptors allow evolution to equip an individual (or species) with receptors that warn of poisons in a given environment.

When the receptors are mature, human newborns like dilute NaCl but reject higher concentrations, presumably because they sting as well as taste salty. The lack of ability to taste sodium in the newborn is unlikely to prove dangerous under normal circumstances; however, six infants died of salt poisoning in a hospital where salt was accidentally substituted for sugar in formula (Finberg, Kiley, & Luttrell, 1963).

Gustotopic Mapping in the Brain

In order for each of the tastes to serve its biological function, investigators have long assumed that each would project to a different part of the brain. Discovery of that gustotopic map has been elusive. However, recent work using an imaging procedure is consistent with such a map (Barretto et al., 2014; Chen, Gabitto, Peng, Ryba, & Zuker, 2011).

Liking for Sweet and Salty Is Dependent on Body Need

Cabanac coined the term "alliesthesia" to describe hedonic changes produced by changing the state of the body. The "Cabanac effect" is the decline in the palatability of sweet following ingestion of sugar (Cabanac, Minaire, & Adair, 1968). In the opposite of this, the injection of insulin depletes the body of glucose and enhances the palatability of sweet. A dramatic example of this was provided by a treatment for schizophrenia pioneered by Manfred Sakel (1938) in the 1930s. Joseph Wortis, an American psychiatrist, introduced the treatment to the United States after observing its use by Sakel in Vienna (see Halmi, 1995). During the treatment some patients experienced intense cravings for carbohydrates. This stimulated Mayer-Gross and Walker (1946) to design a sucrose preference test; they demonstrated that patients were more likely to choose a 30% sucrose solution when their blood glucose was low. This was subsequently supported by more detailed studies (e.g., see Rodin, Wack, Ferrannini, & DeFronzo, 1985).

The liking of salt is similarly dependent on body need. The liking for salt requires no experience, but if an organism is made sodium deficient, that liking intensifies (Bare, 1949) allowing species to regulate sodium intake (Schulkin, 1991). Salt hunger is shown by a variety of species (see Schulkin, 1991 for a review). Rats made sodium deficient will ingest sodium immediately on given the opportunity. In one important experiment, rats were given experience with a T maze when thirsty. One arm of the T contained water, the other contained NaCl. When thirsty, the rats learned to run to the arm containing water and avoided the arm containing NaCl. Subsequently, when made sodium deficient, the rats ran to the NaCl arm of the maze even though they had not previously experienced NaCl taste in the presence of sodium need (Krieckhaus, 1970).

The classic paper of Wilkins and Richter (1940) documented the sad story of a 3.5-year-old child with an adrenal tumor (this leads to loss of sodium). This boy loved salt and added it to his food when allowed to at home. During a hospitalization he was unable to get the salt he craved and he died from loss of sodium (Wilkins & Richter, 1940). The parents' description of the boy's behavior toward salty foods suggests that he liked them on initial exposure to the salty taste.

In humans, exercising (sweating) depletes the body of both water and salt. The liking for these two substances alters such that the human rehydrates in three stages. First, thirst motivates water consumption; during this phase salty taste is not pleasant even though the body needs sodium. In the second phase, salty taste is pleasant again and the athlete ingests salt. Once enough salt is in the body, new thirst motivates enough further water consumption to rehydrate completely (Takamata, Mack, Gillen, & Nadel, 1994). Interestingly, this could be done in one stage by simply making a beverage containing enough salt to appropriately rehydrate. However, such a beverage would taste salty enough to engage the salty taste rejection shown during dehydration. Sports beverages are formulated with less than the physiologically needed salt and thus avoid this salty rejection response.

Taste provides a beautiful example of how hardwired affect can promote survival. Love of sweet and salt ensures that these nutrients will be consumed. Dependence on body need ensures that the correct amounts will be consumed. Aversion to bitter keeps us away from most poisons. The only problem is that this mechanism must have a sensory signal for each nutrient. Evolution could find such signals for sweet, salty, and sour; bitter turned out to be a bit of a problem. There are too many different poisons to have a receptor for each. Evolution did her best and provided 25 receptors along with genetic variation on what these receptors can sense; however, there are still poisons that escape this innate aversion (e.g., lithium chloride).

Curt Richter and "Wisdom of the Body"

The elegance of the body's ability to alter the palatability of sweet and salty to meet body needs led Curt Richter (1942–1943) to propose a general regulatory theory. The origin of the phrase, "wisdom of the body," was a Harvey lecture by Starling (1923) on automatic mechanisms that allow the body to adapt to a variety of circumstances (e.g., the heart beats faster during exercise). Cannon (1939) used this title for his book on homeostasis out of respect for Starling. Richter extended the idea to voluntary behavior. He proposed that body needs requiring resources from the environment might produce craving that would motivate an organism to seek out the needed nutrient (Richter, 1942–1943).

Early studies done by Clara Davis (1939) seemed to support this theory. Davis, a pediatrician, allowed children (beginning at weaning) to eat as they chose from a variety of foods. The children thrived. This led to the widespread belief (which still survives in some quarters today) that humans are born with the capacity to select a healthy diet. Richter (1942–1943) did a series of rat studies confirming sweet and salty cravings resulting from need; however, when wisdom of the body was extended to vitamins, the theory failed. Deficiencies in the water-soluble B vitamins can make an organism ill relatively quickly. Deficiency of vitamin B_1 (thiamin) produces beriberi in humans; rats show weight loss and anorexia. Initially, rat studies were conducted just as they had been for sweet and salty: rats were deprived of the nutrient and, when ill, were given a choice of the same diet or a new diet containing the nutrient. The rats switched immediately to the new diet. However, Paul Rozin, a psychologist who has made revolutionary contributions to our understanding of food behavior, did a critical control: he also offered the rats a third diet deficient in B_1 but with a novel flavor. The rats immediately chose the novel-flavored diet even though it was deficient in B_1. In other words, the rats were not choosing a diet that their bodies knew contained the needed nutrient; rather, they were avoiding the diet that they associated with illness. Thus Rozin demonstrated conditioned aversions to a diet on which the rats had become ill (Rozin & Kalat, 1971).

This appeared to leave the Davis (1939) experiments unexplained, but the psychologist Barbara Rolls (1986) had discovered "sensory specific satiety": pleasure diminishes with an unchanging diet. The babies in the Davis studies were not seeking the nutrients their bodies knew they needed. Rather, they were eating a variety to avoid boredom maximize pleasure. Since all of the foods offered were healthy, they thrived. Had the babies been offered the junk foods of today, it us unlikely the result would have been the same.

Olfaction and Acquired Affect: The Omnivore's Dilemma

Important Distinctions in the Study of Olfaction and Affect

The affect-driven, hard-wired nutrient systems discussed above deal with only a small portion of nutritional challenges. Some species need make few choices since they subsist on limited food sources (e.g., Koala bears and eucalyptus leaves), but consider humans. We are omnivores. We must consume foods that will sustain life and avoid those that will kill us. Rozin coined the term "omnivore's dilemma" to describe this biological imperative (Rozin & Rozin, 1981). Michael Pollan (2006), the food writer, subsequently borrowed Rozin's term to underline the even more complex dilemma that we face in the modern era given the dizzying choices available to us. How do we select a successful diet? We learn. Sensory cues from our environments can acquire the ability to make us experience pleasure or disgust—that is, we can learn to like the foods that do us good and to dislike those that do us harm.

There are two bodies of literature on the learned affect of olfaction. One of these is associated with the biology of eating and the other, evaluative conditioning, originated in cognitive psychology. We discuss studies from these two fields using distinctions not always noted in attempts to integrate this material. First, we distinguish between orthonasal and retronasal olfaction (the two routes by which olfactory volatiles reach olfactory receptors) and second, we distinguish between what we call primary (i.e., hard-wired) and acquired affect.

Historically, studies on the olfactory affect of foods came first, while the more cognitive studies of olfactory affect associated with environmental stimuli tended to come later. We follow that order in summarizing these studies.

Distinction between Orthonasal and Retronasal Olfaction

We smell odors in our environments by sniffing. Air enters the nostrils and passes over bones called "turbinates." These bones provide turbulence to the stream of odorized air so a sample of it moves to the top of the nasal cavity, passes through a small opening called the "olfactory cleft," and reaches the olfactory mucosa where it encounters the ciliated endings of olfactory neurons; the olfactory receptors are on those cilia. This is called "orthonasal olfaction." On the other hand, when food or beverages that emit odors enter the mouth, chewing and swallowing forces the odors up behind the palate and into the nasal cavity from the rear. This is called "retronasal olfaction." This distinction is easily demonstrated with jellybeans. Pinch your nose closed (this prevents the air currents that provide retronasal olfaction) and chew a jellybean. You may taste some sweet or sour, but you will not be able to detect the flavor of the jellybean. Once chewed, swallow and open your nose. The odorized air will rush up behind your palate and stimulate your odor receptors; you will suddenly be able to perceive the flavor of the jellybean. If you are a very good observer, you will notice something else; the sweetness of the jellybean will intensify. The enhancement of sweet taste by certain volatiles may lead to a new way to reduce sugars in foods without sacrificing sweetness (L. M. Bartoshuk & Klee, 2013).

The importance of the distinction between orthonasal and retronasal olfaction has been appreciated only in recent years. Rozin (1982) emphasized the functional differences: orthonasal olfaction tells us about the world outside ourselves, while retronasal olfaction tells us about the food we are eating. Small (Small & Jones-Gotman, 2001) used functional imaging to reveal that the two forms of olfaction do not project to identical brain areas. Retronasal olfaction and taste project to some of the same areas; presumably this is where flavor is created in the brain.

Given the functional differences between retronasal and orthonasal olfaction, are there differences in their affective properties? A colleague once noted that he loved the smell of newly cut grass, but he certainly would not want to eat it (D. G. Laing, personal communication). This illustrates our common-sense knowledge that olfaction plays very different roles in the outside world and in our mouths.

Distinction between Primary (Hard-Wired) and Acquired Affect

Carl Pfaffmann (1960), one of the earliest sensory experts to focus on the affective properties of sensations, emphasized an important distinction in "The Pleasures of Sensation." He called the biological or hard-wired affect (e.g., love of sweet and aversion to bitter; hunger, nausea) "primary affect" and distinguished this from the "acquired affect" associated with sensations that are initially neutral and acquire affect by "one method or another." In evaluative conditioning, the nature of the affect (primary or acquired) that serves as the source for the transfer is not a major concern. One of the tasks of the present chapter is to inquire a bit further into Pfaffmann's distinction. Is there something special about primary affect?

Eating: Primary Affect

Positive Olfactory Affect Is Easy to Create or Alter Using Primary Sources of Affect

With regard to food (and so retronasal olfaction) we note that simple exposure can alter olfactory affect (Cain, 1979). In addition, social factors can change the affect of food odors. Galef (1989) demonstrated that rats show preferences for diet items preferred by another rat. Social exposure can even lead a rat to ingest cayenne pepper (a relatively mild but usually rejected concentration). Birch (1980) found that children could acquire preferences for vegetables by exposure to children who liked those vegetables. Pliner and Pelchat (1986) looked at the similarities of likes and dislikes for children with their parents and with their siblings. Although there were similarities between children and parents, the most impressive similarities were between siblings.

We know that odors can become liked by pairing with sweet. The Zellner–Rozin "flavor–flavor" paradigm was first described in 1983 (Zellner, Rozin, Aron, & Kulish, 1983). Pairing sucrose with teas transferred positive affect from sweetness to the teas. Baeyens and his colleagues later found that pairing Tween 20 (a bitter detergent) can transfer that dislike to flavors. Comparison of these effects (Baeyens, Eelen, Van den Bergh, & Crombez, 1990) demonstrates an interesting feature: enhancement of liking appears to be harder to produce than reduction of liking (Rozin & Zellner, 1985). This may reflect a bias toward learning about harmful stimuli (De Houwer & Thomas, 2001).

We note that the terminology "flavor–flavor" conditioning appropriately suggests that both the unconditioned stimulus (US) and the conditioned stimulus (CS) are chemosensory stimuli, but fails to appropriately distinguish between taste and olfaction. This is important because the nature of affect in these two senses is very different. As noted above, evidence suggests that taste affect is primary, but olfactory affect is acquired.

The Zellner–Rozin paradigm has produced practical benefits. Using sweet as a US has been utilized successfully to improve children's liking for vegetables; sweetening vegetable drinks with glucose increased their palatability (Havermans & Jansen, 2007). A similar study used a liked dip (ketchup, ranch dressing, cinnamon yogurt) to increase the palatability of vegetables. In this case, the affect of the US (dip) may have reflected nutritive properties of the dip (primary) as well as retronasally perceived odors (acquired; Anzman-Frasca, Savage, Marini, Fisher, & Birch, 2012). What is important here is that the transferred affect remained when the sugar was removed.

Pairing flavors with salt to show an increase in the palatability of the flavors is easiest under sodium need. This could be done in humans (and may have been, although we are unaware of any such work), but creating a sodium need is easy in rats and does not evoke concern from institutional review boards. Fudim (1978) made rats sodium deficient with injections of formalin and showed that flavors paired with sodium became more preferred.

Odors can become liked by pairing with macronutrients (sources of calories). Sclafani and his colleagues have used animal models to show conditioned preferences using carbohydrates, fats, and proteins (e.g., see Ackroff & Sclafani, 1991; Figueroa, Sola-Oriol, Borda, Sclafani, & Perez, 2012). Booth, Lee, and McAleavey (1976) and Birch, McPhee, Steinberg, and Sullivan (1990) demonstrated similar effects in humans. Pleasure from drugs of abuse can also make associated odorants liked (e.g., see Ehrman, Robbins, Childress, & O'Brien, 1992).

Recently, umami has been touted as a fifth basic taste. The origin of this was advertising claims by Ajinomoto (a manufacturer of monosodium glutamate). Glutamate receptors have been said to be the receptors for the umami taste; the biological purpose of these receptors is supposed to be the detection of protein. However, protein molecules are too large to be sensed by taste or olfactory receptors; thus the supposed stimulus for umami is not present in intact protein. We now know that taste receptors are found throughout the gastrointestinal (GI) tract (gut). Digestion of protein breaks it into its constituent amino acids, releasing free glutamate that can stimulate the gut glutamate receptors. Apparently, that sensory input signals the brain that an organism has consumed protein and the brain creates a conditioned preference for the sensory properties (usually the retronasal olfaction) of the food eaten (Ackroff & Sclafani, 2011; Prescott, 2004; Yeomans, Gould, Mobini, & Prescott, 2008). This mechanism has the advantage of leading to preferences for many proteins that do not produce an umami taste.

Similarly, fatty acid receptors in the mouth have been linked to fat taste (Gilbertson, 1998). Just as with proteins, fat molecules are too large to stimulate either taste or olfactory receptors; fatty acids are smaller constituents of fats. Digestion breaks down fats releasing fatty acids, which stimulate fatty acid receptors in the gut. Just as with protein, the signal from the gut leads to conditioned preferences for the sensory properties associated with the food containing the fat (usually the retronasal olfaction). Thus both proteins and fats acquire affect by learning.

Negative Olfactory Affect Is Also Easy to Create or Alter Using Primary Sources of Affect

Just as with olfactory pleasure, simple exposure can alter olfactory displeasure (Cain, 1979). The similarities of food likes and dislikes in siblings suggest that social interactions affect dislikes as well as likes.

An experiment with a single child done by Moss (1924) shows an example of the transfer of negative affect from vinegar to orange flavor. Moss squirted solutions into the child's mouth using a medicine dropper. Orange juice was usually the stimulus with episodes of vinegar interspersed. The child lost his fondness for oranges and "very much preferred apples."

In rats, Fanselow and Birk (1982) showed that neutral flavors (almond and vanilla) paired with quinine came to be avoided. In humans, pairing flavors with quinine is not an attractive study and we know of no demonstrations like that in rats; however, as noted above, Baeyens and his colleagues (1990) showed that Tween 20 (a bitter detergent) paired with flavors rendered them less palatable.

Conditioned aversions have been widely studied in both rats and humans. In the 1950s, Garcia, Kimeldorf, and Koelling (1955) observed an aversion to saccharin paired with radiation and suspected GI illness caused by the radiation as the source of the aversion. Some years later lithium chloride was used to produce GI illness in coyotes that were preying on lambs to render the odor and flavor of the lambs unpleasant to the coyotes (Gustavson, Hankins, & Rusiniak, 1974). However, conditioned aversions actually have a much longer history. As early as the 1930s, clinicians attempting to help alcoholics used conditioned aversions to render the odors and flavors of alcoholic beverages unpleasant (Lemere & Voegtlin, 1940; Voegtlin, 1940).

The role of taste and olfaction in conditioned aversions has been explored by a variety of investigators. Garcia, Lasiter, Bermudez-Rattoni, and Deems (1985) suggested that taste is the sensory cue producing these aversions. They were correct for the rat; however, in humans it is difficult or impossible to create genuine taste aversions. The sensory stimuli evoking the aversion is retronasal olfaction (Bartoshuk & Wolfe, 1990). Thus, "food aversion" is more appropriate than "taste aversion" for human research. The biological purpose of a conditioned aversion is to prevent ingestion of a food previously associated with illness. Therefore, conditioning an aversion to an odor that labels the food makes good sense. Given that the stimuli that play the most salient role in labeling food are the retronasal olfaction sensations, calling these aversions "retronasal olfactory aversions" makes even better sense but is not likely to catch on.

Making odors unpleasant by associating them with nausea is an all-too-common experience among college students experimenting with alcohol for the first time. The primacy of nausea in creating food aversions was established by Pelchat (Pelchat, Grill, Rozin, & Jacobs, 1983). Individuals form conditioned aversions to many foods and beverages under the normal conditions of life (Garb & Stunkard, 1974; Logue, Ophir, & Strauss, 1981; Pelchat & Rozin, 1982; Rozin & Vollmecke, 1986; Rozin, Wrzesniewski, & Byrnes, 1998). In addition, such aversions are formed during nausea-inducing radiation (Smith et al., 1984) and chemotherapy (Bernstein & Webster, 1980) treatments for cancer. Of special interest, Bernstein (1978) gave a novel flavor of ice cream to children just before they were about to receive chemotherapy. The children developed a conditioned aversion to that flavor of ice cream. The control children who were not exposed to the novel ice cream developed aversions to items in their normal diets. The children who received the ice cream were less likely to experience these aversions. The novel ice cream served as a scapegoat; the aversions formed to that novel stimulus and thus protected the diet (Bernstein & Webster, 1980).

Evaluative Conditioning: Transfer of Affect

The omnivore's dilemma focuses on the power of olfaction to help us survive by avoiding poison and taking in food that will contribute to good health. However, olfaction has non-nutritive functions as well, especially for nonhuman species. Olfaction can help an organism avoid predators as well as identify potential mates and resources that mean safety (smell of home, smell of kin). As Rozin (1982) noted, retronasal olfaction deals with olfactory sensations arising from food objects in the mouth. Orthonasal olfaction deals with olfactory sensations arising from objects in the world around us. Thanks to evolution we can expect olfactory affect to show different properties depending on its contributions to our survival and to show different properties across different species.

Evaluative conditioning deals with transfer of affect. That affect can be associated with taste and/or olfaction but evaluative conditioning includes transfer of affect among other stimuli as well. As De Houwer and Thomas (2001) noted, "Evaluative conditioning refers to changes in the liking of a stimulus that are due to the fact that the stimulus has been paired with other, positive or negative stimuli." Early work now seen as the intellectual beginnings of evaluative conditioning dealt with a variety of domains. Razran (1940) asked Queens College students to evaluate sociopolitical slogans either while consuming a free lunch or while smelling unpleasant odors. The slogans evaluated during lunch became more positive, while those evaluated while smelling the unpleasant odors became less positive. Staats and Staats (1958) paired national names (e.g., Swedish, Italian) with valenced words (e.g., positive: "happy," "gift"; negative: "ugly," "failure"). The national names changed valence in the direction of the valenced word with which they were paired. Levey and Martin (1975) showed transfer of affect from liked postcards to neutral postcards.

Evaluative conditioning has been described in several excellent reviews (Capaldi & Powley, 1990; De Houwer & Thomas, 2001; Hermans & Baeyens, 2002; Hofmann, De Houwer, Perugini, Baeyens, & Crombez, 2010; Rozin et al., 1998; Rozin & Zellner, 1985; Zellner, 1991; Zucco, 2012). Zucco's account of olfaction in evaluative conditioning offers an important beginning point for this discussion.

Classification of Evaluative Conditioning Paradigms Involving Olfaction

Primary Affect (Sweet, Salty, Calories, Drug Intoxication, Nausea, Etc.). Experiences like hunger and nausea are innately affective; reducing hunger is a positive experience, nausea is a negative experience. Taste sensations (sweet, salty, sour, bitter) are also innately affective. In the language of evaluative conditioning, pairing one of these innately affective experiences with olfactory sensations can be seen as transferring affect. What we wish to emphasize here is that the source of the affect is primary. The acquired olfactory affect that results is powerful. We suggest that olfactory affect acquired from a primary source may be more powerful than olfactory affect acquired from sources that are themselves acquired.

Transfer of Affect from a Valenced Everyday Experience to an Odor. Rozin and colleagues (1998) attempted to transfer affect from a variety of everyday experiences (valenced pictures, hair washing, seeing a dead cockroach) and had some, but limited success. The most powerful result was reduced liking for odors paired with a dead cockroach. Rozin noted that neutral odors for the studies were hard to find. There are some other successful attempts to pair odors with real-world experiences. For example, children made frustrated by an unsolvable maze found odors scenting the room less pleasant (Epple & Herz, 1999). Baeyens, Wrzesniewski, de Houwer, and Eelen (1996) scented the air in bathrooms. For those individuals who reported using the bathroom for a relaxing break, liking for the odor increased. For those who reported bathroom activities associated with displeasure, the liking for the odor decreased.

In sum, the affect of everyday activities could be transferred to orthonasal olfactory sensations, but the transfer was not very impressive.

Transfer of Affect from an Odor to Neutral Stimuli. On the other hand, Todrank showed that people-related odors (liked and disliked) could transfer affect to pictures of faces. Faces paired with liked odors became more liked; pictures paired with disliked odors became less liked (Todrank, Byrnes, Wrzesniewski, & Rozin, 1995; Wrzesniewski, McCauley, & Rozin, 1999). Two additional studies produced similar results (Hermans, Baeyens, & Eelen, 1998; van Reekum, van den Berg, & Frijda, 1999). These studies show that the acquired affect of olfaction can be transferred to neutral objects. Note that these examples involved orthonasal olfaction.

Transfer of Affect from One Odor to Another. Given the frequency with which we encounter olfactory combinations in foods, there must be many opportunities for olfactory affect to be transferred from a liked or disliked odorant to a neutral odorant. Yet this phenomenon receives little attention in the laboratory. Note that this involves retronasal olfaction.

Consider the transfer of affect from one odor to another with orthonasal olfaction. Again it seems that everyday experiences should include many examples of this, but we know of no laboratory studies with positive affect. However, one study might be an example of the transfer of negative olfactory affect. In the Baeyens et al. (1996) bathroom study noted above, individuals who reported fewer positive experiences were presumably using the bathroom for its primary intended purpose: urination or evacuation. These activities transferred negative affect to the scent in the room. Unfortunately, we do not know what part of the bathroom experience produced the negative affect. GI discomfort or pain would have been a primary affect and reducing the odor affect would thus be expected. However, if the smells of urination or evacuation provided the negative affect, this would have been an example of an acquired olfactory negative affect transferring to the room scent.

Transfer of Affect from Retronasal to Orthonasal Olfaction or Vice Versa. Anecdotes show that transfer of retronasally conditioned affect transfers to orthonasal olfaction. For example, one of us (Bartoshuk) developed an aversion to maraschino cherries from eating a box of chocolate-covered cherries while reading comic books (and getting carsick) in the back seat of the family car during a vacation trip. The characteristic volatile flavoring the cherries was benzaldehyde. The same volatile is used to scent hand soap. Bartoshuk now assiduously avoid such hand soaps, as well as benzaldehyde in anything (e.g., marzipan pastries). On the positive side, one can imagine experiencing a new flavor in a food containing calories and later experiencing pleasure when smelling that food.

It is harder to think of anecdotes showing transfer from orthonasal olfaction to retronasal olfaction. One can imagine orthonasal odors that become liked but that liking would not be likely to transfer to ingesting that volatile and thus perceiving it retronasally.

Can We Come to Any Conclusions about the Power of the Transfer of Affect Involving Olfaction? We suspect that it is too early to draw many definitive conclusions, but offer some thoughts. As suggested above, the acquisition of olfactory affect in the context of food is very powerful. A novel olfactory sensation (perceived retronasally) paired once with nausea can condition a lifelong aversion. Conditioning preference tends to take more pairings, but the positive affect resulting is very powerful as well. Simply thinking about one's favorite foods provides ample evidence of this. These examples involve retronasal olfaction. On the other hand, the difficulties encountered in many experiments attempting to transfer olfactory affect to a variety of neutral items or to transfer affect from some nonolfactory stimulus to a neutral olfactory stimulus suggest weaker effects. Needless to say, the use of the terms "powerful" and "weak" are poorly defined. We are left with the thought that one approach might be to measure the intensity of the olfactory affect involved in these various studies. We consider this quantification of affect in the section "How Do We Measure Affect?"

Is There Any Evidence for Innate Olfactory Affect?

We are concentrating on learned or acquired olfactory affect in this chapter, but the question about innate olfactory affect is still open. Early work argued against innate olfactory affect in humans. Engen and Lipsitt (cited in Engen, 1982; Engen & Engen, 1997) performed an experiment with 1- and 2-year-old children that suggested that children can perceive but are indifferent to odors. The children (with their mothers nearby) were seated in front of a table with a screen showing a colorful tree; several toys were placed in front of the screen. Once the child appeared to be engaged with the toys, odorants were presented with atomizers through small holes in the screen. Graduate students in psychology served as observers; they were in another room behind a one-way mirror and so could not smell the odorants. The child's reaction to the odorant was rated as "pleasant, neutral, or unpleasant." Two of the stimuli used are considered to be pleasant to adults: amyl acetate (banana) and lavender. The other two stimuli are considered to be unpleasant to adults: dimethyl disulfide (rotten cabbage) and butyric acid (vomit). The odorants had been matched for perceived intensity by adults. The odorants were detected (often the child stopped playing with the toys briefly and looked vigilant), but the most common rating of the child's affect was "neutral." A variety of studies show that as children age, their hedonic responses to olfactory stimuli come to resemble those of adults (see Engen & Engen, 1997, for a review).

Do such studies prove there is no innate orthonasal olfactory affect? The answer must be no. The difficulty of doing research with young children limits the number of odorants that can be tested. The possibility remains that some odorants do evoke innate affect.

Although species other than humans can learn the significance of olfactory cues, nature also uses hard-wired solutions for these species. For example, innate olfactory preferences have been claimed for drosophila (Semmelhack & Wang, 2009). Herz notes that for species "restricted to specific habitats" (specialists), hard-wired responses to certain odorants are biologically wise (Herz, Beland, & Hellerstein, 2004). Mice appear to show innate aversions to certain odors associated with predators. Mutant mice in which specific olfactory glomeruli were absent failed to show those aversions, even though they could detect the odors and learn to avoid them (Kobayakawa et al., 2007). Innate olfactory aversions have also been claimed for the rat (Johnson et al., 2012), zebrafish (Hussain et al., 2013) and drosophila (Semmelhack & Wang, 2009). In particular, physiological evidence has identified specific receptors (trace amine-associated receptors [TAARS]) that appear to "constitute a distinct olfactory subsystem" that detects "mostly aversive odors" (Johnson et al., 2012). In zebrafish, one of those receptors (TAAR13c) has been associated with the "death-associated" odor cadaverine (Hussain et al., 2013).

Humans have TAARs, but the evidence in humans for any innate olfactory aversion is not impressive. For one thing, any argument for innate olfactory aversion in humans must include a control for pain/irritation. Many odor volatiles we consider aversive are also irritants; that is, they stimulate the trigeminal system (Herz, 2006). The aversion to irritation is hard-wired. Thus, to claim that an odorant produces hard-wired aversion, one must show it does not evoke irritation. This is relatively easy to do since the presence of an irritant in a volatile can be detected. Irritation can be localized to the nostril stimulated; pure olfactory input cannot be so localized (Schneider & Schmidt, 1967).

Some authors have noted that innate olfactory affect may be harnessed in different ways by different species. For example, Hussain and colleagues (2013) noted that while cadaverine, putrescine, and other biogenic diamines produce avoidance in zebrafish, these same odorants can act as attractants for species that feed on carcasses.

Does the importance of innate aversions in some nonhuman species suggest that there are innate olfactory aversions in humans as well? The senior author, Sakano, of the mouse article described above (Kobayakawa et al., 2007) was interviewed about the research (Callaway, 2007). The interview notes, "Humans probably have a similar system for discerning smells, but learned behaviours can sometimes over-rule innate ones." However, generalists (like humans) can live in a variety of habitats; the ability to adapt as needed is biologically wise in this group, which supports the value of learning (Herz et al., 2004). Evidence to date does not support innate olfactory aversions in humans.

If There Were Innate Olfactory Affect in Humans, How Would We Find It?

In 350 B.C.E., Aristotle wrote about olfaction in his treatise *On Sense and the Sensible* (Beare, 1906). He described two classes of odors, the first group associated with foods. Aristotle notes that these are

> agreeable as long as animals have an appetite for the food, but they are not agreeable to them when sated and no longer in want of it. The other class of odours consists of those agreeable in their essential nature, e.g., those of flowers. . . . Of this species of odour man alone is sensible.

Are there likely to be innately positive odors in humans? Goff and Klee (2006) made an interesting argument for the biological utility of hard-wiring affect for some odorants. There are important nutrients that serve chemically as the source of volatiles emitted by fruits and vegetables. If such volatiles were innately pleasant, this would increase consumption of those fruits and vegetables. Interestingly, the sensations evoked by those volatiles tend to be floral. Was Aristotle right? Could our love of the smells of flowers reflect hard-wired love of volatiles signaling the presence of nutrients? If so, is there any way to prove this?

Transfer of Olfactory Affect Along Chains?

We can think of evaluative olfactory affect chains. For example, consider a newborn's first nursing experience. The odors of mother's milk (as well as the odors associated with mother herself) are paired with sweet (in Pfaffmann's [1960] terminology, a primary affect). Suppose that our newborn's mother wears a distinctive lily-of-the-valley perfume. That scent becomes liked. Now imagine our newborn, growing up and going to school where her kindergarten teacher wears the same perfume and introduces her to play dough. Play dough's distinctive odor becomes liked and later transmits its affect to the lilac smell of the bouquet placed in her playroom at home.

Once we begin to think of olfactory affect chains, additional questions arise. Is there a difference between the first link in a chain (created by primary affect) and additional links (created by acquired affect)? To the best of our knowledge, this is not a question that arises in the literature on evaluative conditioning. If such a difference were to be identified, could this provide a way to identify any volatiles that produce hard-wired olfactory affect and thus behave as primary sources of affect?

Another question raised by the chain metaphor relates to the Cabanac effect. Consuming sugar can reduce liking for sweet; injecting insulin can enhance liking for sweet. In one study, Cabanac (1971) showed that liking for orange odor declined after consumption of sugar. It is likely that the liking for orange odor results in most people because orange odor and sweet have been paired in their lives. Could it be that the affect for orange odor has retained some of the properties of the affect for sweet? Would liking for roast beef (presumably acquired from fat ingestion) show a decline after consumption of sugar? This has never been tested to the best of our knowledge.

Why Does Pleasure Sometimes Lead Us Astray?

In spite of the elegance of nature's solutions to the omnivore's dilemma, a number of nutritional disorders (e.g., obesity) testify to her failure to endow us with perfect food wisdom. Part of the problem is that nature uses pleasure to help us survive when we are very young, but that same pleasure begins to be maladaptive when we age. Consider the pleasure associated with macronutrients. Fats are critical sources of calories when we are growing. However, the learning mechanism that ensures we will love the odors and flavors of foods containing energy-rich fats when we are young continues through our lifespan. Once we are past producing young, evolution cares little about our fates. The positive affect we have accumulated toward the odors and flavors of high-fat foods ultimately contributes to obesity, metabolic syndrome, and so forth. The many books written on the subject of weight loss illustrate the difficulty of countering this love of high-fat foods. If any of these books worked, there would be little need for the rest.

How Do We Measure Affect?

Galileo (1564–1642) is supposed to have said, "Measure what is measurable and make measureable what is not so." Debates on what can be measured with regard to human sensory experience have raged for years. In 1932, the British Association for the Advancement of Science appointed a committee chaired by Allan Ferguson, a physicist, to debate "Quantitative Estimates of Sensory Events." The committee published its final report in 1940 (Ferguson et al., 1940). Perhaps, given the number of physicists on the committee, it is not surprising that the measurement of subjective sensory experiences aroused considerable skepticism (Michell, 1999). S. S. Stevens (1946) became involved with the debate because the committee chose his sone scale (loudness) for discussion. This motivated Stevens to publish his famous paper "On the Theory of Scales of Measurement," in *Science* in which he classified scales as nominal, ordinal, interval, and ratio. Fortunately for psychology, Stevens's views prevailed and measures of perceived intensity of sensations are now respectable.

The measurement issue to be discussed here concerns comparisons of sensations. It is not enough to know we are experiencing pleasure or pain; we want to know how our experiences compare to those of others. How can we do this? There are those among us who claim that they can: mind readers, psychics, and some psychophysicists who misuse scales. The sections that follow discuss that misuse.

Early Attempts to Compare Affective Experiences: Visual Analogue and Category Scales

Attempts to quantify experience go back many years. The oldest scales appear to be category scales. For example, the Greek astronomer Hipparchus (190–120 B.C.E.) devised a 6-point scale to quantify the brightness of stars. More recent examples: food scientists created a 9-point scale that can be used for sensory (e.g., sweetness) or hedonic (e.g., dislike–like sweetness) intensity, and clinicians created a 10-point scale for pain intensity. In 1932, Likert constructed a 6-point category scale for the measurement of attitudes. Interestingly, the Likert-scale type was so widely used that some erroneously now use "Likert" as a synonym for "category" scale.

In the 1960s, the category scale morphed into the visual analogue scale (VAS). Early examples were devised to measure hunger. For example, Spence and Ehrenberg (1964) asked subjects to rate their hunger on a line labeled "not hungry at all" at one end and "very hungry" at the other end, while Silverstone and Stunkard (1968) used the labels "not at all hungry" and "as hungry as you have ever felt." However, the formal introduction of the VAS appeared in the "Section of Measurement in Medicine," a special portion of the prestigious British journal *Proceedings of the Royal Society of Medicine*. This section was introduced to the journal in 1965 with an inaugural essay (Cohen, 1965) noting, "It is not surprising that this Section should enter so late into the Society's activities, for mensuration appears late in the advance of medical knowledge." Of special interest to those in the behavioral sciences, this essay discussed measurement only as seen by the physical sciences. However, 4 years later, Aitken (1969) published his "Measurement of Feelings Using Visual Analogue Scales" in this section (Zealley & Aitken, 1969). He noted,

> An understanding of many problems in clinical research presupposes that it is possible to communicate the desired information from patient to clinician in a way amenable to measurement. . . . For the measurement of feelings, communication based on a simple visual analogue seems appropriate.

Of special interest here, Aitken went on to note a profoundly important limitation: "The same word used by different people need not convey that they experience the same feeling, neither does comparable positioning of marks on lines." In spite of that clear warning, others went on to use the VAS as if values on such a scale could be directly compared across individuals or groups. Later in this chapter, we present two examples of this misuse: one from taste and one from pain.

Measurement Theory

Sensory Scales

VAS and category scales are essentially atheoretical. There are many of these and they have been devised to measure single attributes (e.g., sweetness, pain intensity). The VAS was considered by many to be an advance over a category scale because the VAS has ratio properties (Price, McGrath, Rafii, & Buckingham, 1983)—that is, distance on the VAS is like distance on a ruler. A designation at 4 inches denotes a perceived intensity double that of a designation at 2 inches. This is not true of designations on a category scale; these are ordinal only (Stevens, 1946).

On the other hand, measurement theory evolved over much the same time frame as these practical scales. The earliest of the measurement theorists who is still well known to us is Gustav Fechner. He formalized three methods of threshold measurement that still remain today. He focused on two kinds of thresholds: absolute and relative. The absolute threshold was the lowest magnitude of stimulus that a person could experience; the relative threshold was the amount that a stimulus had to be increased to produce a just-noticeable difference (JND). He created a scale of perceived intensity from these two measures in the following way. Beginning at the absolute threshold, intensity is reflected by the number of JNDs up to the stimulus of interest.

The reign of this theorist ended with the work of S. S. Stevens in the 1960s. Stevens pointed out a fatal flaw in the JND scale: it lacked ratio properties. For example, if we were to measure loudness with a JND scale, a loudness of eight JNDs would be louder than twice the loudness of four JNDs. It is as if the subjective size of the JND is growing with stimulus intensity. Stevens tackled this problem head on. He devised methods with the intention of providing ratings with ratio properties. For example, the most popular of the new direct methods introduced by Stevens was magnitude estimation. In brief, if we want to measure sweetness with magnitude estimation, we might ask a subject to assign a number to the sweetness of a given sucrose solution. Then, when we provided a different concentration of sucrose, the instructions to the subject would be to assign a number to the second solution that reflects its relation to the first. If it were twice as sweet, it should be assigned a number twice as large, and so forth. Assuming that subjects can do this, the resulting ratings will have ratio properties. Duncan Luce provided the theoretical underpinning for this critical assumption (Luce, Steingrimsson, & Narens, 2010).

Hedonic Scales

Although opinions vary on this point, many psychophysicists (the authors included) believe that the perceived intensities of hedonic experiences can be rated on scales similar to those used for conventional sensory experiences (brightness, loudness, etc.), but with valence added. Thus we can use a sensory scale to measure sweetness and a hedonic scale to measure liking–disliking of sweetness.

Development of Methods for Valid Comparisons

Earliest Usage of Scales Focused on Comparing Stimuli

The commercial impact of food preferences has motivated a great deal of hedonic scaling: Is coffee A liked better than coffee B? This is a legitimate comparison since each subject can taste each of the samples to be compared; this is a within-subject comparison that can be made with virtually any scale.

However, we now know that there are important differences across individuals in the intensities of our experiences. In order to measure these, some investigators began to use the methods devised to compare samples. But this usage makes an implicit assumption: the labels on the scales denote the same perceived intensities to all subjects. This was recognized as an error by a variety of experts.

As noted above, one of those experts was R. C. B. Aitken (1969), who sought to measure depression in patients in the Royal Edinburgh Hospital. He and a colleague asked patients to mark a horizontal 100 millimeter line labeled "normal" at one end and "most depressed" at the other end (Zealley & Aitken, 1969). Aitken's realization that the VAS could not be used to compare individuals (or groups) was very important but was essentially ignored by his colleagues. Additional experts who provided such warnings (e.g., see Biernat & Manis, 1994; Birnbaum, 1999; Narens & Luce, 1983) are reviewed in Bartoshuk et al. (2002).

Comparisons of pain across individuals and groups provide an example of one of the most widespread errors. The most common pain scales are the 10-point scale and its VAS analogue. The bottom of the scale is 0 or no pain. The top of the scale is some indication of an individual's maximum pain,(i.e., the most intense pain ever experienced [or imagined]). Consider attempts to compare pain in women and men. If there were a systematic difference in the most intense pain for women and men, the scale could not provide valid comparisons between women and men. That such a difference does exist can be demonstrated (Bartoshuk, Duffy, Chapo, et al., 2004). We asked subjects to rate the perceived intensity of a variety of everyday experiences including these two: the most intense pain ever experienced (naming the pain) and the brightest light ever seen. Among the women who chose childbirth as their worst pain, their worst pain was about 20% more intense than their brightest light. On the other hand, among the men, their worst pain was about equal to their brightest light. If we can assume that these women and men show no systematic difference in their perception of brightness, we have demonstrated that for these women, childbirth pain was about 20% more intense than the most intense pain those men experienced. The problem becomes even more complex. Pain is so variable that no investigator can know if the particular women and men in a given study show the same difference we saw; the difference could be worse, less, or not present at all. Only valid comparisons can provide this information. We noted above that some investigators ask subjects to consider the top of the pain scale to denote the most intense imaginable pain (e.g., see Price et al., 1983). This seems to suggest that some investigators believe that even though actual pains experienced can vary enormously across subjects, we all can imagine the same "worst pain." Unfortunately, without mind readers and psychics we cannot prove this. However, simply asking subjects about their worst imaginable pain is illuminating. One creative subject told us that being sucked into a black hole would qualify, but others simply tell us that the most intense pain they can imagine is the most intense pain they have ever experienced (Bartoshuk, 2014). This does not suggest that "imaginable pain" is the same for all.

A Solution to This Dilemma Evolved from Taste Studies

In 1932, Arthur L. Fox, a chemist working at Dupont, synthesized some PTC (phenylthiocarbamide). Some was spilled accidentally and a colleague visiting at the time commented on how bitter the crystals were. Fox did not perceive them as bitter. This led to a demonstration at the annual meeting of the American Association for the Advancement of Science (AAAS); about three-quarters of the 2,000 attendees who took part could taste the crystals (tasters) while the remaining quarter could not (nontasters; Blakeslee & Fox, 1932). A family study seemed to suggest that nontasting was a Mendelian recessive: two nontaster parents always produced nontaster children, whereas if one or both parents were tasters, a child could be a taster (Snyder, 1931). This was the first demonstrated genetic taste difference. The early studies used thresholds to sort subjects into nontasters (high thresholds) and tasters (low thresholds). Even this relatively primitive psychophysics led the way to an amazing number of studies from demonstrating that the Dionne quintuplets were all tasters (Ford & Mason, 1941) to studies relating taster/nontaster status to food preferences and health risks (Fischer, Griffin, & Rockey, 1966).

The next important development was the discovery by J. C. Stevens (1959) that humans are very good at matching stimuli of different qualities for intensity using magnitude estimation. Note that although many have used magnitude estimation to scale the perceived intensities of single attributes (e.g., for sweetness) magnitude estimation can be used to rate sensations of many different qualities on a common scale.

Once we move beyond single-attribute scales, a solution emerges. Consider a demonstration of the error and a possible solution in taste. Suppose we recruit two groups: one with a high density of fungiform papillae (the structures that house taste buds on the anterior tongue) and one with a low density. We ask all subjects to rate the sweetness of a cola from "no sweetness" to "the sweetest sensation I have ever experienced." The two groups will behave in a similar manner—that is, both groups will rate the sweetness to be about two-thirds of the distance from no sweetness to sweetest ever experienced. Now put earphones on each subject and ask them to adjust the loudness of a tone to match the sweetness of the cola. Those with the most fungiform papillae will set the loudness to about 90 decibels; those with the fewest will set the loudness to about 80 decibels. We know a great deal about loudness. For example, each increase of 10 decibels is equivalent to doubling the loudness. Thus, the subjects with the most fungiform papillae matched the sweetness they perceived to twice the loudness. We can infer that these subjects experienced twice the sweetness from the cola.

The first experiment is an example of using a single attribute scale (sweetness) to compare two different groups of people. The second experiment uses a technique formalized as "magnitude matching" that asks subjects to rate a sensation of interest, sweetness, relative to an unrelated sensation, loudness (see Bartoshuk, 1979; Bartoshuk, Duffy, Green, et al., 2004; Hall, Bartoshuk, Cain, & Stevens, 1975; Marks, Borg, & Westerlund, 1992). Once we do this, we see that those with the most fungiform papillae are actually experiencing twice the sweetness of the cola. The first experiment implicitly assumed that "the sweetest sensation ever experienced" is the same for all. That is not true. It turns out that the more fungiform papillae you have, the more intense taste is. Thus, those with the most fungiform papillae have a greater capacity to experience sweetness. For them, the cola is twice as sweet. Incidentally, those subjects who experience the most intense tastes are called "supertasters."

Note that the discussions both for pain and taste show that the solution to the problem posed by comparisons across groups is to use a "standard" unrelated to the sensation to be compared. That the standard (e.g., the 90-decibel sound in the taste example, brightness of the sun in the pain example) is not related to the sensation to be compared (taste and pain, respectively) is an assumption. Thus, even though magnitude matching avoids the errors of making comparisons with single-attribute category or VASs, magnitude matching only provides valid comparisons when the standard chosen is genuinely independent of the stimuli to be compared. However, we can reduce the possibility of bad standard choices by using multiple standards.

What Kinds of Errors Result from Invalid Comparisons?

For taste and pain, we have discussed the kinds of errors that result from erroneously assuming that scale intensity descriptors denote the same absolute perceived intensities to all (Bartoshuk et al., 2002; Dionne, Bartoshuk, Mogel, & Witter, 2005). The most common error is to fail to reveal differences that are real. However, in a few cases, a reversal artifact occurs—that is, an apparent difference between two groups can actually be in the wrong direction (Bartoshuk, Duffy, Chapo, et al., 2004; Dionne et al., 2005; Snyder, Prescott, & Bartoshuk, 2006).

Conclusions

Innate taste affect and acquired olfactory affect contribute to survival in humans and other species. There is still much to be learned about the acquisition of olfactory affect.

Evaluative conditioning has taught us about the transfer of affect among olfactory stimuli as well as between olfaction and other everyday experiences. We suggest that adding the distinction between retronasal and orthonasal olfaction may provide some clarification. These two olfactory functions serve very different purposes and have quite different contributions to make to our survival. All species require food and so there may be considerable overlap across species in how we use retronasal olfaction to avoid poisons and find healthy food. However, lower species seem to depend on orthonasal olfaction for safety in their environments much more than humans do. This need for safety may have provided the evolutionary pressure to create hard-wired olfactory affect to guide these species to safety. Does hard-wired olfactory affect exist to some extent in humans even though we have so many other ways to find safe environments? Some investigators seem to favor this possibility, but no evidence supports this at present.

Evaluative conditioning focuses on the transfer of affect. Some olfactory generalizations are possible. In the food world, transfer of affect from primary sources to olfactory stimuli is common and powerful. Transfer of affect involving nonfood experiences is less impressive. Will evaluative conditioning involving olfaction give us new insights about evaluative conditioning in general?

Our growing sophistication in psychophysical measurement is giving us new tools to quantify affective differences among us. With valid comparisons, we can now look at variables of great interest to us (affective differences across sex, age, health status, etc.) as well as differences across cultures, ethnicities, and so forth. The insights to be gained from valid affective comparisons are likely to have benefits we can hardly imagine now.

PART III

DEVELOPMENTAL PERSPECTIVES

CHAPTER 14

The Development of Facial Expressions

Current Perspectives on Infant Emotions

Linda A. Camras, Serah S. Fatani, Brittney R. Fraumeni, and Michael M. Shuster

Although the relevance of facial expression to emotion is widely acknowledged, the nature of the relationship between them has been subject to considerable debate. As emphasized in the previous edition of this volume, facial expressions are a particularly important focus of attention for researchers studying infant emotional development. There are two primary reasons why this is true. First, infants are unable to verbally report their emotions and therefore researchers must rely on nonverbal indicators of their affective states. Second, starting with Darwin (1872/1998), many influential theories covering emotion (e.g., Ekman, 1972; Izard, 1991; Tomkins, 1962) have allotted a special place to the role of emotional facial expressions. In the previous edition of this handbook, our chapter presented a number of infant emotion theories that occupy the current landscape of research on infant emotion. In the present chapter, we both revisit these theories and selectively review what we consider the most relevant empirical research on infant emotional expression. While we include seminal early research in this area, the bulk of our focus is on more recent studies. As we will see, many of these studies have been conducted by investigators aligned with one or the other theories that we describe. Yet, as we shall also see, much of the research is not designed to discriminate among these theories but instead can be considered consistent with a number of different perspectives. Still, contemporary research on infant expression indisputably contributes to our overall knowledge of this important aspect of emotion and emotional development. Furthermore, it contributes to the building of a research "database" that may eventually help us arrive at a consensus regarding the most appropriate theoretical framework within which to situate our empirical observations and research findings.

Background

Charles Darwin's (1872/1998) *The Expression of the Emotions in Man and Animals* is most often cited as the seminal work on emotional expression, providing a detailed account of expressive behavior across both animal species and human cultures. Darwin argued that expressive behavior in both animals and humans could be explained in terms of three principles: serviceable associated habits, antithetical actions, and nervous system excitation. According to the principle of serviceable associated habits, some expressive behaviors are derived from instrumental actions that can serve adaptive functions when carried out in their entirety. For example, one component of the anger expression (baring the teeth) originated in the action of biting. However, Darwin was notably ambiguous regarding the current adaptive value of emotional expressions and their relationship to human motivation (see Fridlund, 1994, for discussion). Nonetheless, starting with Silvan Tomkins (1962), most recent and contemporary emotion theorists (e.g., Ekman, 1994, 2003; Izard & Ackerman, 2000; Izard, 1991) implicitly share the view that emotions are primary motivational forces in humans and that much of human behavior is organized in the service of emotion-related functions and goals.

In addition to advocating the central role of emotion in human motivation, Tomkins also revived scientific interest in emotional facial expression—a topic that had languished in the 20th century. As cogently reviewed and critiqued by Ekman (1982), several studies conducted from the 1920s through the 1950s had purported to find no systematic relationship between facial expression and emotion in either adults or infants. Nevertheless, Tomkins encouraged two young investigators, Paul Ekman and Carroll Izard, to pursue a series of studies on the recognition of emotional facial expressions in a variety of Western and non-Western cultures. These investigations included Ekman, Sorenson, and Friesen's (1969) landmark study of emotion recognition by the Fore people, a preliterate New Guinea tribe. Since that time, a number of studies with adults (reviewed by Matsumoto, Keltner, Shiota, O'Sullivan, & Frank, 2008) have linked emotional expression to other components of emotion responding (in particular, self-reported feelings). At the same time, there are vocal opponents to both the thesis of universality and the notion that facial expressions that are a core component of emotion (e.g., Barrett, 2006; Barrett, Wilson-Mendenhal, & Barsalou, 2015; Fridlund, 1994; Russell, 1994). Nonetheless, many contemporary psychologists still accept the premise that the prototypical emotional expressions described for adults are related in some important way to human emotions as motivational states.

Emotional Expression in Infancy

One plausible extension of the adult-based theories of facial expression is the proposal that a similar relationship between expression and emotion exists throughout the lifespan. Yet the implications of findings from the adult literature for the development of expressive behavior are not straightforward. More than one developmental pathway might lead to the outcomes reported for adults. In fact, as we describe below, a number of investigators hold that infant facial expressions do not correspond to adult-like discrete emotions and have proposed alternative developmental models. One prominent theory proposed by Michael Lewis (2014) holds that facial expressions initially are action patterns tied to specific physical events in the infant's world. Only through a complex developmental process do they eventually become tied to adult-like emotions. The details of this important model are presented elsewhere in this handbook (see Chapters 15 and 45, this volume) and thus are not reviewed herein.

As in the previous version of this chapter, our review of other theoretical models focuses on three questions that are central to understanding the development of emotional expression during infancy and beyond:

1. How do facial expressions become organized during the course of development?
2. What is the relation between facial expressions and emotion-eliciting situations?
3. What is the relationship between facial expressions and other emotion-related behavioral responses (e.g., emotion "action tendencies")?

These three questions are not unrelated. In particular, as described below, investigators often have sought to address the first one by examining evidence regarding the second and third questions across development.

Differential Emotions Theory

Although several related versions of discrete-emotion theories have been proposed in the adult literature, few of these have included an explicit developmental component. One such theory is Izard's differential-emotions theory (DET; Ackerman, Abe, & Izard, 1998; Izard, 1991; Izard & Malatesta, 1987). Following Tomkins (1962), Izard has argued that emotions (rather than drives) are the primary motivators of human behavior. Presumably an individual experiencing an emotion is motivated to pursue goals associated with its adaptive function. Thus, emotions motivate the individual's selection and organization of behaviors around these adaptive goals. Selection and organization of such behaviors are also acknowledged to depend upon situational factors, the individual's personality, and other aspects of his or her developmental history.

In its original formulation, DET proposed that infant expressive behavior is generally not discretionary, but instead is an automatic readout of the emotion system. However, several important caveats to this principle were later recognized, leading Izard (e.g., 2009; Izard, Woodbum, & Finlon, 2010) to revise his views. These caveats are related to our three focal questions regarding expressive development. First, DET proponents acknowledge that some fleeting facial expressions observed in the first 2 months of life may not be expressions of emotion (Izard & Abe, 2004). According to DET, at this very early age the neural circuits involved in facial expressions at maturity are still lacking in infants, and infant expressions such as smiles during sleep or during transitional states (e.g., waking up from a nap) may reflect random central nervous system activity (Ackerman et al., 1998). Thus, in response to our first question concerning how facial expressions become organized, DET proponents propose that expressive reorganization occurs early in development as a result of neurological maturation.

The second exception to the automatic readout hypothesis suggests that expressive impulses sometimes may be too weak to produce observable expressive behavior. Presumably this might result in an absence of the predicted facial expression—but not in the production of a facial configuration corresponding to a different emotion. Last, according to DET, expression production may be regulated by older infants, children, and adults according to social and personal display rules that are acquired over the course of development. This is accomplished by overriding the automatic output of expressive behavior via a voluntary control system that exists separately from emotion. As a result, older infants, children, and adults may not always produce facial expressions corresponding to their true emotions. However, infants past the neonatal stage but younger than approximately 1 year are presumed not to exert such voluntary control over their facial behavior (Izard et al., 1995). Thus, in response to our second question concerning the relationship between expression and emotion-eliciting situations, DET proposes that observable facial expressions produced by infants during their first year of life may not always occur in emotion-eliciting situations, but those that do occur should invariably correspond to the elicited emotion. In contrast, older children and adults may voluntarily produce expressions corresponding to nonexperienced emotions.

Perhaps surprisingly, DET proponents have not specifically addressed our third focal question, concerning the relationship between infant facial expressions and emotion-related action patterns. Although DET acknowledges that emotional expression includes nonfacial behaviors (e.g., vocalizations), instrumental actions are not considered to be a core component of emotion. Thus, relationships between facial expressions and action patterns in infancy have not been specified or subjected to investigation. Instead, as described below, the primary focus in DET-related research with infants has been on the patterning of emotional expression across development and the relationship between expressive behavior and emotion-eliciting incentive events.

To facilitate the study of infants' expressive development, Izard and his colleagues developed the MAX and AFFEX coding systems (Izard, 1995; Izard, Dougherty, & Hembree, 1983) for use in scoring infant expressive behavior and identifying facial configurations that are the expressions of discrete emotions or blends of such emotions. Using these systems, Izard and his colleagues have measured expressive behavior in response to a number of eliciting situations. In several of their studies (Abe & Izard, 1999; Izard & Abe, 2004; Izard, Hembree, & Huebner, 1987), they have reported that infants produce facial expressions representing appropriate emotion responses to the incentive events. Izard et al. (1995) have also examined the relative frequency of full-face versus partial emotional expressions or blends in infants of different ages, as well as the stability of individual differences across infants in the production of various facial configurations. According to Izard's view, younger infants should produce more full-face expressions and fewer partial expressions or blends, because full-face expressions are presumed to be less controlled and regulated. Furthermore, morphological stability of the MAX-specified facial configurations across infancy has been reported (Izard et al., 1995) and is considered evidence for their sharing emotion meaning with the prototypical expressions described for adults. Last, Izard and colleagues have conducted a number of judgment studies in which they report that observers perceive the MAX-specified facial configurations to represent their presumed emotions (Huebner & Izard, 1988; Izard, 1971; Izard et al., 1995; Izard, Huebner, Risser, McGinnes, & Dougherty, 1980).

As reviewed in Camras and Shutter (2010), all of these forms of evidence are controversial. For example, Oster (2005) has pointed to important differences in the morphology of emotional expressions described for adults and those specified in the MAX and AFFEX coding systems. In addition, Oster's own judgment studies (Oster, Hegley, & Nagel, 1992) suggest that several MAX- and AFFEX-specified expressions are perceived as representing distress rather than discrete negative emotions. Other investigators (Matias & Cohn, 1993) have found that blends rather than full-face expressions are predominant during mothers' interactions with young infants. Last, observation of infant expressive behavior in response to a number of different eliciting situations has revealed patterns of expressive responses that do not appear to reflect the discrete negative emotions presumed to be experienced by the majority of infants. We return to these findings below.

Differentiation Theories of Emotional Development

Prior to the advent of contemporary discrete-emotion theories, the most prominent view of infant emotional development portrayed ontogeny as a process of differentiation and integration. In 1932, Katherine Bridges published a highly influential monograph that dominated the literature on infant expressive development for several decades. In this monograph, she described infant emotions as originating in a state of diffuse excitement that differentiates first to generate delight and distress, and then to produce more distinct emotion states such as fear, anger, elation, and affection. More recently, Alan Sroufe as well as Michael Lewis have produced theories of emotional development that retain the notion of specific emotions deriving from less differentiated earlier reactions. According to Lewis (The Emergence of Human Emotions, Chapter 15, this volume), basic action patterns of approach and withdrawal may be the starting point for their later differentiation into discrete emotions. According to Sroufe (1996), the emergence of emotions can be described in terms of three developmental steps: pre-emotion reactions during the newborn period, precursor emotions during the first half year of life, and more mature emotions during the second half year. Although he describes these steps in detail only for joy, fear, and anger, Sroufe contends that the analysis can be extended to other emotions.

Sroufe (1996) implicitly attributes the reorganization of emotional expression during early infancy to maturational processes. Thus, his view of how expressions become organized (and reorganized) over the course of early development (i.e., the mechanisms of developmental change) is similar to that proposed by DET. However, in response to our second two questions, he describes very different patterns of relationships between facial expressions and emotion-eliciting situations, as well as between such expressions and emotion-related behavioral responses. More specifically, Sroufe distinguishes between positive and negative expressions and between positive and negative emotional states occurring early in development. However, beyond these broad-based valence distinctions, he does not propose a consistently tight correspondence between specific emotional expressions and the less differentiated emotional states that precede the development of mature discrete emotions. For example, Sroufe distinguishes between positive and negative facial expressions (i.e., smiles vs. distress expressions), but does not distinguish between distress expressions accompanying wariness (the precursor to fear) and frustration (the precursor of anger). Instead, wariness and frustration are distinguished in terms of both their eliciting circumstances and an infant's nonfacial responses (e.g., avoidance vs. diffuse attack). Thus, facial expressions are systematically related to both emotion-eliciting situations and emotion-related behaviors, but not in the manner proposed by DET (i.e., as involving a one-to-one correspondence between specific expressions and corresponding discrete emotions).

Because Sroufe's (1996) position is not represented elsewhere in this volume, we present a more complete description of his model. According to Sroufe, neonatal pre-emotion reactions (i.e., smiling, distress) are automatic reflexive responses to quantitative, rather than qualitative, aspects of stimulation (e.g., temporal and intensity features of arousal). For example, smiling can be produced by gentle modulated arousal, while distress results from more intense arousal buildup. Because Sroufe believes that eliciting stimuli for these reactions can be identified that are somewhat analogous to the later elicitors of more mature emotions (e.g., physical restraint for anger), he considers these neonatal reactions to be prototypes for later-developing, more discrete emotions. Nonetheless, because Sroufe defines emotions as subjective reactions requiring some degree of cognitive evaluation, these early precognitive reactions are not themselves considered emotions.

Following the neonatal period, precursor emotions (e.g., pleasure, wariness, frustration) emerge. These are considered true emotions, because the infant has begun to develop the cognitive ability to process stimulus content; however, they are still regarded as precursors, because they involve only the simple cognitive process of relating present experiences to past experiences. Thus, pleasure arises from stimulus recognition, wariness from recognition failure, and frustration from inability to execute a familiar (i.e., recognizable) behavioral routine. Of particular relevance to the topic of this chapter, Sroufe (1996) states that some precursor emotions are not distinguishable in terms of their facial or vocal expressive components. For example, wariness and frustration reactions are similarly manifested in crying and distress. After the first 6 months, basic emotions (e.g., joy, fear, and anger) begin to emerge. Sroufe views these as mature emotions, because they involve more complex cognitive evaluation processes. For example, fear is elicited by the perception of a threat, as opposed to a more general failure to recognize a stimulus. Fear and anger are differentially manifested in more specific behavioral responses (e.g., avoidance vs. diffuse attack).

Also of particular relevance for this chapter, Sroufe asserts that reliable differences in the facial expressions for these emotions emerge some time after the emergence of the emotions themselves. Thus, Sroufe's theory is distinct from DET in its contention that there are not distinct facial expressions corresponding to distinct emotions at all ages. For example, according to Sroufe (1996), "few or no elements of the fear face are seen in the distress of wariness" (p. 65). Earlier and later forms of emotions and emotional expressions are related through their developmental history rather than through their morphology.

An Ontogenetic View of Expressive Development

Focusing more specifically on expressive behavior rather than emotional development in general, Oster (2005) considers a broader range of facial expressions than either Sroufe or Izard does. Rather than confining her efforts to a search for the origins of adult emotional facial configurations, Oster seeks to investigate the infant's entire expressive repertoire. According to her ontogenetic view, an infant shows a variety of distinctive facial expressions that have important signal value within the context of the infant's world, going beyond or even regardless of their relationship to discrete emotions. Because the adaptational demands of the environment differ for infants and adults, she argues that it is reasonable to believe that their emotional and expressive repertoires may differ accordingly.

Although Oster (2005) has not articulated a specific position on the question of how facial expressions get organized over the course of development (i.e., our first focal question), her view implicitly suggests that expressions are tied to emotion-related states from the beginning, but that emotion states themselves may change with development. In principle, this position is similar to Sroufe's (1996), although Oster identifies a different set of emotion-related states preceding the development of discrete emotions (e.g., attempts by the infant to regulate negative affect). In response to our second focal question (regarding relations between situations and emotional expressions), Oster's discussion, like Sroufe's, implies that facial expressions are systematically related to situations that elicit these emotional states. Unlike Sroufe, Oster does not discuss relationships between expressions and nonfacial emotion-related actions on the part of the infant (our third focal question). Instead, she relies on analyses of the temporal patterning of facial expressions, their situational occurrence, and observers' interpretations of the expressions to make inferences about the emotion states underlying infants' expressive behavior.

As an example of her perspective in practice, Oster has studied the situational occurrence of "pouting," a mouth configuration that would be identified as a component of sadness according to the MAX and AFFEX coding systems. However, based on her observations, Oster proposes that "pouting" reflects an effort by the infant to regulate distress, and that the label of "sadness" fails to capture its more specific meaning and signal value. Examining infant expressions by means of her fine-grained BabyFACS (an infant-oriented version of Ekman, Friesen, & Hager's [2002] anatomically based Facial Action Coding System [FACS]; Oster, 2012), Oster has also highlighted morphological differences between the discrete negative emotional expressions proposed for infants according to MAX and adult facial configurations corresponding to the same emotions (e.g., adult anger and fear prototypes). These morphological differences suggest that the meanings of adult and infant expressions may not be identical. In addition, Oster notes the broad situational occurrence of MAX-specified pain and anger faces that are often produced in the context of infant crying. Like several other investigators (e.g., Camras, 1991; Sroufe, 1996), she concludes that currently there is no convincing evidence that these

MAX-specified expressions correspond to discrete adult-like emotions. Instead, they may reflect a more generalized distress reaction or a more specific level or type of distress that does not correspond to a discrete-emotion label (e.g., intense distress or modulated distress rather than "anger" or "sadness"). To determine the true meaning of infant emotional expressions, Oster advocates an empirical approach to expressive development that takes infancy itself as its point of origin, seeks to identify infants' repertoire of expressive behaviors, and attempts to determine their adaptive value for infants themselves as well as their ontogenetic relationship to expressive behavior in older individuals. According to Oster, whether or not this relationship involves a true differentiation process remains to be determined.

The Functionalist Framework

The functionalist approach to emotion was proposed by Barrett and Campos (1987) to rectify discrete-emotion theories' tendency to focus narrowly on a set of core components situated within the person. According to the functionalist approach, an emotion is a relational process through which an individual attempts to establish, change, or maintain some significant aspect of his or her relationship to the external or internal environment. Emotions can acquire their significance via several processes. Perhaps the most important of these are social signaling (i.e., observation of others' expressive responses) and appraisal of the event's relevance to one's personal goals. The elicited emotion reflects the nature of that relationship and includes an open class of responses designed to attain (or maintain) a desired goal state. For example, an event appraised as involving a significant loss might evoke responses designed to recoup the loss or to acquire an acceptable substitute. Of importance, the specific responses themselves (e.g., crying, searching for the lost object, seeking comfort) are not predetermined by an innate emotion program, but are drawn from the individual's entire response repertoire in the service of achieving the person's particular goal for that emotion episode—that is, emotion responses are functional rather than fixed or preprogrammed. Nonetheless, the functionalist approach acknowledges that there may be intrinsic links between specific emotions (or emotion families) and particular responses (e.g., action tendencies, facial expressions, physiological patterning). However, these links are not invariant and are subservient to the context-dependent selection of responses designed to achieve the individual's emotion goals.

With respect to how infant expressions become organized (our first focal question), functionalists propose that this occurs in conjunction with infants' social development. Consistent with its overall conceptualization of the emotion process, functionalism views facial expressions primarily as social signals serving to communicate emotions to others, rather than as direct readouts of emotions themselves. Thus, regarding relationships between facial expressions and emotion situations (our second focal question), functionalists assert that facial expressions may or may not be generated, depending on whether they would be serviceable in the particular emotion situation. Importantly, functionalists do not believe that the absence of facial signaling in an emotion episode necessarily reflects the suppression of "naturally" produced expressive behavior. Although expressive behavior indeed may sometimes be altered in accordance with social display rules, this reflects a change in the evaluation of the expression's functionality, rather than the suppression of an inherent automatic readout of the emotion. According to the functionalist perspective, socialization processes are important in establishing the conditions under which emotion signals (including facial expressions) are produced. Developmental changes in expression–emotion relationships reflect an individual's socialization experiences in conjunction with his or her evaluation of the effectiveness of expressive behavior.

In response to our third focal question, functionalists would propose an indirect rather than a direct relationship between facial expressions and other emotion-related behaviors. Because functionalists view all emotion-related behaviors as discretionary, co-occurrences of specific facial expressions and instrumental behaviors would not necessarily be expected. In fact, functionalists have argued that facial expressions and instrumental behaviors may be produced as alternative responses in emotion situations, depending on the individual's assessment of their relative functionality. Thus, in response to our third focal question, functionalists would predict that relationships between facial expressions and other emotion-related behaviors might not be observed within an individual, but might be observed as substitute responses to the same emotion situation.

Functionalism represents an important advance in developmental theorizing about expressive behavior. Although it does not elaborate on the specific mechanisms of expression production (i.e., processes that determine whether expressions are generated, and if so, which ones), the functionalist approach has provided an important alternative to theories that focus on relatively rigid relationships among a set of core emotion components. It encourages investigators to view emotion as a more flexible system of responses oriented toward achieving an individual's goals.

Sociocultural Models

More recently, Holodynski and Friedlmeier (2006) have presented a socioculturally based internalization model of emotional development spanning infancy and childhood. With respect to infancy, they propose, as differentiation theorists do, that infant facial expressions initially reflect precursor emotions (e.g., distress, pleasure, fearful tension) and are not selectively associated with discrete-emotion-specific causes or coordinated with emotion-specific behaviors. However, caregivers interpret these diffuse infant expressions within their contexts of occurrence and thus respond to infants with appropriate actions. At the same time, caregivers shape links between specific facial expressions and discrete emotions through their own behavior. That is, caregivers mirror infants' expressive behavior during their interactions with infants, but do so selectively and in exaggerated form. For example, when an infant cries in circumstances considered sadness appropriate by the caregiver, then that caregiver may respond with an exaggerated sadness expression while offering comfort to the infant—that is, the caregiver displays both exaggerated (i.e., prototypical) facial expressions and emotion-appropriate motive-serving actions. Infants thus acquire these expression–emotion relationships, which are later reflected in their own expressive and emotional behavior. Holodynski and Friedlmeier's model therefore provides a clear proposal for each of the focal questions we address in this chapter. According to their model, socialization is the means through which diffuse expressions of positive affect or distress are organized into the specific facial configurations corresponding to discrete emotions that are selectively associated with emotion-related situations and behavior responses.

Holodynski and Friedlmeier's (2006) model incorporates a number of findings from the developmental literature regarding expressive mirroring during mother–infant interaction. At the same time, their proposals regarding the linking of discrete-emotion expressions and emotion-specific functional actions require further substantiation. In particular, given that early social interactions may differ widely across cultures, further research involving non-Western mothers and infants is required to further substantiate their proposal regarding mechanisms of expressive development. Nevertheless, Holodynski and Friedlmeier present an intriguing model that has the potential to bridge the gap between infant and adult expressive behavior.

A related approach to conceptualizing sociocultural influences on emotional development is Keller's (2007) ecocultural model. This theory differs from Holodynski and Friedlmeier's (2006) model in that it emphasizes cultural influences on the degree of infants' and children's expressivity rather than caregivers' shaping the morphology of discrete-emotion expressions (Kärtner, Holodynski, & Wörmann, 2013). In this model, a culture's valuing of either autonomy or relatedness to others influences the expressivity of culture members, and this influence is mediated by the value placed on emotional expression in that particular culture (Keller & Otto, 2009). For example, in Nso culture, less emotion is shown in order to maintain the value of group cohesion, while in German culture, more emotion is shown to allow for greater autonomy (Keller & Otto, 2009). In collectivistic cultures there is the expectation that children as well as adults will regulate their emotional expression, whereas individualistic cultures encourage expressing emotions to a greater extent (Keller, 2007).

Regarding development, Keller would claim that facial expressiveness is organized during development by parents and other culture members who encourage more or less emotional expressivity (Keller & Otto, 2009). For instance, in Nso culture, crying is shamed and an infant is discouraged from making vocal cries along with crying facial expressions, whereas German mothers attempt to determine the reason the child is crying by listening to pitch and examining their child's expressions (Keller & Otto, 2009). Further recent research motivated by this model is reviewed below.

The Dynamical Systems Perspective

Like the functionalist perspective, the dynamical systems approach to emotional development emphasizes flexibility in the organization of emotion responses and variability from individual to individual (Camras & Witherington, 2005; Haviland-Jones, Boulifard, & Magai, 2001; Magai & Haviland-Jones, 2002). Originating outside the social sciences, the dynamical systems framework has been proposed as a general model that can be used to account for the organization of complex systems of various sorts (see Kelso, 1995). Because it provides a unique and novel perspective on system organization and interrelationships among system components, the dynamical systems approach presents a provocative alternative to the theoretical models described above.

The dynamical systems perspective addresses the question of system organization (our first focal question) by asserting a broader principle of self-organization, rather than narrower principles of either top-down maturational control or shaping via socialization (Fogel & Thelen, 1987; Fogel et al., 1992). With regard to relationships between facial expressions and both eliciting circumstances and emotion-related behavioral responses (i.e., our second and third focal questions), the principle of self-organization implies a flexible relationship among these systems components, as determined by the particulars of the situational context and the individual's developmental history. We expand on these ideas below.

According to the dynamical systems perspective, emotions may be conceived of as "attractor states"—that is, frequently observed organizations of emotion system components (Fogel & Thelen, 1987). However, dynamical systems attractors may themselves involve considerable variability in their details. Thus, in the case of emotion, the dynamical systems approach—like the functionalist approach—asserts that any specific episode may or may not include a particular emotion component (e.g., an emotional facial expression). Furthermore, at a lower level of analysis, emotion components themselves (e.g., facial expressions) may vary in their details. Such variability may also reflect the influence of lower-order contextual factors that influence the formation of an attractor. For example, Fogel, Nelson-Goens, Hsu, and Shapiro (2000) found that different types of mother–infant interactions are related to specific variants of infant smiling. Fogel, Messinger, and their colleagues (e.g., Messinger, Fogel, & Dickson, 1999, 2001) propose that such expressive variability engenders variability in emotional experience, because emotion itself emerges from the interaction of its constituent components.

Dynamical systems approaches are particularly concerned with processes leading to system change both across real time and across development (Fogel & Thelen, 1987; Thelen, 1989). According to this perspective, qualitative shifts in the organization of a system (termed "phase shifts") will occur when some key system component (termed the "control parameter") reaches a critical threshold. For example, Wolff (1987) observed that increasing the intensity of stimulus input sometimes itself produced a qualitative change in an infant's expressive behavior (e.g., from smiling to crying). Across development, a major reorganization of emotion responding may also occur when some developmental variable reaches its critical threshold. For example, a number of investigators (Emde & Koenig, 1969; Fogel & Thelen, 1987; Sroufe, 1996; Wolff, 1987) have noted heterochronicity in the development of infant emotional responses (e.g., the early appearance of smiles dissociated from other components of the presumed corresponding emotion). According to a dynamical systems perspective, such expressive components may become part of an organized emotional response when some (as yet unidentified) component of the system achieves threshold. Importantly, control parameters may differ across episodes occurring both within a narrow time frame and across development. For example, the intensification of either hunger or pain above a certain threshold may lead to infant distress. Across development, a major reorganization of emotion responding may occur when motor development, language development, or some other developmental variable reaches a critical threshold (Campos, Kermoian, & Zumbahlen, 1992; Parladé & Iverson, 2011). Two unique features of dynamical systems models of change are (1) the system demonstrates increased instability as the control parameter reaches its critical threshold; and (2) as it approaches the point of transition, the system becomes more responsive to external perturbations. For example, as hunger increases, an infant may be more likely to cry in response to being accidentally poked by the caregiver.

In many circumstances, emotion attractors (e.g., assemblies of appraisals, expressions, neurophysiological responses) may correspond to what are often considered to be universal discrete emotions—that is, universal environmental circumstances may exist that serve as "control parameters," leading to the organization of a set of responses that have been associated with anger, fear, sadness, and so on (Camras, 2011). In this sense, such emotions might be considered "innate," but not in the traditional sense of the term. Here, the "innateness" of the emotion lies in the universality of environmental "control parameters" that engender the organization of responses as much as in the sets of responses themselves.

Various scholars have applied dynamical systems principles somewhat differently to provide accounts of infant emotional development. For example, Fogel et al. (1992) view emotions as emerging de novo from the self-organized interactions of components, including some that are not emotion specific (e.g., gaze, posture, instrumental actions). In contrast, Marc Lewis retains the notion that discrete emotions are preexisting hardwired assemblies of expressive, physiological, and phenomenological components, but views these assemblies as components within larger self-organized dynamical systems (i.e., emotion–appraisal amalgams; Lewis & Douglas, 1998). With respect to emotional facial expressions, the former position implies that unique relationships between facial configurations and emotional experience should not be expected. The latter position implies that an invariant concordance between certain facial expressions and their corresponding affective experiences should exist.

Because advocates of both these positions can offer plausible (but different) sorts of evidence consistent with their view, we have sought to develop a third position that can accommodate the widest range of findings to date (see Camras, 2011, for details). This effort originated in Camras's (1992) observational study of her daughter's expressive behavior during the first 9 weeks of life. Initially adopting the perspective of discrete-emotion theories as it was originally conceived, Camras made a number of unexpected observations that could not easily be explained by DET's account of infant expressive behavior. Subsequent research (described below), as well as a review of the literature (Camras, Malatesta, & Izard, 1991), similarly revealed phenomena indicating that DET's initial account of infant expressive development required modification.

Several anomalous phenomena were identified, including (1) the systematic occurrence of codable "emotional" expressions in situations unlikely to have elicited the corresponding discrete emotion (e.g., nonemotional neonatal smiling [Emde & Koenig, 1969], "surprise" expressions produced by infants who were unlikely to be experiencing surprise [Camras, Lambrecht, & Michel, 1996]); (2) the nonoccurrence of emotional expressions corresponding to the emotion presumably experienced by infants (e.g., absence of fear expressions in infants judged to be afraid on the visual cliff [Hiatt, Campos, & Emde, 1979], absence of surprise expressions in infants judged to be surprised by an expectancy violation [Camras, 2000; Camras et al., 2002]); and (3) rapid shifts among MAX-designated facial expressions for anger, sadness, and physical distress/pain during bouts of intense crying occurring in response to almost any form of negative elicitor (including MAX-specified pain expressions in circumstances during which pain was unlikely to be experienced; Camras, 1992).

To explain these findings, Camras (2000) has proposed that infant emotions and infant facial expressions constitute overlapping but partly separate dynamical systems. More specifically, to explain the first anomaly described above, Camras and her colleagues (1996; Michel, Camras, & Sullivan, 1992) drew upon dynamical systems research in the area of nonfacial motoric action, and in particular upon the concept of the "coordinative motor structure" (i.e., a grouping of muscle actions that are synergistically linked to one another; see also Fogel, 1985). Thus they proposed that infant facial expressions may sometimes be produced in non-emotion-related circumstances via self-organizing processes of recruitment among "lower-order" facial muscle movements. For example, Camras et al. (1996) showed that 5- and 7-month-old infants will raise their brows as they open their mouths to incorporate an object—that is, opening the mouth recruits a synergistically related raised brow movement producing an expression of "surprise" in nonsurprising situations.

To explain the second set of anomalous findings, Camras (2000; Camras et al., 2002) proposed that facial expressions are nonobligatory components of emotion episodes and are produced only when their corresponding control parameters are present at the necessary threshold. In dynamical systems terms, discrete-emotion attractors (i.e., larger ensembles of emotion components) can be variable, and thus may or may not include a prototypical emotional expression in any one instance. This view is similar to the functionalists' notion that facial expressions are produced only when they serve a communicative function. However, dynamical systems proponents would recognize the potential for a broader set of control parameters to determine whether or not a facial expression is produced. These may include socialization variables and maturational influences but also other factors such as head position and gaze direction. For example, Michel et al. (1992) showed that infants raised their brows when looking upward to view an attractive object, but not when looking downward. In this case, head position and gaze direction served as "control parameters" determining whether or not the infant produced a facial expression codable as "interest" in an interest-relevant situation.

To explain the third set of anomalous findings, Camras (1992) proposed that the facial configurations depicted by DET as reflecting discrete anger, sadness, or physical pain may represent negative affective states that do not correspond to traditional categories of discrete emotions. Like Oster (2005), she suggested that some of these expressions may reflect different intensities of a more general state of "distress"—in other words, negative emotion that is relatively undifferentiated with respect to distinguishable functional goals (e.g., removing an obstacle vs. escaping danger) in very early infancy. Some forms of negative emotional expression may also reflect infants' efforts to modulate that distress (Oster, 2005) and/or the influence of non-emotion-related factors such as head position and gaze direction. For example, Camras et al. (2007) suggested that differences in head position and/or gaze direction during negative emotion episodes may sometimes determine whether infants produce brow configurations associated with prototypical expressions of fear, sadness, or anger.

As indicated above, Camras (2011) extended these views to present a broader proposal regarding emotional development. This proposal seeks to incorporate aspects of the several theoretical perspectives described above, most particularly, the differentiation and the dynamical systems viewpoints. Called the differentiation and dynamical integration (DDI) perspective, its guiding idea is to assert that components of emotion emerge heterochronically and become loosely organized into emotion systems (i.e., dynamical systems attractors) that become more differentiated over the course of development. Initially, these loosely organized emotions may be distinguished only in terms of excitement versus distress(similar—though not identical—to Bridges's 1932 proposal). However, the set of available emotion components increases as language development, cognitive development, motor development, and cultural socialization proceed. New attractor states emerge as these components are organized into more specific subsystems (e.g., anger, sadness, and fear rather than generalized negative affect). For example, consistent with this proposal, Bennett, Bendersky, and Lewis (2005) found more differentiated facial responding to different negative emotion elicitors in 12-month-old in comparison to 4-month-old infants (although considerable overlap still occurred).

Importantly, very different sorts of "control parameters" may catalyze the reorganization of emotion-related responses across development. For example, the development of self-produced locomotion might enable greater differentiation of instrumental responses associated with anger versus fear while a newly acquired emotion vocabulary might come to anchor an association of different behaviors labeled separately as "angry" by adults (e.g., hitting and angry facial expressions; see Barrett, Lindquist, & Gendron, 2007, for a similar view). In dynamical systems terms, the emergence of each new attractor (i.e., assembly of responses) would be considered a phase shift. The development of each emotion might involve several phase shifts as more elaborated forms of an emotion progressively emerge.

Relevant Research on Infant Emotional Expression

Since the last edition of this handbook, several important lines of research have been initiated or have continued to be pursued that are particularly relevant to the theories reviewed above. These include studies of both positive and negative emotion and emotional expressions. We begin with studies of positive emotion, in particular, infant smiling.

In neonates, smiles occur primarily during rapid eye movement (REM) sleep states and are generally considered to be endogenous (i.e., produced by internally generated cycles of arousal and arousal modulation; Emde & Koenig, 1969; Sroufe, 1996; Wolff, 1987). Investigators studying such smiles generally have concurred with Sroufe (1996, as described above) in interpreting them as being "pre-emotional," either because they involve no cognitive evaluation and/or because they are not associated with eliciting stimuli that are generally considered to be linked to pleasure or positive feelings. In subsequent studies, Messinger and his colleagues (2002; Dondi et al., 2007) extended the investigation of neonatal smiles by conducting fine-grained coding of their morphology using Oster's (2012) BabyFACS. Messinger et al. (2002) focused particularly on the presence of cheek raising (i.e., contraction of obicularis oculi or AU6 in

FACS terminology), which has been proposed to distinguish between smiles reflecting genuine positive affect (termed "Duchenne smiles") in contrast to nongenuine smiles (e.g., smiles that reflect no positive emotion but are generated in accordance with cultural or personal display rules in adults). This research showed that Duchenne smiles often are produced by neonates, raising questions about the validity of using the Duchenne smile as a universal marker of genuine positive affect. As such, it is inconsistent with early versions of DET that proposed an invariant link between emotion and facial expression in young infants. Instead, as noted by Messinger (2008, p. 191), "neonatal smiles illustrate the dynamic systems emphasis on heterochronicity; that is, the neonatal smile appears to develop physically before it is integrated into patterns of cognitive engagement and social interaction that provide evidence for joyful emotion."

Social smiling (smiling while gazing at a human face) emerges during the second month of life and becomes integrated into patterns of coordinated face-to-face interactions between infants and their caregivers. A number of highly detailed studies of such interactions have been conducted primarily in Western cultures (e.g., Lavelli & Fogel, 2013; see Messinger & Fogel, 2007, for a review of earlier investigations). These studies suggest that interactive smiling may comprise an important foundation for the development of a positive emotional relationship between mothers and infants. Furthermore, such studies show that smiles both with and without cheek raising are produced during the course of such positive interactions. While both types of smiles occur in situations that would be expected to elicit positive emotions (e.g., various types of play interactions; Messinger et al., 2001), Duchenne smiles are rated higher on joy/happiness than are non-Duchenne smiles, leading Messinger, Mattson, Mahoor, and Cohn (2012) to suggest that the cheek-lifting component communicates the intensity of the positive emotion underlying the smile rather than its veracity (i.e., its expression of genuine as opposed to simulated positive emotion). Messinger makes a similar argument regarding the function of cheek lifting when it serves as a component of negative emotional expressions. While not necessarily inconsistent with several of the theories described above, Messinger and his colleagues (2012) again interpret their data within the context of a dynamical systems framework in which emotions are considered to be self-organized systems that emerge from the self-organization of their constituent components. Different forms of smiling contribute to different forms of positive emotion.

Social smiling has often been described as if it were a purely maturational phenomenon. However, recent cross-cultural studies have suggested that its development is importantly influenced by sociocultural factors. For example, Keller and her colleagues (e.g., Wörmann, Holodynski, Kärtner, & Keller, 2012) have compared the development of social smiling in a Western and non-Western society (i.e., Germany and the Nso people of Cameroon, respectively). Consistent with the cultural values of an independence-oriented society (as described above), German mothers value positive emotional exchanges between mothers and infants. Consistent with the values of an interdependence-oriented society, Nso mothers value contentment and minimization of negative emotion in their infants. Social smiling appeared to emerge at approximately the same age in infants from both cultures. However, its later course of development differs in the two societies in ways that appear to reflect their differing cultural values and normative maternal behavior (Kärtner et al., 2013). More specifically, between 6 and 12 weeks of infant age, mutual gazing and smiling increased for German mothers and infants substantially more than for Nso mothers and infants. The investigators in these studies emphasize their consistency with Keller's (2007) ecocultural model, as well as Holodynski and Friedlmeier's (2006) internalization model. However, their findings are not inconsistent with any of the theoretical perspectives reviewed earlier in this chapter since none of these models precludes the influence of sociocultural factors on the development of emotion communication. Thus, some of the most interesting recent research in the area of infant facial expression is not of the type that critically distinguishes among the theoretical perspectives described above. Instead, it adds to our knowledge regarding particular aspects of development that are the main focus of one or another extant developmental model. On the positive side, the fact that such research is noncontroversial can be seen as reflecting a substantial degree of consensus regarding some important contributors to infant emotional development.

Regarding negative emotional expressions, probably the most controversial line of recent research has been the study of fetal facial expressions. This had been made possible by the advent of sophisticated 4-D ultrasound technology. At present, only a few studies have made use of this opportunity and fewer still have utilized the fine-grained coding systems developed for the study of postnatal infants' facial expressions. However, both Dondi, Gervasi, Valente, Vacca, Borana, et al. (2014) and Reissland, Francis, and Mason (2011, 2013) have used FACS-based coding to analyze facial movements of infants as young as 20 weeks postgestational age. Facial expressions associated with distress in postnatal infants were observed in even the youngest prenatal fetuses. For example, Dondi et al. (2014) identified configurations considered to be both "cry-faces" and "pre-cry faces" according to Oster's (2012) BabyFACS. Of importance, these expressions were produced in a circumstance during which no distress would be expected to occur (i.e., during noninvasive ultrasound scanning that did not involve perturbation of the fetus). In addition, such expressions were brief in duration and interspersed with other expressions not associated with negative emotion (e.g., smiling, mouthing). Such a dissociation between eliciting context and facial configuration is consistent with the dynamical systems principle of heterochronicity as earlier described. More specifically, distress facial expressions may first emerge in dissociation from negative emotion. Readers familiar with our earlier chapter will note that this position represents a change from the view we advocated in the previous edition of this handbook in which we suggested that an invariant relationship between distress expressions and negative emotion might indeed exist at (and presumably before) birth. However, we would now propose that this relationship develops later via a combination of maturational processes and socialization experiences. These remain to be specified at each point of developmental change. However, we continue to assert that dynamical systems concepts such as attractor state, control parameters, and phase shifts can provide an invaluable framework for understanding and conceptualizing the nature of emotional development.

Beyond our theoretically relevant change in position, the possibility of heterochronicity in the development of distress and its indicators may have important implications for the politically charged current debate regarding fetal pain—that is, although studies have shown that very premature infants do show distress expressions in response to invasive procedures performed after birth (e.g., heel lancing as studied by Slater et al., 2009), the reverse may not necessarily be true. Distress expressions alone cannot be considered invariable indicators of fetal pain or distress in the absence of other evidence.

Regarding the postnatal development of negative emotional expressions, Michael Lewis and his colleagues have continued their long-standing productive line of research on MAX-specified anger and sadness expressions using a contingency learning procedure (see Chapter 15, this volume and Lewis, 2014). In this procedure, infants first learn to produce a desirable audiovisual stimulus by movement of their arm. This may be followed by an extinction condition (involving removal of the stimulus) or a contingency removal condition (in which the stimulus event continues to occur but is no longer controlled by the infant's behavior). In several studies, Lewis and his colleagues (see Chapter 15, this volume and Lewis, 2014) have found different patterns of facial responding to extinction versus loss of contingency, as well as differentiated relationships between MAX-specified anger and sadness expressions and other infant responses. For example, in one important investigation, Lewis, Ramsay, and Sullivan (2006) found that MAX-specified anger expressions were associated with increased heart rate, while MAX-specified sadness expressions were associated with increased cortisol responding when 4-month-olds experienced contingency learning followed by extinction. More recently, Crossman, Sullivan, Hitchcock, and Lewis (2009) found evidence that anger expressions and persistent arm pulling were associated with extinction following perceived contingent control over the stimulus, whereas sadness expressions and lesser arm pulling were associated with removal of a desirable stimulus over which the infant never perceived contingent control. Anger expressions and arm pulling showed similar patterns of increase and decrease across the several key episodes of the procedure. The investigators interpreted their findings as supporting a motivational model in which anger expressions index an approach motivational tendency and sadness expressions index a withdrawal motivational tendency. As noted by the authors, this model does not assume one-to-one correspondence of facial expressions with discrete emotion nor is it primarily concerned with the organization of discrete-emotion expressions. Nonetheless, their studies provide important data relevant to this issue. In the context of their procedure, interpreting the MAX-specified anger and sadness expressions as indexing approach and avoidance tendencies appears reasonable. However, extrapolating to other contexts may be problematic. For example, in an earlier investigation, Sullivan and Lewis (2003) found that when contingent learning was followed by extinction, then both arm pulling and MAX-specified anger expressions increased. However, when contingent learning was followed by loss of the contingency (i.e., loss of stimulus control rather than loss of the desirable stimulus entirely), then covariance between potentially instrumental arm pulling and anger expressions was not found. Instead, MAX-specified anger expressions increased while arm pulling decreased as it was discovered to no longer be functional. These findings suggest that by 4–5 months of age, the links between facial expressions and other action patterns are already flexible in that they are responsive to the particulars of environmental circumstances.

Other studies have explored the relationship between negative facial expressions and negative emotion in a wider array of eliciting situations. As described in the previous edition of this handbook, Camras et al. (2007) conducted a collaborative investigation of 11-month-old European American, Japanese, and Chinese infants responding to an anger/frustration-eliciting situation (arm restraint) and a fear-eliciting situation (a disembodied growling gorilla head). MAX-specified anger expressions were found to predominate in both the anger/frustration situation in which infants struggled to be released from arm restraint and also in the fear situation in which infants produced more bodily stilling, suggesting a withdrawal rather than an approach response. Other mismatches between infant facial expressions and their situationally based predicted emotions have also been documented (Bennett, Bendersky, & Lewis, 2002; Bennett et al., 2005). Such findings suggest that anger expressions may sometimes be associated with intense negative emotion of various types. Further research is necessary to shed light on the factors that influence the contextually variable organization of facial and nonfacial responses within different emotion-eliciting contexts. However, at present, it might seem inadvisable to rely on any single indicator (such as facial expression) to serve as a measure of discrete emotions in infants.

Consistent with this idea, other recent research focusing on infants' and young children's emotional responding has tended not to rely solely on facial behavior. For example, Roben et al. (2012) measured both facial and body behavior in their study of relationships among temperament, crawling experience, and infants' responses in the arm-restraint procedure. Similarly, Melinder, Forbes, Tronick, Fikke, and Gredebäck (2010) include both facial and body behavior in their system for scoring infant responses to the still-face procedure (in which mothers abruptly cease face-to-face interaction with their infants). In studies of toddlers and young children, both Buss and her colleagues (e.g., Hutt, Buss, & Kiel, 2013) and Potegal and his colleagues (e.g., He, Qiu, Park, Xu, & Potegal, 2013) included both facial and body behaviors in their scoring systems. In all cases, researchers made contextually based interpretations of the infants' behaviors (anger in the case of Roben et al. [2012], and protest in the case of Melinder et al. [2010]) that might be considered appropriate to the situation. Still, concluding that infants are angry (or protesting) in such situations is not the same as concluding that the facial expression itself is an invariant marker of that emotion.

Concluding Remarks

To summarize our view of expressive development, we concur with other dynamical systems thinkers in asserting that facial expressions and other components of discrete emotions develop heterochronically—that is, they are not initially associated with one another in the fetus or in very young infants. We further propose that during the course of development, these facial configurations eventually become linked more strongly to other components of their corresponding discrete emotions. Like many others, we believe that this occurs via a combination of maturational processes and socialization experiences.

However, we also wish to suggest that a one-to-one invariant relationship between the prototypical facial expressions and other components of discrete emotions may never arise. In dynamical systems terms, discrete-emotion attractors (i.e., larger ensembles of emotion components) may be variable even in adulthood and thus may or may not include a prototypical emotional facial expression in any particular instance. In addition, as dynamical systems thinkers, we believe that prototypical "emotional" facial configurations may also serve as components of non-emotion-related "attractor states." Thus, they may be systematically produced in non-emotion-related contexts (e.g., when women lift their brows and open their mouths to produce a "surprise" expression while putting on mascara).

Future Directions

In the previous edition of this volume, we identified several directions for future research that would further contribute to our understanding of infant emotional and expressive development, and would allow scholars to evaluate the relative merits and limitations of each theoretical approach described above. Since that time, only limited progress has been made toward these goals. We therefore conclude by reiterating these earlier suggestions.

First, we believe that it is critically important for future researchers to more extensively document the factors associated with the production of various emotional expressions across a wide variety of situations and across a broad developmental time period. This is an essential gap that must be filled in order to proceed to create an account of expressive development within any theoretical framework. To provide a specific example from the dynamical systems perspective, once we determine the age and circumstances under which prototypical fear expressions are produced, we can seek to identify developmental phase shifts and determine the relevant "control parameters" for this expression. Similarly, investigators utilizing other approaches can determine whether the eliciting factors for this expression are consistent with their own theoretical perspective.

Second, we wish to reemphasize our belief that a satisfactory account of emotional expression must also explain the variability described for the emotional expression prototypes themselves. For example, as highlighted by Oster (2005), several different facial configurations are included as "sad" expressions within the MAX and AFFEX coding systems, and these may have very different meanings. With respect to smiling, Fogel and his colleagues (2000) have conducted exemplary work in identifying contextual factors systematically associated with variants of this expression. Further studies should focus on explaining variability within the prototypical expressions described for other discrete emotions. One unique contribution of the dynamical systems approach to the development of emotional expression is to conceptualize both expressions and emotions as variable attractor states rather than fixed entities, and thus to motivate efforts to understand their variability.

In conclusion, we also feel it is important to emphasize that none of the developmental perspectives described above are necessarily inconsistent with findings in the adult literature of various correspondences between emotional expressions and self-reported feeling states. However, we also call for studies that further explore the relationship between facial expression and emotion in older children and adults. By generating more extensive data on children's and adults' production of facial expressions in a wide range of circumstances, we can best ensure that our models accurately reflect the true relationship between expression and emotion throughout the lifespan.

CHAPTER 15

THE EMERGENCE OF HUMAN EMOTIONS

Michael Lewis

Here in this chapter, the emergence of the emotional life of humans is considered. In spite of some interest in age differences in emotional expression, there has been relatively little focus on the developmental process itself. Rather, specific emotions, such as fear, joy, anger, and sadness, have been studied, with claims focusing either on the innate features and processes or on socialization factors each most often studied in isolation. Even methodology differs, with some studies exploring enduring states such as moods, using maternal or child reports, as well as actual measurement of the infant's/child's behavior. Different contexts for different emotions have been studied. Fear, for example, has been examined by looking at the visual cliff paradigm or in the approach of a stranger (Lewis & Rosenblum, 1974). The claim that these contexts and the behaviors examined represent fear is now being challenged (Adolph, Kretch, & LoBue, 2014). From their analysis, we can gather that rather than fear, what has been examined is the infant's/toddler's attention to changes in his or her physical and social worlds. Changes bring attention, and with it, orientation toward the change, cessation of ongoing activity, and physiological responses such as changes in heart rate or cortisol (Lewis, Kagan, Kalafat, & Campbell, 1966). The idea is that the determination of the valence of the change, a cognitive-evaluative process, appears to allow for more specific responses including fearfulness, wariness, and interest, a multiple emotional response (Lewis, 2011; Lewis, Goldberg, & Rausch, 1967; Lewis & Rosenblum, 1974; Sroufe & Wunsch, 1972). Other emotions such as sadness or anger have also been examined, with greater agreement as to what behaviors might represent these emotions, although there is still no consensus in regard to anger.

While the study of individual emotions provides valuable information, what will be proposed here, as elsewhere,[1] is that what is needed to advance our understanding of emotional development is a framework for the developmental process itself, as well as a more complete understanding of the importance of action patterns and the role of consciousness and other cognitions in the creation of human emotional life. This requires an articulation and integration of what has been learned about development in the last 30 years. The framework for the model I propose is both biological and constructional, as well as their interaction. I look at both the evolutionary-derived givens that define human beings, including early structures that allow the child to enter and engage his or her physical and social world—action patterns—as well as the uniqueness of each child both in his or her temperament, another biological feature, as well as the child's unique social and cognitive experiences and their interaction. In addition, a cognitive-attributional approach is required as the child's cognitive development proceeds.

This bioconstructivist framework cannot exist without consideration of the rise of consciousness as a developmental process and the role it plays in the life of the child as he or she engages in a reciprocal interaction with his or her world. Most developmental models lack such a view, leaning on models of either innate evolutionary-derived features and processes or on learning, the cauldron of such learning being the mother–infant interaction. Although more of this will be made later, it seems clear enough that the social interaction of mother and infant cannot produce the feelings of, say, anger, only what situations evoke it, how often, and how they are expressed. The feeling per se, anger, is likely a given, much like our seeing "red," or an early reflex such as the Moro response. While we know which cones fire at a certain wavelength, the experience of redness is not learned. The same is true for the Moro reflex. Consider another case, that of walking: the reflex for this is available at birth and exists as a feature of humanness. This model is similar to Kant's (1781/1958) proposal in that experience is assimilated into innate structures, although it is possible that experience can produce structures (Hume, 1739/1888). More likely it is some mixture, but nevertheless, there are some innate structures so that the newborn can survive long enough for experience to have an effect. Although these may be biological givens, individual differences as a function of temperament and interaction with the social world can modify them and utilize them for a variety of functions other than the reflex itself. Both evolutionary givens and a constructivist process have merit and here I do not pit one against the other, but rather utilize the development of consciousness as a bridge between the two (Lewis, 2014).

Figure 15.1 displays the model to be articulated; it suggests a major developmental transition that has as its center the emergence of consciousness, prior to which emotional features such as innate action patterns, made up of facial, vocal, and body movement, as well as physiological processes in context, are transformed by consciousness into ideas, mostly ideas about the self and therefore, feelings. While action patterns in context are open to socialization as well as individual differences like temperament, the processes, but not the content, of consciousness is made up mostly by maturation of specific brain regions. These early action patterns, as well as new action patterns of self-consciousness, are transformed by ideas and are therefore *most* open to socialization processes.

Perhaps the best example of this process can be seen in the study of disgust. Consider this example:

> Soon after birth, Maron is given a sour tasting food. His nostrils flare, his upper lip raises, and his tongue protrudes from his mouth. "He really doesn't like it," his father says, "What a disgusted face." In fact, the facial coding systems of Izard or Ekman would measure his facial expression as one of disgust. Five years later, after Maron sees his younger brother throw up, he says, "How disgusting," while at the same time lifting his upper lip and flaring his nostrils. His facial and motor behaviors again would be scored as disgust. He is disgusted by the look of the vomit. At age 13, Maron watches a TV news report where a Vietnamese army officer raises a pistol to a prisoner's head and shoots him dead. "That's disgusting," he says as he flares his nostrils and raises his upper lip.

We can see in this vignette, the developmental process that any theory of emotional development has to attend to. While the action pattern of the facial expression of disgust remains relatively consistent over time, the same face can have many meanings. On the other hand, even the facial expression might have changed for many reasons. For

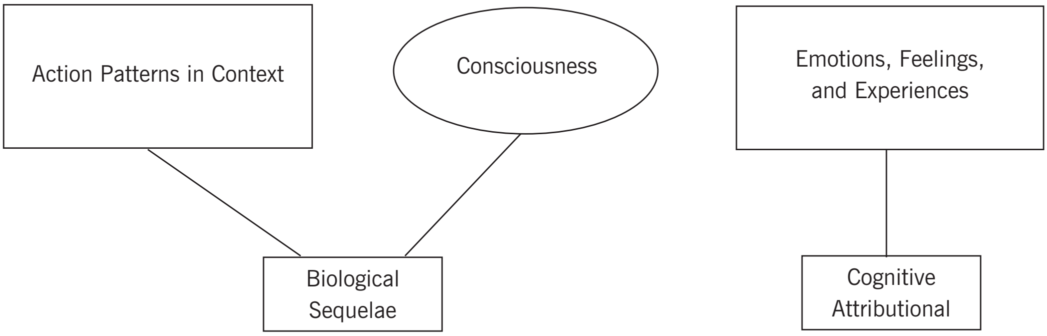

FIGURE 15.1. The development of the emotional life of the human child.

example, in any culture where such facial expressions are frowned upon, the facial movement could be suppressed. Or if Maron thought that showing a disgust face might hurt his brother's feelings, he might not show it, either by hiding his face or by transforming it into some other facial expression. Later, as an adolescent he may react to the killing with an exaggerated face of disgust in order to impress others as to his feelings about such inhuman behavior as the killing of another person. In a study of nurses, Ekman (1985) suggested that in order to properly care for patients, nurses needed to suppress their disgust looks. While he claimed that they could do so, he claimed that small disgust movements were still detectable.

This facial expression that we see occur during Maron's early life will be called action patterns. At the beginning of life these are elicited by specific physical events in the infant's world. However, with maturation and with the effects of the child's social niche, the action pattern is transformed. His facial movement, as well as other features of his action pattern, are not learned; they are the consequences of the evolved adaptive process, but are highly flexible and are influenced by his history of transactions within his particular social environment. We humans have many of these action patterns, and as has been shown, they can be found in our emotional, social, and cognitive domains. We have used a variety of names for these action patterns: instincts, innate releasing mechanisms, genotypic behavior, procedural rules, and the machinery of the self, among others. It is now appreciated that the human newborn arrives with a multitude of complex behavioral patterns that connect him or her to his or her physical world (Gopnik, Meltzoff, & Kuhl, 1999).

The difficulties with observing these unique action patterns are many. They include our inability to understand how to parse events in the world in order to look at the infant's response to them. Following Darwin's (1872) suggestion that anger is an approach emotion to overcome a specific barrier, my colleagues and I have attempted to study anger by looking at a highly specific event such as the blocking of a previously attained goal (Lewis, Alessandri, & Sullivan, 1990). Although elsewhere we have spent considerable time talking about the anger action pattern, we have in the past looked at other action patterns and found that for the very young infant the action pattern of interest is not learned and consists of receptor orientation, cessation of bodily motion, and heart rate decreases when looking or listening to sounds in the physical world (Kagan & Lewis, 1965; Lewis, Kagan, & Kalafat, 1966; Lewis, Kagan, Kalafat, & Campbell, 1966). Moreover, the newborn shows a disgust-like action pattern to something tasting bitter, but as has been shown by Mennella (2012), early exposure to bitter tastes is quite capable of affecting individual differences in the disgust action pattern. While disagreement about these biologically derived action patterns exists, it seems there is sufficient evidence of their existence to use them within a theory of development. The problem of most concern has to do with individual differences in an action pattern that are temperamentally based. Because one child has an easy temperament, his or her disgust face is likely to occur less often than a child who has a difficult temperament. These temperament differences can hold for any action pattern, and we need to study this variation.

Now, let us look at the developmental pattern that the vignette about Maron's disgust reveals. His early disgust face was to the bitter taste and reflected an unlearned action pattern. All information about the precipitating event and his reaction to it exists for him only at the machine level of self. Maron's action pattern at 5 years of age when seeing his brother's upset stomach has the same facial features as when he was a newborn, but now there has been considerable development. He has had many experiences of disgust. Smells and tastes originally produced them but now he can be disgusted by such things as seeing a bug or a snake. Even pictures are capable of producing disgust, for example, a picture of a dead or mutilated body, or even feces. The list of events now capable of eliciting disgust has expanded and includes representations of physical events such as pictures of things (see Disgust, Chapter 46, this volume).

By this age, Maron has also acquired information about the causes of disgust reactions. He knows that vomiting means that his brother is sick, either from something he has eaten, or some thought that might have caused him discomfort, even like looking at a picture of something he thinks is horribly disgusting like a running nose. He also knows what may happen after he is no longer sick. In addition, he knows about his disgust, and can remember how he felt when he had been sick. His disgust, still an action pattern, is now full of ideas including words for it in his language.

Without doubt the most important developmental change that has taken place is that Maron feels—that is, he has the ability to experience his disgust. He can also give to this feeling all sorts of meaning, including causes and consequences (see Understanding Emotion, Chapter 16, this volume). He knows that he is disgusted, and if he chooses, he can mask his facial expression or even exaggerate it, depending on whether he wants to make his brother feel better or worse. *For Maron, the action pattern and his experiences of it in context have become for him the unit of his emotional life, and these are inseparable.*

Important developmental events have occurred that are in need of further study. For example, what was Maron's history of disgust elicitors? Has he experienced many situations of disgust? What is his temperament like, and how easily is he disgusted? How readily does he recover from a disgust elicitor? What did his parents do or say to him when he was disgusted? Did they use the term "disgusting" in any other context? For example, did they say to him, "Your behavior is disgusting"? We also need to know what Maron knows about disgust. Does he know what events produce it for him? What does he think about others' expression of disgust? It is also important for any theory of development to study whether individual differences in the disgust action pattern in infancy are maintained after consciousness emerges. The relation among individual differences in early disgust, socialization rules, and the emergence of consciousness are in need of study. To answer these questions requires much more knowledge of the developmental trajectories for individuals in their particular family and culture.

Maron at 13 years of age exhibits moral disgust. For him, the observation of a moral violation elicits disgust. While someone being shot itself may elicit Maron's disgust because of body disfigurement, it is more likely that the cruelty of the action of someone killing another has become the elicitor of his disgust. What is remarkable is that at 13 he shows us the same action pattern that is now elicited by his ideas of right and wrong. The developmental process appears to utilize this action pattern for a different elicitor—knowledge about rules, goals, and standards that are ideas about what is right or wrong. The utilization of the same action pattern conserves this innate pattern while adding to the physical elicitors ideas as elicitors. It is as if the energy or motive power of the original action pattern has become functionally independent of its original elicitor and can now be used by the culture to enforce its moral codes.

The child's trajectory over age allows us to study the possible models of development. We can observe that while new elicitors produce disgust, many of the original ones continue to do so. The model suggested by such a case is one we have called an "additive growth model," wherein the old elicitors are not replaced but new ones are added to them (Lewis, 1997). There is little transformation in the nature of the action pattern. What is transformed is mediated by the emergence of consciousness. With self-reflection Maron knows that he is disgusted and he knows that if he behaves in a certain way, others like his brother will know he is disgusted. The recursive idea of "he knows that he knows that he is disgusted by his vomit" takes place only after the emergence of his consciousness.

This transformation may help our understanding of phylogenetic change. While disgust may be an action pattern existing for many animals besides humans, it is only humans with consciousness who can utilize such ideas. While we have been discussing the disgust action pattern, we could have just as easily considered others. For all action patterns, consciousness brings new elicitors in addition to specific events of the physical world. Sadness over the loss of a desired object becomes sadness over the idea of the potential loss; fear over uncertainty becomes fear over the idea of uncertainty, or its opposite, excitement over what might come next. We know little about these transformations and there is much to learn. What we do know is that these transformations have something to do with the emergent ability to have ideas, ideas about the self and how the world works. Individual differences in this transformation have to do with both the culture in which the child is embedded and his or her temperament.

Problems of Language

For purposes of clarity we need to consider several commonly used words, such as "emotion," "experience," "consciousness," and "feelings." Emotions are what have been defined above. Feelings indicate our thoughts about ourselves. "Feelings," "thoughts about ourselves," and "experiences" are all terms having similar meaning; they are my experience of me, or what is meant by consciousness. The task in studying the development of emotions is not only to find ways to observe these action patterns in context and to measure them, but of equal importance, to study the child's experience of them.

Darwin (1872) suggested that emotions were action patterns, having external signs as well as internal states that could be found in expressions in the face, voice, and posture of humans and beasts. Certainly, in everyday life we seem to believe that facial expressions and internal states are likely to go together. When someone cries at a funeral, we tend to assume that he or she is sad. Yet, we humans are capable of masking our behavior. Deception in terms of facial expression is as real a feature of emotional life as facial expressions reflecting what we are really experiencing. While internal changes may exist, the history of the study of emotion over the last 100 years reveals that we have not been able to measure them very well (Bard, 1934; Cannon, 1927; Lewis, 2011). This lack of measurement has led to the belief that there are no internal changes and that all there is are thoughts. Such a belief holds that the discrete emotions are nothing more than different ways of thinking about things. Emotion only as thought relegates emotion to second-class status by making it an epiphenomenon of thought. The model argues against these strong forms that suggest that emotions are action patterns or that they are only thoughts; rather, emotions involve both.

In the theory of emotional development presented here, Darwin's (1872) thoughts about action patterns are that they are shared by many animals including humans. However, biological properties interact with human consciousness in specific cultures. Consider the example we call "sadness." Sad behavior over loss seems likely to be either innate or readily learned. However, one child may have more sadness than another as a function of his or her temperament and environmental differences in the amount of loss that occurred, and these will affect and produce individual differences.

The problem of the nature of emotion also makes the study of development that much harder. For example, do children have the same emotions as adults? Does the child's sadness over his or her mother leaving him or her at the babysitter's represent the same sadness that the child's mother feels when she leaves the child? When we address the question of whether human adults have the same action patterns and thoughts that children do, we are immediately met by the same question in an adult. For example, when I say I am fearful of a hornet stinging me, do I mean that I have the same feeling as when I say I am fearful that there is someone following me down a dark street? Is fear in one situation the same as fear in another? These questions lead to the belief that my experiences of myself and my action patterns are only loosely related and that they may be different things. We assume that our experiences, our thoughts about our action patterns in context, are not the same as the action patterns themselves. Thus, my experience of my fear is likely to differ as a function of the causes that elicit it.

Emotional life is made up of a set of three features. The first is *emotional elicitors*, physical events in the world and later in the infant's development of his or her thoughts or ideas. The second feature is the *action patterns*, including expressions that have evolved and that are located somewhere in the body. The third is *the ability of the child to experience his or her action patterns*, the ability to think of him- or herself. By dividing the term "emotion" into these features, the development of emotional life becomes clearer.

Also, there is probably no advantage in using the common term "emotion" to cover what we may mean since the term has a surfeit of meanings. As in both Lewis and Michalson's (1983) and Frijda's (1986) classification system, the term "emotion" was deconstructed into several of its component parts as just mentioned.

Thus, action patterns are innate responses based on our evolutionary past that are adaptive behaviors designed for action in response to specific environmental events; these events are called *elicitors*. However, because innate responses are inherently plastic, they are affected by individual differences in children's temperaments, their concurrent environmental conditions, and the cultural rules that we call "socialization." Because of this inherent flexibility, the difficulties in finding a close association between an elicitor and an action pattern should not be taken to negate the assumption that there are such innate responses. In addition to this inherent flexibility, two other difficulties exist that make the association between physical events and action even more difficult to observe. One has to do with the nature of the elicitor itself. For the most part the elicitors used in research to date tend to be multiple (e.g., holding down an infant's arms and restraining him or her is made up of multiple elicitors including movement toward the child, physical contact, smiling, and unexplained action that is not in keeping with the preceding events). Since multiple elicitors are involved, the association between them and a single action pattern would be hard to observe. One solution to this problem is to very carefully select the elicitor to be used. In our work, we used a single specific elicitor, the blockage of a learned response to a desired goal, to study anger since from Darwin (1872) on it has been argued that such a blockage should elicit anger, which is just what we observed in infants as young as 2 months old (Lewis et al., 1990). When careful choices of elicitors are made, we are more likely to find a greater association between them and specific action patterns.

Multiple Emotions

Another issue that is likely to prevent our ability to examine innate response is the real possibility that multiple emotions, even to a specific elicitor, are more likely the rule than single emotions. At least our adult sense suggests that at the funeral of a friend we may likely experience both sadness and fear, or at the wedding of a daughter both joy and sadness. The nature of emotional life may be made up of a fugue, with the flow of emotions and thoughts entwined so that multiple emotions rather than *an* emotion may be what our lives are made up of. It is only when we try to study them in the laboratory that we break the flow apart.

If we reject the idea of an innate response to a specific context, we are left with the unanswered question of how action patterns, including facial and bodily expressions as well as physiological responses, are organized (see The Development of Facial Expressions, Chapter 14, this volume). The idea that these complex coherences are socialized, that is, they are learned, is difficult to imagine and there is no direct evidential support that they are acquired. It is mostly the fact that there is difficulty in finding specificity between facial expression and contexts that moves us toward accepting the acquired theoretical viewpoint. At the moment we need to accept the idea that action patterns such as fear, joy, and sadness are part of the human condition, but at the same time these action patterns are inherently flexible.

Feelings

We all use the term "feeling" in describing our emotions. I can say to you that I am feeling happy, and it is because of both our common language and mentalism, that is, your knowledge that you and I share internal states such as thoughts, desires, motives, and the like, that you can find in yourself what I am feeling. In fact, my feeling of happiness may make you feel happy. But what, then, does feeling happy mean? As suggested, the terms "feelings," "thoughts about myself," "experience of me," and "consciousness" all speak to the process that assesses something about me.

The child's ability to access either his or her bodily states or thought about him- or herself is dependent on the child's ability to be able to know about him- or herself; first, that there is a self, a me, and second, that there is some unique combination between the self and action patterns in context. It is this self-referential ability that is used to denote the term "consciousness." Consciousness is not about the aboutness of what is accessed, the content; it is the process of accessing itself.

But there is another use of the word "feeling" and for that matter the word "self-experiencing," and it is this usage that gets us into difficulties when we discuss emotional development. Consider how we might think about these two different meanings of the word "feeling." I am at the dentist's office and he wants to fill a cavity. He gives me a shot of Novocain and after a moment or two he pricks my gums and asks, "Do you *feel* this?," meaning, "Does it hurt?" My answer is that I do not *feel* it. He then begins to perform a procedure. If we had a meter that was capable of measuring pain at the pain receptors in my gums or along the neural pathway from the receptors to some central processor, it would register as pain. From a physiological perspective I have pain, but I do not *feel* pain. It does not mean that the body does not experience the pain in some way, nor does it mean that much pain will not have a powerful effect later in life. What it does mean is that I am not conscious of the pain; I do not feel it.

Another example does not involve pain, since some might say that pain is a special case. A patient with her corpus callosum severed because of her epileptic attacks is asked to haptically finger a wooden number under a blanket so that she cannot see her fingers move nor see the number, and by raising her fingers, she tells the experimenter what number she felt, a question that she can answer easily. However, when the experimenter asks her to tell out loud what the number was, she cannot tell him; "I don't know," she says. She clearly knows since she raised her fingers correctly but yet she does not know what it is that she knows (Gazzaniga, 1988). But isn't this what we mean by consciousness?

Our bodies have a life of their own; they know many things that we, our consciousness, do not know. Our bodies know that when we eat too much sugar, they need to secrete insulin. This is something known by ourselves, that is, by our bodies, but not known by our consciousness. We cannot readily access many things that are happening in us. In all these examples we can see that some part of us, our body, is experiencing something that enables other parts of our body to act. But we, our conscious selves, do not know of it, and therefore we cannot feel it.

This claim, therefore, is that before we can think about ourselves, before there is self-referential behavior, and therefore before consciousness, the infant may have or be in a particular state as a consequence of a particular elicitor; however, the infant is not able to think about or experience that state as we adults do. Thus, if we restrict feeling to the body, then, of course, we can say a newborn feels pain. But if we mean that the infant can access this bodily state and know that it is his or her pain, then no, he or she does not feel pain. The infant does not have the privilege of the first person, reflected in the statement, "I am in pain." To avoid the problem with the word "feeling" I use the terms "experience" or "consciousness" to speak not of bodily action, but of ideas about the self.

Consciousness

The issue of consciousness is tied to feelings and plays an important role in any theory of emotional development (see Lewis, 2014). Since the development of consciousness is central, ways to measure it are important. Looking at self-referential measures, such as touching the marked nose while looking in the mirror, enables us to understand that the child knows that the image *there* in the mirror is located *here* in space, the same here in which I stand; this is also demonstrated in self-referential language such as in the use of personal pronouns like "me" and "mine," and in pretend play in which the child reveals that he or she knows that something he or she is doing is not literal. When we talk about consciousness we are not making reference to a consciousness that is not conscious since in effect this is what Freud tried to do.

However, if we stop for a moment and think about all the different things we do that we are not conscious of, from solving a problem to rote physical activity, or from speaking sentences without knowing what will come next to suddenly remembering, it seems clear that there is something in there, and that something is likely to be sets of processes, habits, and the like. Some who are interested in this problem have called the thing inside *procedural rules*, others have called them *action patterns*, *instincts*, or *innate releasing mechanisms*, and still others *preconsciousness* or even *unconsciousness*. This thing or things inside us are not unconscious but rather not conscious. Perhaps it is useful to think of them as *the machinery of the self* or core bodily processes; this machinery is a highly organized, complex, evolutionary-adapted set of processes that control both the internal workings of our bodies and much of our dealings with the outside world. This machinery is innate but highly plastic and capable of learning. But what is it? Is it a modular system made up of many parts that are organized in some fashion, or some highly interactive system in which the activity of the whole system is what determines the outcome?

So when does consciousness emerge in the human child or, for that matter, when does it emerge in the evolution of life on earth? To ask this question is to suppose that there is a way to measure consciousness. I have proposed and tried to show that there are measures that are related to consciousness and that is self-referential behavior. The ability to make reference to oneself is a reasonable measure of consciousness that can be measured by self-recognition in mirrors as well as in the use of personal pronouns and in pretend play. I do not go into the argument here since a considerable amount of time has been spent on it elsewhere (Lewis & Ramsay, 2004), however, the coherence between these measures and the subsequent development of the self-conscious emotions such as embarrassment, shame, and pride suggest that these self-referential measures are a good approximation. Our studies suggest that consciousness develops in the human child sometime in the middle of the second year of life and that it can be seen in self-referential behaviors. The rise of consciousness has a profound effect on the development of a child's emotional life (Lewis, Sullivan, Stanger, & Weiss, 1989).

There is a claim that consciousness is only an idea and that for other cultures this consciousness either does not occur or that it is a collective consciousness (Keller et al., 2004; Markus & Katayama, 1991). However, such an argument has to do with the aboutness of consciousness and that is not what I am referring to. The aboutness is a cultural artifact. However, consciousness, the self-referential ability, is more likely a function of the nature of the human brain. Shweder (1985) has shown that in some cultures there is a we–self aboutness. However, even in we–self cultures there is no question that when a woman is menstruating, and therefore considered to be polluted, it is the woman herself who is not touchable. Even in we–self cultures the idea of a person bounded and separated from other such selves plays some role.

Having consciousness creates the challenge of maintaining our identity in the face of change. The function of the self-concept is to construct identity—that is, to maintain the cognition that all of this is me (Lewis, 1997). Sometimes it means adding pieces together, sometimes it requires a separation of parts. Sometimes the elimination of one or more parts and sometime the distortion of parts or even a distortion of the composition of the whole is necessary. All of the thoughts about ourselves are designed to maintain the idea of "me."

Toward a Theory of Emotional Development

> And the Lord God planted a garden . . . in Eden . . . and caused to grow out of the ground every tree . . . and the tree of life in the midst of the garden and the tree of knowledge of good and evil. . . . God commanded the man, saying that "Every tree in the garden now mayest freely eat but of the tree of knowledge of good and evil thou shall not eat of it for if on the day thou eateth thereof thou shalt surely die.". . . . And the serpent [to encourage evil, said,] "Ye shall surely not die for God doth know that on the day ye eat thereof your eyes will be open ye will be as God knowing good and evil. . . ."
>
> She [Eve] took of its fruit and did eat and give also onto her husband with her and he did eat and the *eyes of both of them were open and they felt that they were naked.* And they *did hide* from the Lord God and when he called to them they did not answer. And he said to them, "Why are you hiding from me?" And they answered, "*Because we are naked*," and he knew therefore that they had eaten of the tree of knowledge (Genesis 2:8–3:11 King James Version).

This story provides a framework for the theory of emotional development that has been proposed. In the beginning, Genesis argues for the existence of the early action patterns such as interest, joy, happiness, and curiosity, which can be seen in Adam and Eve's behavior in the Garden of Eden. The particular action pattern talked about was curiosity, which we know is an approach emotion—that is, it leads toward action in the world. In this case, it was the eating of the apple. The eating of the apple from the tree of knowledge made them wise. From our point of view, this gaining of wisdom was about themselves: "They did eat and the eyes of both of them were open and they *felt* that they were naked." The consequence of this acquisition of knowledge, the story tells us, resulted in a new set of emotions, in particular, the self-conscious emotion of shame. They knew they were naked and were ashamed. This story suggests a progression: Early emotions lead to knowledge, what we call cognitions, in particular cognitions about the self, which in turn lead to the self-conscious emotion of shame. This creation story matches the developmental theory that we follow.

In the issue of development, it needs to be emphasized that while the early emotions may have biological roots, emotional life is embedded in the child's social and cognitive development and that this embeddedness gives to the basic biological form its content and meaning. In humans, the earliest development of emotional life resembles what we see in other animals, the common action patterns in context between animals and us. Later, emotional development is dependent on the emergence of consciousness. These have been called the self-conscious emotions. Thus, to begin with, emotions are tied to a behavior–environment connection. Darwin (1872) described this connection well when he suggested that emotions in man and animals are action patterns that are tied to particular situations because these action patterns proved to be adaptive, and therefore were likely to survive. Many of these action patterns are common across species, differing as a function of the different physical features and environmental niches each species possesses and inhabits. Here we have chosen the term "action patterns" because it is broad enough to encompass emotional, social, and cognitive behaviors.

In the second and third year of life, these action patterns interact with the emergent consciousness, consciousness here being taken to mean the idea of "me." It is a mental state best captured by the phrase "I am [emotion word]." While the emergence of consciousness has a biological basis, it does not concern the nature of the child's aboutness. Rather, it is the idea that the human child and then the adult has the capacity to consider its aboutness. Once consciousness appears in the human child there emerges as a consequence a transformation, in part of which a new set of emotions, those that involve the self in action, emerge. Unlike the earlier emotions, these self-conscious emotions are elicited by cognitions that involve the self and are less elicited by the literal world; thus, "I am proud" because I achieved a sought-after goal by my own efforts. These new emotions are based on ideas and like the earlier emotions exist because of their adaptive significance.

Our emotional lives are first characterized by the existence of these early action patterns, then by the emergence of consciousness, which in turn gives rise to the self-conscious action patterns. Both the early and later action patterns are innate responses tied both to the literal world and to the world of ideas. Even so, they are readily affected by environments. These environmental influences are what constitute the familial and cultural rules that surround the child from birth, and perhaps even from before birth. As I have already shown, disgust is an example of this development since it captures well what is proposed.

Figure 15.2 shows in schematic form the theory proposed. As can be seen, emotional development over the first 3 years of life is divided into the early action patterns, called the primary emotions by some; the rise of consciousness; creation of emotions, both primary and the exposed self-conscious emotions; and, finally, the full emotional life, including all the human emotional repertoire. It is an additive model of development. The first 3 years of life have been focused on since much of this process of development similar to adult humans is present.

One major problem with articulating a model of the emergence of emotional life has to do with the appropriate markers for the emotions. Are we making reference solely to emotional expressions

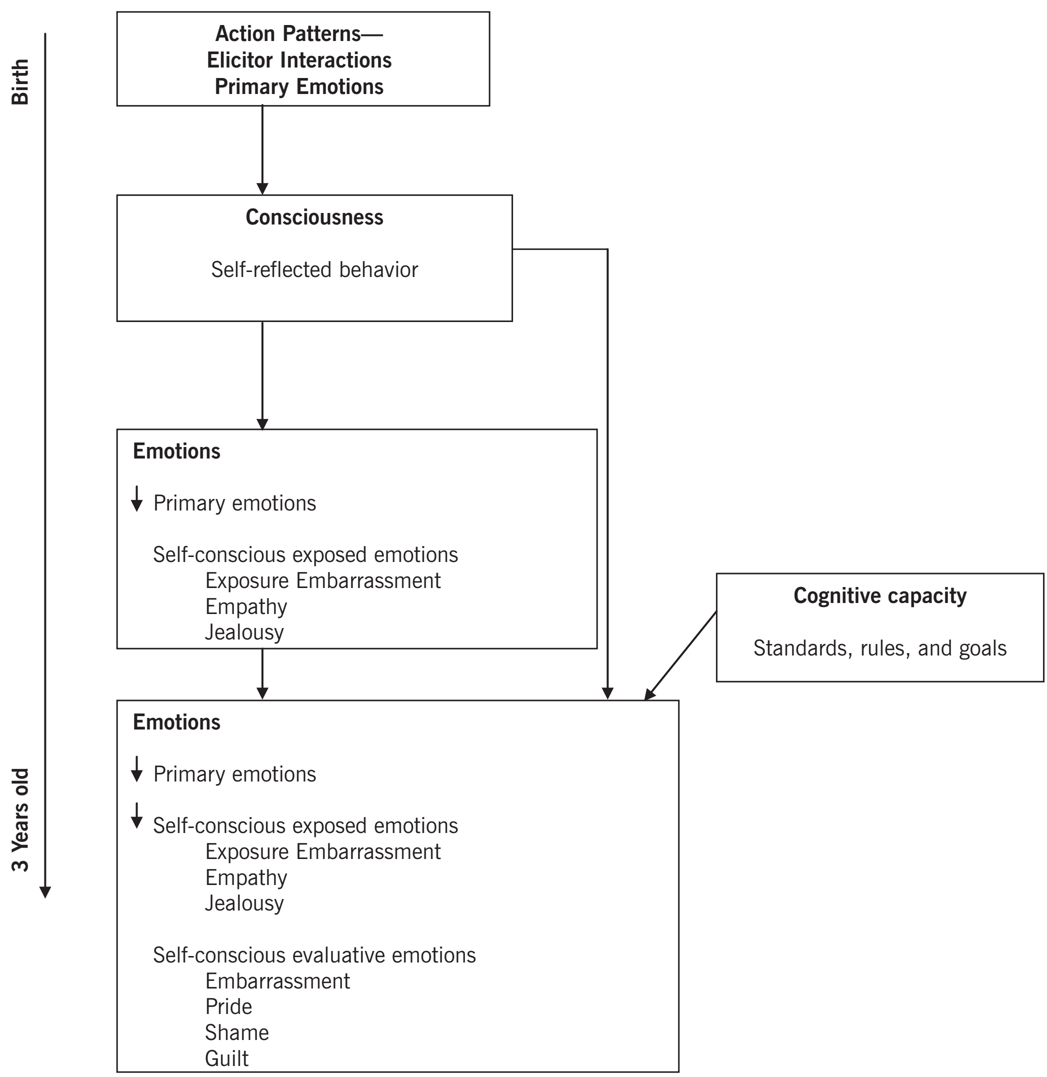

FIGURE 15.2. An additive model of the developmental model in emotional life.

and elicitors or to emotional experiences? The ability to do more than observe the emitted behaviors of the child is all that is possible. In order to get at emotional experiences, we need language in the form of "I am sad" or "I am ashamed." Since during much of the first 3 years the language of the child is quite limited, the study of emotional experience is difficult. Likewise, the study of internal emotional state development is difficult because there has been little success to date in finding a unique configuration of a neurophysiological measure that marks unique emotions in adults, children, or infants (Lewis, 2011).

What we are left observing are emotional expression and behavior in context. Observation of behavior in context allows us, at least from the adult meaning system, to assume that the child's expression reflects an emotion. Observation of anger over frustration, or joy when a mother appears, allows us to accept that an internal state of anger or joy exists. With these limitations in mind, the following discussion and mapping of emotional development can take place.

Bridges (1932), and more recently Sroufe (1996), proposed that at birth the infant shows a bipolar emotional life. On the one hand, there is general distress marked by crying and irritability. On the other hand, there is pleasure marked by satiation, attention, and responsivity to the environment. Attention to and interest in the environment appears from the beginning of life, and we can place this in the positive pole; or we can separate this, thus suggesting a tripartite division with pleasure at one end, distress at the other, and interest as a separate dimension (Lewis & Michalson, 1983).

However, other early dimensions of emotional life can be made. This scheme relies on the idea that at the very beginning of life there are two primary action patterns, which here I call the approach and withdrawal patterns. In the 1950s, Schneirla (1959), like many before him—including Darwin, Cannon, Watson, and Allport, to name but a few—was intrigued by the concept of a biphasic behavioral pattern. As Schneirla wrote, "The aspect of towardness or awayness is common in animal behavior" and these are "applicable to *all* motivated behavior in *all* animals" (pp. 1, 2; see also Allport & Allport, 1921; Cannon, 1927; Darwin, 1872; Watson, 1914).

If it is indeed the case that the basic pattern is one of approach and withdrawal, these could be the starting point in the early undifferentiated action patterns of the newborn. Figure 15.3 presents the scheme utilizing these two behavioral action patterns, and although there are some data on differential brain hemisphere differences to support such a scheme, it is presented here for heuristic reasons. It is interesting to note that both anger and joy have been associated with activation in the left frontal area of the brain. Studies of the right and left hemispheres suggest that anger and joy approach emotions can be found on the left side, while the withdrawal emotions of sadness and disgust can be found on the right side. That hemisphere's reaction appears to support such a view (Davidson, 1994; Harmon-Jones, 2003).

To begin with, infants show general approach behavior, an engagement with the social and object environment. This engagement or approach mode soon differentiates into three of the primary action patterns: joy, anger, and interest. I include interest as an emotional behavior, although some might not. The joy action pattern is related to contexts involving social stimuli such as faces and voices, and also to contexts of control or mastery on objects as well as people. The anger action pattern is related to the overcoming of a blocked goal. The interest action pattern is related to attending

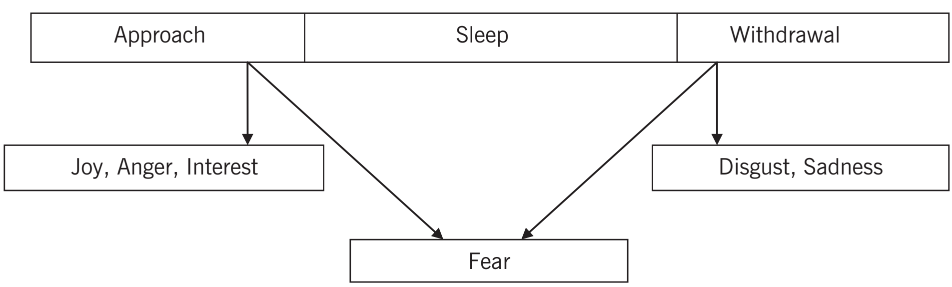

FIGURE 15.3. Development of the differentiated early action patterns. From Lewis (2014, p. 73). Copyright 2014 by Michael Lewis. Reprinted with permission from The Guilford Press.

to novel and familiar events, both social and nonsocial; it is mostly controlled by context change, although there may be some innate elicitors.

The basic withdrawal action pattern is designed to remove the infant from active engagement with the world. The two primary emotions that are derived from this pattern are disgust and sadness. Disgust is an action pattern adapted to remove from the mouth noxious tastes and smells and thus acts to disengage the infants' appetitive behavior. Sadness is an action pattern evoked by the loss of both people and objects.

In these cases the withdrawal pattern removes the infant from active engagement and turns action into inaction. At the beginning it is associated with sleep, which is also a mechanism for disengagement with the outside world. The literature on early sleep patterns suggests that the newborn spends a high percentage of time sleeping, and of experiencing rapid-eye-movement (REM) sleep, which rapidly decreases over the first 3 months. This disengagement from the outside world appears to be necessary for the development of normal brain function as well as for the reinstatement of information obtained from the approach action patterns. The approach and withdrawal patterns are likely to work in some synchronous fashion.

I have left fear, one of the early action patterns, for last. Although one might believe that fear too is a withdrawal action pattern, it seems that it is a consequence of a combined approach and withdrawal pattern. Fear is a response to either an unfamiliar context or to some prewired-like mechanism, similar to what ethnologists describe as innate releasing mechanisms (IRMs). While the work of Mineka, Keir, and Price (1980) reveal that some animals, like snakes or spiders, may not innately elicit fearful behavior in children, they appear to be prewired in some way and therefore need minimum experience to turn the animals into feared creatures.

If unfamiliar or innate stimuli only elicited fear, with withdrawal tendencies, there would be no trouble classifying them as part of the withdrawal pattern. However, consider that if unfamiliarity only elicited fear, how could the child learn about new things? If there was no movement toward, nothing new could be added to the child's repertoire. Clearly, the child has to both withdraw for safety, and approach, as in interest, to learn and profit from novelty. Indeed, that is just what we see when we examine children's behavior, both toward the visual cliff as well as to the approach of a stranger. In both cases the infant shows what has been called "wariness," which may be part of the interest action pattern including eye openness (Lee, Susskind, & Anderson, 2013), while also showing a cessation of activity and movement away (Adolph et al., 2014). In fact, if the infant is allowed to crawl on the floor with his or her mother present, when the stranger approaches, the child will move away from the unfamiliar person, go toward his or her mother, and hide behind her, all of which fits into a fear-like action pattern, while at the same time looking out at the stranger. This behavior combines the approach with the withdrawal patterns of action.

This view of the emergence of the primary emotions grows out of the two basic action modes of approach and withdrawal. At the beginning of life, these two modes are undifferentiated but quickly develop as maturation takes place, into the action pattern-context-specific patterns that we see by 2–3 months. While not enough data are available, there is some reason to believe that these two basic action modes are connected to hemisphere differences in the brain, as well as to the autonomic nervous system (ANS), in particular heart rate changes, and through these changes to changes in the vagus nerves that increase information by acting on the perceptual/cognitive system of the child (Lacey, Bateman, & VanLehn, 1953; Porges, 1986, 2011). Thus, while the description here is somewhat similar to Bridges' (1932), it places the emergence and differentiation of these early emotions within the more general framework of general approach–withdrawal action modes that rapidly develop into the Darwinian idea of differential action patterns associated with specific contexts.

With this in mind the model of emotional development can be seen in its complete form. While our discussion of the various problems associated with studying these early action patterns has been considered, it is to their early development that we now turn our attention. There is considerable information available, mostly around facial expression in context, although some bodily activity is also available, to demonstrate that they emerge in the first 8–9 months of life, especially if the context for their elicitation is taken into account. Sroufe (1996), while also differentiating a smile from distress, does not consider them emotions but instead, automatic reflexes in response to quantitative rather than qualitative aspects of stimuli—that is, to the temporal and intensity features of arousal. They are not emotions since they do not contain a cognitive component. By 6 months they emerge as basic emotions given the onset of some cognition. These six primary facial patterns appear in the early months of life when we look at context specificity. While these six emotions are mentioned by most researchers, others have considered other emotions in this early grouping, including some of what have been called self-conscious emotions. When discussing the self-conscious emotions, Lewis (see Chapter 45, this volume) discusses why these emotions are likely not to be present in the early months of life, mostly because considerable cognitive capacities are necessary for their elicitation, cognitions that are not available to the infant in the first year of life.

In the first 8 or 9 months of life, children's emotional behavior reflects the emergence of the six early emotions, or as Darwin (1872) called them, action patterns, and they are not learned, although they are affected by the environment in which the child is raised. Moreover, there is no reason to assume that mentalism is necessary for their appearance.

Sometime in the second half of the second year of life, the emergence of consciousness, the mental representation of "me"—seen in self-referential behavior—occurs. When it does, it gives rise to the self-conscious exposed emotions, which include embarrassment, empathy, and jealousy. Finally, with the child's acquisition of socialization rules about standards, rules, and goals, the evaluative self-conscious emotions such as guilt, pride, and shame emerge (see Lewis, Chapter 45, this volume). Next, the work on these early emotions is considered.

Interest

Whether we consider interest an emotion or a cognitive action pattern depends on our perspective. If we call interest "attention," then it is quite clear that from the very beginning of life infants show this emotion. In the early 1960s, Kagan and I, as well as others, demonstrated that infants could attend to external stimuli including visual, auditory, and tactile events. Attention was measured by receptor orientation, including eye gaze and turning toward the source of the stimulus, as well as by physiological responses including heart rate and respiration rate changes. There is little doubt that from the beginning of life infants show interest in the world around them. The details of the studies have been discussed elsewhere, and the reader is referred to them for further information in regard to this emotional action pattern (Kagan & Lewis, 1965; Lewis, Kagan, & Kalafat, 1966; Lewis, Kagan, Zavala, & Grossberg, 1964; Lewis, Meyers, Kagan, & Grossberg, 1963).

Fear

The interest in infant fear originally centered around the attempt to understand the infant's early social life. Capitalizing on the animal data on imprinting, Bowlby (1969), as well as others, argued that infants' fear response to a stranger reflects the child's attachment to his or her mother. Since fear develops in order to terminate the child's indiscriminate approach to all other people, it reflects the child's imprinting on the familiar. Thus, fear has an adaptive function: protection of the child from strangers who might do him or her harm.

A second area of interest in fear had as it source an interest in the child's perceptual–cognitive development and used the fear response as a measure of the child's cognitive ability. For example, Gibson's visual cliff experiment used fear as a measure of the child's ability to distinguish spatial depth (Gibson & Walk, 1960). In this experiment the infant, prior to walking but able to crawl, is placed on a platform that creates an illusion in which one half of the platform seems to drop off by several feet. The fear response was reported to show that the infant had gained the perceptual–cognitive ability through interaction with its physical world, and thus recognized the potential of falling. The approach of a stranger and the visual cliff are still used to elicit a fear response. Although these two experiments sometimes reveal the facial action pattern of fear as measured by any of the facial coding systems, what is seen most is bodily hesitation and movement at times away, in addition to an attentive face, sometimes called "wariness."

Earlier, it was suggested that fear has both a withdrawal and an approach component. It is clear that stimuli that elicit fear can also elicit approach behavior. For example, incongruity or discrepancy is thought to elicit fear, but can also elicit smiling and laughter. While most theories, especially those using fear as a marker of the child becoming imprinted or attached to its mother, view fear as a consequence of discrepancy, discrepancy itself is not a sufficient cause for fear. In a series of studies we have been able to show that the specific context in which the discrepancy appears determines to a considerable extent whether there is a fear-like or a joy-like response (Dodd & Lewis, 1969). Sroufe showed that many events that can potentially produce laughter, such as gently tossing the baby in the air or playing peek-a-boo with the infant, can also produce fear and upset (Sroufe & Wunsch, 1972). Fear also appears in contexts where there are sudden changes in the physical features of the environment or when experiencing pain.

Individual differences in temperament may also play an important role in what elicitors produce fear behavior. Perhaps the simplest example of this is observing individual differences in infants when they are tossed in the air: one infant laughs and smiles at this unusual stimulation, while the other is frightened and may even cry. Context and temperament are deeply involved in the fear response. As a working hypothesis, I suspect that difficult temperaments are likely to increase the withdrawal component of fear, while easy temperaments are likely to increase the approach component.

From a developmental perspective there is a connection between maturing cognitive processes and the contexts that elicit fear. While there was a strong belief that fear required cognitive capacities, which do not emerge until after the first half of the first year of life (Sroufe, Waters, & Matas, 1974), there are now data to support the idea that simple associations with pain can cause fear. Thus, Izard has reported fear faces in infants being inoculated, and we have shown that a fear face is part of what Pavlov (1960) and Simonov (1964) have called a "defensive reflex," the response to the sudden onset of something unexpected (Izard, Hembree, & Huebner, 1987; Ramsay & Lewis, 1994; Sullivan, Lewis, & Alessandri, 1991).

While fear may appear early, cognitive factors need to play a more important role in the second half of the first year of life. What is clear is that such cognitive capacities as memory and the ability to make comparisons underlie fearfulness (Schaffer, 1974). Moreover, Decarie (1974) suggests that object permanence may be another important cognitive factor. If this theory is correct, it may explain some of the individual differences in the timing of the onset of fear (e.g., Bronson [1974] has shown stranger fear in 3-month-old infants, and I have reported that gifted children are likely to show stranger fear prior to 6 months [Schaffer, 1974; Spitz, 1965]). If cognitive capacities emerge earlier in some infants than in others, the children with precocious cognitive development are likely to show fear responses earlier. We need to keep in mind that cognitive maturation also must interact with children's temperament.

However we consider the emergence and development of fear, the discrepancy factor continues to be implicated in studying the difference between familiar and unfamiliar people, with unfamiliar people sometimes eliciting fear-like responses, certainly after 3 months. Even here, though, there are some interesting contextual factors in responses to strangers. In a series of studies, we have examined whether the nature of the unfamiliar person might play a role in infant and toddler fearfulness. We had male and female young children and male and female adults, all strangers, approach infants ages 7–19 months in a stranger-approach situation. Infants show wariness at the approach of the unfamiliar adult but joy and attention at the approach of the unfamiliar child (Lewis & Brooks, 1974). This phenomenon can be seen in public places like airports where stranger infants and toddlers will approach each other but avoid or move away from stranger adults. Such findings as these support our view that unfamiliarity and discrepancy are an insufficient explanation as elicitors producing the fear response since the unfamiliar adult is more like the mother—less discrepant—than the strange child. These findings suggest that either past experiences or biological factors like IRMs play some role in determining the early fear action pattern. Many different experimental paradigms have been used to elicit fear in young children besides stranger approach and the visual cliff, including loud and sudden noises and robot toys moving toward the child. To some degree all appear to elicit mostly a wary response. Even so, large individual differences are shown. One might assume that a fearful child would show high fear to any one of these different elicitors, and at the extreme ends of the spectrum of fearfulness that may be the case, yet the results of several studies reveal only weak consistency in children's fear across different elicitors (Campos & Stenberg, 1981).

Anger

When asked, most parents report that their infants show anger. They report that this can be seen in the infant when being fed: the infant turns his or her head away and raises his or her hands to push the spoon away. Research, too, seems to support our everyday observations**.** Part of our problem is in the reporting. American mothers report more anger in their infants than do Japanese mothers (Otaki, Durreit, Richards, Nyquist, & Pennebaker, 1986). Such a finding either means that (1) American babies actually show more anger responses than do Japanese babies or that (2) American mothers are more likely to see more angry behavior than Japanese mothers because of their varying interpretations of the child's behavior. Parental reports of anger, perhaps just like most of the other early action patterns, have multiple meanings, including embedded cultural meanings. For example, anger as an attempt to overcome a blocked goal is often confused with aggression or hate and linked to acting-out or violent behaviors.

Nevertheless, it has been argued that infants' anger is, in general, and for adults some of the time, an approach emotion (Harmon-Jones, 2004), and its evolutionary adaptive significance is in its motivating property of action toward overcoming a barrier. While angry faces have been reported when 8-month-olds' hands are held and constrained, anger is seen earlier in life when an infant's learned response to a goal is blocked (Lewis et al., 1990).

Joy

Joy has been studied primarily in terms of a smiling face, with much of the research conducted in the early 1960s and 1970s. Smiling is present from the beginning days of life and is likely state dependent during the neonatal period—that is, a smile occurs almost reflexively and does not seem to be related to any specific contexts. Smiling even appears during sleep in the newborn. However, smiling behavior as a response to social objects including other infants, children, adults, and animals with human-like faces appears between 6 and 8 weeks and is more likely to occur in these contexts than others; however, gentle tactile stimulation also appears to elicit enjoyment behavior in 8-week-olds (Ambrose, 1961, 1963). Expressions of enjoyment in very early life are closely tied to the physical quality of stimulation, which can be auditory, tactile, or visual. However, enjoyment of social events and stimulation increases dramatically by 4 months of age, with social smiling peaking between 12 and 14 weeks of age in home-reared infants in Western culture. Infants at this age seem to enjoy people and will smile readily at most children and adults who interact pleasantly with them. After 16 weeks, however, most infants can discriminate among faces. Then, familiarity and the behavioral style of the interactive partner become important factors in smiling behavior, suggesting that smiling and enjoyment are now being influenced by the infant's growing cognitive development. By age 12 months infants vary in their social smiling, reflecting not only temperament differences but possible differences in their quality of enjoyment within social situations (Fogel, Nelson-Goens, Hsu, & Shapiro, 2000; Jones, Raag, & Collins, 1990).

While smiling is present early, laughter appears somewhat later. Blurton-Jones (1971) characterizes laughter or a play face as a wide-open mouth expression with sounds adults associate with laughter. The play face seems to make its appearance by 4 or 5 months in normally developing infants and occurs at first to vigorous auditory and tactile stimulation, seen in the infant's response to tickling. After 7 months, visual stimulation becomes more effective in eliciting this laughter expression. By 12 months incongruency and novelty, especially if it involves the infant's own participation, elicit laughter and the play face—for example, in games such as peek-a-boo.

Finally, what we know about atypical development may be of use in understanding joy. Studies of infants with Down's syndrome show that while social smiling peaks at the same mental age, that is, 4–5 months, as it does for typically developing infants, the intensity of enjoyment appears to be less. Moreover, infants with Down's syndrome are not able to sustain social enjoyment in spontaneous interactions to the same degree as infants without the syndrome and they may also be less likely to initiate smiling (Carvajal & Iglesias, 1997; Kasari & Sigman, 1996).

Of interest in the development of joy is the work on blind infants. Visual input for the first 3 months does not appear to be necessary for smiling to occur since blind children produce recognizable spontaneous smiling, an early action pattern. The argument that one needs to see the expression of another in order to organize one's own expression does not find support here in the case of the blind (Galati, Miceli, & Sini, 2001). However, after this period children who are blind begin to show different patterns of smiling, suggesting that the interaction with the visual world begins to have an effect on these early patterns.

While smiling and enjoyment have been studied for the most part in the context of social interactions, there has been considerable neglect in studying enjoyment (with or without a smiling face) in contexts that are not social. In particular, there is relatively little study of infants' responses to mastery. This is somewhat surprising but in keeping with the overestimation of the theoretical linking of emotional development with social contexts and social development. There is every reason to assume that in the development of enjoyment, the organism's interaction with its physical world, a necessity for survival, requires enjoyment

(Watson, 1972). The overestimation of the child's emotional expressions as only signals to others has led to the study of the role of emotions as motives. As such, enjoyment around action on objects (as well as people) is an important action pattern necessary for exploring, learning, and remembering and has a significant adaptive function as the child interacts with his or her physical world.

Work in our laboratory around learning as well as in response to goal blockage demonstrates that when infants as young as 2 months are provided the opportunity, through pulling a string to cause a picture to appear, enjoyment occurs. In other words, enjoyment is associated with learning that their action causes something to happen. Moreover, we have also demonstrated that when 4-month-old infants learn the contingency between their arm pull and an outcome, those who show more enjoyment (smile more) are more likely to remember that their arm pull caused something to happen (Hitchcock, 2002).

While these studies are quite clear in showing that smiling and enjoyment can be seen in both social interaction and object mastery contexts, more study is necessary to explore the mastery aspect of enjoyment. It is necessary to also explore how smiling behavior in social interactions may differ from smiling mastery in the object world. Given that there is some evidence that there are different kinds of smiles (at least in adults), we may be able to make some distinctions within the emotion of joy/enjoyment, depending on the particular context.

"Duchenne smile" refers to a smile that engages both the mouth and the eye muscles. Ekman (1985) considers the Duchenne smile to be a true expression of joy. A smile that involves only the mouth and not the eyes is considered to be a pretend or false expression of joy. Given the importance of smiling behavior in social commerce, the ability to distinguish between false smiles and true smiles becomes important for the detection of deception.

Sadness

Sadness is often associated with loss but can occur for other reasons as well. Sadness typifies the withdrawal aspect of the original modes of approach and withdrawal patterns. Its adaptive significance is unclear, but its association with crying behavior suggests that it serves as a powerful signal to the caregiver of the child's discomfort. The action pattern, when it includes crying, is complex as it both causes a cessation or reduction of action and at the same time the cry feature constitutes an active response for others to help.

Perhaps crying, while being a component of sadness at the beginning of life, is an action pattern designed as a powerful signal calling for care. It seems that at least in the early weeks of life, crying (usually interpreted as sadness) is not elicited by loss but by discomfort. Loss requires sufficient cognitions such as a sense of object permanence in order to remember that there existed something or somebody who is now lost.

While crying is the most visible aspect of the emotion of sadness, it is important to remember that some of the other features as described by Darwin (1872) may lead us to a better understanding of the adaptive significance of the action pattern. Recall that Darwin suggested the cessation of activity, repetitive motions such as gentle rocking, "languid circulation," and decreases in respiration, as well as particular facial expressions, are other aspects of sadness. While crying is often used to mark sadness, adults who cry for joy or even when angry are examples that suggest that crying alone is an insufficient marker of sadness.

Perhaps an example of sadness without crying is the cessation of action and movement, as demonstrated in the work of Suomi (1991) with monkeys, who has shown that when a monkey mother leaves her baby, the baby shows a decrease in its activity, including vocalizations, as well as an increase in its cortisol stress response. He argues that this reduction of motor activity is adaptive for the infant for two reasons. First, the cessation of activity decreases metabolism and thus the need for food, necessary since its mother's absence means the infant is not being fed. Second, decreased activity decreases noise, and thus limits the possibility of discovery by a predator that without the protection of its mother endangers the baby.

Our problem with studying the early emergence of sadness rests on the use of the crying response to signal the action pattern. So, for example, in studies of crying, a behavior seen at the very beginning of life, different types of cries can be used by caregivers to differentiate the different types of discomfort—for example, cries of pain have a different pattern than cries of hunger (Bachorowski & Owren, 2008). However, we need to remember that it is possible to differentiate a sad face from a crying face. The sad face has brows that are raised and angular with narrowing of the eyes. The mouth is drawn down, often with the lower lips protruding and covers the upper lip in a pouting-like expression. Most important, crying does not have to occur (Oster, 1978).

The study of sadness is like that of the other action patterns: it is often explored in the mother–infant interaction, and in particular in what has been called the *en face* experimental paradigm. In this paradigm, mother and infant sit across from each other and engage in social and affective exchanges. When signaled, the mother, without warning, suddenly drops her head and stops engaging the child. Among the many possible responses of the child, some infants show sadness. The sadness shown by the infant is thought to reflect the infant's loss of its mother. Since the behaviors are studied in 3-month-olds, the infant's response of sadness appears to reflect the loss of its mother and therefore is considered to be part of the ongoing establishment of an attachment between the infant and his or her mother. While the findings are impressive, the sadness seen may reflect the loss of the interaction rather than a measure of attachment to a specific person and may reflect the sudden change and loss of something enjoyable; using the paradigm with a stranger might help resolve the problem (Lewis, 2010).

Another way to look at sadness is through the learning and goal-blockage paradigm that we previously discussed. While most infants respond to the loss of the picture with arm pulling and an angry action pattern, at least 15% of them show a sadness action pattern at the loss. Sad facial expression, cessation of activity, and little change in heart rate fit the action pattern as described by Darwin (1872). While we see the sad response as nonadaptive in this situation, it is clear that the elicitor of this action pattern is the loss either of control or of the picture presented as a consequence of the pulling. However, in another study, for one group we did not terminate the pictures' appearance as the blockage, but only terminated the control of their appearance in an attempt to examine whether it was the loss of control or loss of the picture. To study this, the group that lost control saw the pictures at the same level as the other group, but their arm pull did not control the picture onset. Sadness was still observed, indicating that sadness was produced by the loss of control (Bendersky & Lewis, 1998; Sullivan & Lewis, 2003).

It should be noted that the sadness action pattern is seen in response to the loss of control of objects as well as to the loss of control of people. These findings strongly suggest, and reinforce the idea, that individual differences related to temperament may play an important role in the action pattern displayed. They also point to the problem already mentioned, namely, that the same context may elicit multiple action patterns. Later in life the same context but with different interpretations as to the meaning of the elicitor may do the same thing. Our learning paradigm studies show that the action pattern of sadness can occur in both social and nonsocial contexts. However, we must keep in mind that the crying response, most often used to indicate sadness, is not seen in the nonsocial context; we do not use crying as part of our definition of a sad action pattern. Rather, we see crying behavior as a general response to any sort of discomfort, including pain, the physical discomfort of a soiled diaper, or ever hunger and gas. Crying may elicit sadness and concern on the part of the caregiver but caution should be used in labeling it as a marker of sadness.

Disgust

Of all the early emotions, disgust appears to be the one that is most immediate and likely to require the least cognitive capacity. It is an adaptive response designed for dispelling from the mouth objects that do not taste or smell good. The disgust action pattern is immediately obvious: it consists of opening the mouth and raising the nose, which causes the upper lip to rise. The tongue can protrude from the mouth but does not do so in all cases. The disgust action pattern has much in common with the contempt or shame patterns and can in infancy be mistaken for them. Certainly, the disgust action pattern can be seen in various forms throughout life and has an interesting developmental course (see Disgust, Chapter 46, this volume; Rozin, Haidt, & McCauley, 2008).

Even newborns show this action pattern: their responses to bitter and sour tastes are distinct from their responses to water and sweet solutions (Rosenstein & Oster, 1988). Quinine and other bitter tastes are potent and rapid elicitors of disgust. The developmental course of the disgust action pattern has been little studied, mostly because the action pattern is so clear in the newborn period and therefore a developmental pattern is not likely to be seen. Moreover, disgust seems to be part of the withdrawal pattern and needs little cognition. Support for this conclusion comes from Steiner's (1979) extensive studies of disgust and enjoyment taste reactions in a variety of infants with disabilities. The disgust expression was recognizable in all populations studied despite their considerable variation in cognitive and motor control. Because of this finding Steiner argued that disgust expressions across a wide range of cognitive and motor dysfunctions are controlled by the brainstem and therefore need little cognitive ability. While there are large individual differences in the stimuli that elicit disgust, no work on individual differences early in life have been reported. In our studies of individual differences in 4-month-olds' responses to lemon applied to their tongues, we observed large individual differences, although no consistent individual differences over time were noted.

Perhaps the most interesting aspect of disgust expressions, and the one about which little is known, is how the subtle variations in responsiveness observed even in newborns are related to individual differences in nervous system functioning or other factors, such as temperament. Another question of interest is: When does this expression begin to occur in response to nontaste stimuli, and to representation? The presumption is that disgust occurs later to new elicitors and representations rather than to actual tastes or smells. Nontaste stimuli that might be sufficient to produce a disgust response in infants have not yet been reported, but can be imagined since disgust signals stimulus rejection or withdrawal. Although data are lacking, a too-rapid or too-sudden occurrence of a stimulus might elicit disgust expressions if the stimulus overwhelms the infant's ability to process it. We have observed this response on some occasions in the learning paradigm. Sometimes an infant pulls the string so rapidly that the stimulus appears within a second of its previous appearance and *before* the infant's reaction to the first appearance has subsided. When this occurs, we have seen nose wrinkling or asymmetrical mouth and lip movements in response, suggesting a kind of recoil reaction to the overwhelming, too-rapid reoccurrence of the elicitor. Such observations suggest that prior to 6 months of age components of disgust may occur in response to visual and auditory stimulation, setting the stage for their later function in social situations. Nevertheless, the forms of disgust observed in this case do not involve the intense, gaping reactions observed in response to bitter tastes.

Clearly, the disgust action pattern is a withdrawal response, with the infant rejecting the unacceptable taste and/or smell. Because of the significance for adults of the disgust emotional expression, the child's disgust response is often seen as rejection of what the parents are doing, such as feeding the child. The child's disgust therefore often elicits a strong negative feeling in the caregiver since it may be interpreted as a rejection of him or her. As we have seen, disgust in one person often elicits shame and anger in another. For example, Gottman (1994) has argued that the disgust expression in one marital partner is often the elicitor of anger and depression in the other.

Because the disgust action pattern is easily observed at the beginning of life and continues across the lifespan, we have used it as a prototype of a more general developmental pattern. Clearly, disgust facial patterns are observed very early, and therefore little learning is needed for the development of disgust. To begin with, it is clear that tastes and smells are the literal elicitors of disgust. However, with development, disgust can be elicited by ideas (e.g., moral disgust), or by seeing mauled bodies or bodily discharges. With the development of new cognitive capacities as well as the effects of socialization, the biologically based action pattern of disgust can be used for the rejection of bad ideas and images. It is also used to describe rejecting interpersonal interactions such as "You are disgusting."

Perhaps this is the fate of all of the early action patterns? I suspect that this may be so. What we need to understand is how these early adaptive action patterns interact with the maturing cognitive and social capacities as well as the knowledge the child gains to produce new patterns and new elicitors. It may be that the biological underpinnings of these early action patterns reflect their motivational power, which with maturity produces action patterns associated with thoughts and ideas.

Although not usually discussed as one of the early action patterns, it would be remiss not to mention prosocial-like action patterns. While this is not discussed here (see de Waal, 2008; Warneken & Tomasello, 2009; and Zaki & Mitchell, 2013, for more details), the early existence of these early action patterns are also transformed by self-consciousness (see Chapter 45, this volume).

The Emergence of Self-Conscious Emotions

Figure 15.4 indicates that a new cognitive capacity emerges somewhere in the second half of the second year of life. The emergence of consciousness or self-referential behavior gives rise to a new class of emotions. These have been called *self-conscious emotions* and include embarrassment, empathy, and envy. Although little work exists in the development of these emotions, several studies support the emergence of embarrassment at this point in development. Lewis et al. (1989) have shown that the emergence of embarrassment only takes place after consciousness or self-recognition occurs. Empathy, too, emerges in relation to self-recognition (Bischof-Kohler, 1991).

Two points are to be noticed about this class of emotions. First, the observation of these emotions requires measuring not only a facial expression but bodily and vocal behaviors as well. Whereas the earlier emotions can be observed readily in specific facial configurations, these new emotions require measurement of bodily behavior. Embarrassment, for example, is best measured by nervous touching, smiling, gaze aversion, and return behaviors. The second important point related to the emergence of these emotions is that while they reflect self-consciousness, they do not require self-evaluation. The emergence of these self-conscious emotions is related uniquely to the cognitive milestone of paying attention to the self.

Figure 15.4 shows a second cognitive milestone that occurs sometime between 2 and 3 years of age. This ability is characterized by children's capacity to evaluate their behavior against a standard; the standard can be either external, as in the case of parental or teacher sanction or praise, or internal, as in the case of children developing their own standards. This capacity to evaluate personal behavior relative to a standard develops in the third year of life. The ability to compare personal behavior to a

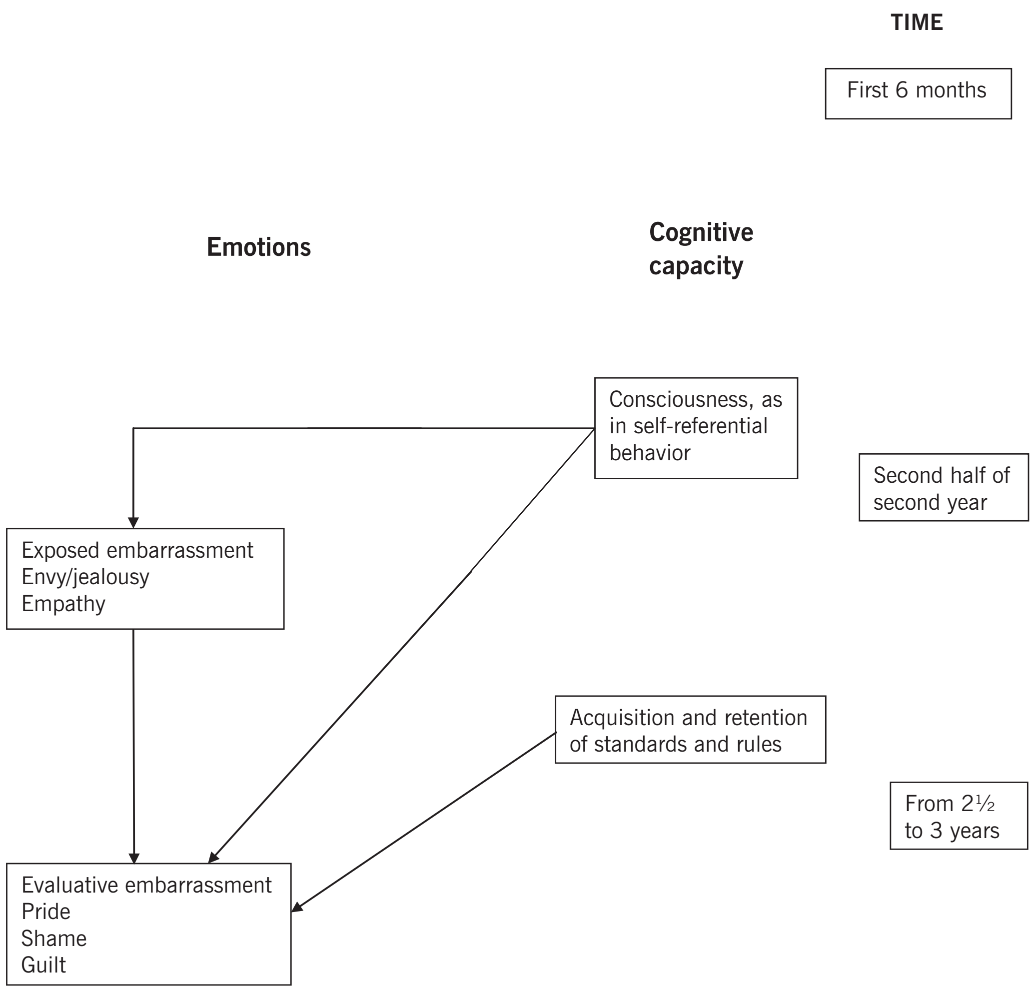

FIGURE 15.4. Cognitive capacities as they relate to the self-conscious emotions.

standard gives rise to another set of emotions. We have called these *self-conscious evaluative emotions*; they include pride, shame, and guilt, among others. These emotions require that children have a sense of self and be capable of comparing their own behavior against standards. If children fail vis-à-vis the standard, they are likely to feel shame, guilt, or regret. If they succeed, they are likely to feel pride (Lewis, 1992a). It is important to note that pride and shame are quite different from happiness and sadness. For example, we can win a lottery and feel quite happy about winning the money; however, we would not feel pride, because we would not view the winning of the lottery as having anything to do with our behavior. The same is true for failure: we might feel sad if we were not able to do something, but if it was not our fault, then we would not feel shame or guilt. These complex social evaluative emotions make their appearance at about 3 years of age (Lewis, 1992b; Stipek, Recchia, & McClintic, 1992; see also Chapter 45, this volume, for more details).

Thus, by 3 years of age, the emotional life of a child has become highly differentiated. From the original set of action patterns, the child comes within 3 years to possess an elaborate and complex emotional life. While the emotional life of the 3-year-old will continue to be elaborated and will expand, the basic structures necessary for this expansion have already been formed. New experiences, additional meaning, and more elaborate cognitive capacities will all serve to enhance and elaborate the child's emotional life.

CHAPTER 16

UNDERSTANDING EMOTION

Paul L. Harris, Marc de Rosnay, and Francisco Pons

Awareness of Emotion

In this chapter, we offer an account of children's emotional development that highlights some of its distinctively human characteristics. Darwin's (1998) emphasis on the continuity between men and animals in their expression of emotion and subsequent research on the nonverbal expression of emotion have tended to obscure those distinctively human characteristics. In particular, the ways in which human beings talk about their emotions and reflect upon them in the context of conversation has been neglected as a key aspect of emotional development.

We begin by describing children's developing ability to put their feelings—and those of other people—into words. Next, we consider how children's emotion concepts become more complex with development. We emphasize that children increasingly understand how a person's emotional reaction depends on how he or she interprets a given situation and not on the situation itself. We provide two illustrations of this claim: children's emerging understanding of belief-based emotions and their understanding of the links between emotion and transgression. We then turn to a discussion of individual differences in children's developing understanding of emotions. We conclude by emphasizing another important link between language and emotion. Thus, we review the increasingly solid evidence that children who are given frequent opportunities to engage in conversation about emotions generally end up with a more accurate and comprehensive understanding, both of their own emotional lives and those of other people.

Talking about Emotion

Psychological theories of emotion, whether focused on children or adults, have been strongly influenced by Darwin's (1998) emphasis on the continuities between human beings and nonhuman primates with respect to both the function and the communication of emotions (Ekman, 1982). However, human beings, unlike other primates, can put their emotions into words. This linguistic mode of expression might serve only to amplify a preexisting mode of nonverbal communication. However, it is more likely that it produces a psychological revolution. After all, it allows human beings to communicate what they feel not just about ongoing situations but also about past, future, recurrent, or hypothetical situations. It also allows them to hear about and contemplate the emotionally charged experiences of other people in situations that they may not have encountered for themselves. These conversations and narratives—which begin in early childhood—provide our species with a unique opportunity to reactivate and explore a wide range of emotional experiences, carrying us well beyond the confines of our own current or firsthand emotional experience.

When do children start to deliberately communicate about emotion? There is intriguing evidence that preverbal toddlers can be taught to use manual gestures to comment on emotions (Vallotton, 2008). For example, 11-month-old Cathy looked at a stuffed toy spider, pounded her fist on her chest (the gesture that she had been taught for fear), and then looked at her caregiver. The caregiver commented on her fear of the spider, eliciting a nod from Cathy. Fifteen-month-old Ellie, hearing another child crying nearby, drew her forefinger down her cheek (the gesture for sad) and, looking at a caregiver, made the gestures for bottle and sleepy/nap. These observations suggest that even before they have any words for emotions, toddlers can report intentionally and appropriately on their own feelings as well as those of someone else.

Children start to talk about emotions at approximately 2 years of age. To analyze such talk, Wellman, Harris, Banerjee, and Sinclair (1995) studied a small group of children whose language production had been recorded on an intensive, longitudinal basis from 2 to 5 years. Wellman et al. (1995) concentrated on all those utterances in which children referred to either an emotion or, for comparison purposes, to a mental state that is not an emotion, namely, pain. The analysis showed that even 2-year-olds talk systematically about emotion. They refer to a small set of emotional states—both positive (feeling happy or feeling good, laughing, and feeling love or loving) and negative (feeling angry or mad; feeling frightened, scared, or afraid; and feeling sad or crying).

Children talk most often about their own emotions but they also talk about the emotions of other people. Moreover, consistent with the proposals made by Widen (see The Development of Children's Concepts of Emotion, Chapter 17, this volume), children's attributions of emotion are not exclusively triggered by the recognition of animate facial expressions. They also attribute emotions to dolls, stuffed animals, and made-up characters. Moreover, as just noted, 2-year-olds talk about emotional states—feeling good or feeling love—that have no obvious facial signature.

Arguably, when young children put their own feelings into words, they are not engaged in any self-conscious reporting of their experience. Rather, as Wittgenstein (1953) suggested, such early emotion utterances could be seen as vocal substitutes—on a par with exclamations such as "Ouch" or "Yuck"—for the nonverbal expression of emotion. However, close examination of 2-year-olds' utterances shows that this interpretation is ill founded. If children's references to emotion were simply a substitute for the ordinary facial and behavioral expression of emotion, we would expect them to be produced more or less exclusively in the context of ongoing or current emotions. However, about half of 2-year-olds' references to emotions are concerned with past, future, and recurrent feelings, and the same pattern is found among 3- and 4-year-olds.

By implication, we can think of children's utterances about emotion as referential reports, not as lexical substitutes for scowls and smiles. Indeed, Wittgenstein's (1953) analysis is not even appropriate for children's pain utterances. Here too, children talk not only about current pains, they also refer to pains that they might experience in the future or have experienced in the past. More generally, many of children's utterances about emotion can be categorized as descriptive utterances. Instrumental utterances, aimed at obtaining sympathy or influencing the emotional state of another person (Dunn, Brown, & Beardsall, 1991; Wellman et al., 1995), are less frequent. Indeed, this bias toward descriptive commentary is evident even below 2 years of age. Dunn, Bretherton, and Munn (1987) found that children between 18 and 24 months used conversation about feelings primarily to offer a descriptive comment about their own feelings or those of another person. That said, it is worth emphasizing that their mothers—to whom most of these comments were directed—used such conversations in a more didactic or pragmatic fashion. Clancy (1999) reported similar findings for Japanese mothers; they also frequently use talk about emotion for didactic purposes, for example, to affirm or counter their 2-year-olds' suggestion that a particular person or creature is scary.

Talking about Past Emotion

Lagattuta and Wellman (2002) looked in more detail at how children talk about negative as compared with positive emotions. Like Wellman et al. (1995), they examined the utterances of a small group of children whose language production had been studied on an intensive, longitudinal basis from 2 to 5 years. Overall, children and their parents tended to talk about current emotions, with a bias toward positive rather than negative emotions. Nevertheless, when past emotions were discussed there was a tendency to focus on negative rather than positive emotions. This bias toward the negative was true for both children and adults. Talk about negative emotions also included about three times as many causal elaborations as compared with talk about positive emotions, and again this bias emerged among children as well as adults. Moreover, when children and adults posed an open-ended, as opposed to a closed question about emotion, such questions were about three times more frequent for negative than positive emotions. Overall, then, Lagattuta and Wellman (2002) found that conversations about past emotional experiences are especially frequent, elaborate, and open-ended in the case of negative emotions.

Ordinarily, our emotional reactions are especially intense immediately after a precipitating event. They gradually become weaker as that event recedes in time. Given the ubiquity of this waning process, it is not surprising that even 4-year-olds understand that it occurs (Harris, 1983; Harris, Guz, Lipian, & Man-Shu, 1985). However, despite its ubiquity, this waning process is not inevitable. Past emotions can be reactivated by reminders—events or cues that trigger memories of earlier emotionally charged encounters.

Lagattuta and Wellman (2001) examined the understanding of that reactivation process by young children ages 3–5 years. Consider, for example, the following story about a negative emotion that is subsequently reactivated in otherwise positive circumstances: "Suzie feels sad when the neighbor's black spotted dog scares away her rabbit. Many days later, the neighbor's dog slowly walks over, sits down and wags its tail real friendly. Suzie starts to feel sad." Children listened to such stories and were then asked about the feelings of the protagonist: "Why does Suzie start to feel sad right now?" and were scored for the frequency with which they produced so-called cognitive-cuing explanations, involving references to a cue in the present situation that made the protagonist think about a past event, for example: "The dog makes her think about the lost rabbit." Children were especially likely to produce such cognitive-cuing explanations for stories involving a prior negative emotion, as exemplified by the story about Suzie's dog. They were less likely to provide such explanations for stories involving a prior positive emotion.

Arguably, conversations about past emotions help children to understand the reactivation process. When children engage in a conversation about a past event, they might experience a reactivation of the emotion that they felt earlier. Indeed, to the extent that conversations about past negative emotions tend to be especially probing and elaborate, children might become particularly alert to the ways in which negative—as opposed to positive emotions—can be reactivated by such conversational reminders. Alternatively, when ruminating about a past event children might display the emotion associated with that event and thereby puzzle their parents with a demeanor that is not consonant with their current circumstances. Concerned parental questioning ("What's the matter?") might then prompt children to think about their emotional state and its cause. Such questioning is especially likely to occur when the child appears upset in otherwise positive circumstances. Thus, according to either of these two analyses, we might plausibly expect conversation to help children understand how reminders of the past, especially reminders of negative events, can reactivate otherwise dormant feelings.

Taken together, the various findings on children's conversations about emotion highlight the extent to which children's emotional experiences and their reflection on such experiences are not tied to the current moment. Language allows children to put their current feelings into words but it also allows them to talk about future emotions and to revisit past emotions. Probably by virtue of such conversations, children are especially aware of the fact that past emotions can be reactivated by reminders.

Desires, Beliefs, and Emotion

In the previous section, we discussed the child's ability to talk about emotions in global terms. In this section, we consider in more detail how children conceptualize the emotions that they talk about and the way in which their conception of those emotions changes in the course of development. One simple and attractive proposal is that children develop an increasingly elaborate set of scripts for particular emotions. Thus, they identify the type of situations that elicit various emotions—fear, sadness, anger, happiness, and so forth—as well as the typical actions and expressions that accompany a particular emotional state (Barden, Zelco, Duncan, & Masters, 1980; Harris, Olthof, Meerum Terwogt, & Hardman, 1987; Trabasso, Stein, & Johnson, 1981; Widen, Chapter 17, this volume; Widen & Russell, 2008).

This notion of script-based knowledge has several advantages. It assimilates children's understanding of emotions to a wider body of research on children's recall and understanding of sequentially organized events (Nelson & Gruendel, 1979). It highlights the fact that an understanding of emotions calls for a causal understanding of the connections among its sequential components. It is also sufficiently flexible to be of service if we look outside of the Western world to children's understanding of emotions in cultures where different emotional themes are prominent. For example, Lutz (1987) used this approach in her analysis of the emotion concepts of children on the island of Ifaluk in the Western Pacific. Finally, the notion of an emotion script fits comfortably with the possibility, raised in the previous section, that children's understanding might be elaborated not just in the context of emotionally charged encounters but in the context of discussions in which past emotionally charged episodes are likely to be rehearsed and organized into a coherent, narrative sequence.

However, it is important to recognize some important challenges for the script metaphor. The same objective situation can elicit different emotions depending on the appraisal that a given protagonist makes of that situation. This means that if the child attempts to store a list of scripts for emotion in which situations are conceptualized as the major elicitors of emotion, it will be necessary to store different scripts for different people even with respect to the same situation. An alternative, and more economical, solution is to define the eliciting situation in more psychological terms. For example, it is possible to define situations that provoke happiness as "situations that are judged by an actor to bring about the fulfillment of his or her goals." This definition acknowledges that emotions are not scripts in any ordinary sense of the term. More specifically, they do not begin with the kind of objective and visible event that we normally associate with scripts (e.g., the action of sitting down at a table might be seen as the first move in the dinner script). Rather, they begin with a causal event that is inherently psychological, namely, a person appraising a situation. Thus, a fruitful approach to children's understanding of emotion is to acknowledge that children may indeed construct scripts for given emotions but key elements of those scripts will include a psychological cause—a diagnosis, not of the objective situation that faces the protagonist but rather an analysis of how the protagonist appraises that situation. Making the same point differently, it is not just psychologists who have to recognize the role of appraisal processes in emotion. Young children should do the same. Indeed, as we describe below, they increasingly do so in the course of development.

The limitations of a focus on objective events as causes can be highlighted in another way. Children with autism are often good at remembering recurrent sequences of events. Indeed, part of the clinical picture of autism is a disposition to become upset at an unexpected departure from a routine sequence. In some ways, their script-sensitive memory serves children with autism quite well with respect to understanding emotions. They appropriately judge that certain situations (getting nice things to eat, birthday parties) make people happy, whereas other situations (having to go to bed early, falling over) make people unhappy (Baron-Cohen, 1991; Tan & Harris, 1991). Similarly, Ozonoff, Pennington, and Rogers (1990) showed that children with autism could select the appropriate facial expression to go with the depiction of various emotionally charged situations. For example, they chose a sad face for a picture of a child looking at a broken toy and an angry face for a picture of two children fighting. Yet despite this apparent familiarity with routine scripts for various emotions, children with autism perform poorly, in comparison to nonautistic controls, when a correct attribution of emotion requires them to go beyond the objective situation and consider how a protagonist's beliefs influence his or her appraisal of that objective situation (Baron-Cohen, 1991; Harris, 1991). The clear implication is that typically developing children realize that it is not situations in themselves that cause emotions but the way in which they are appraised.

Accepting this argument, we can ask in more detail how children come to understand the appraisal process. First, even toddlers appreciate the role that desires or preferences play in determining a protagonist's appraisal and the ensuing emotion. For example, they understand that someone may want to be given more crackers or more broccoli depending on whether they have expressed a liking for one or the other (Repacholi & Gopnik, 1997). Similarly, preschoolers understand that a toy elephant might feel happy to be given milk if it wants milk, whereas a toy horse may feel upset, if it preferred juice instead (Harris, Johnson, Hutton, Andrews, & Cooke, 1989; Yuill, 1984).

However, it is only around 5–6 years that children recognize the impact of beliefs on emotion. Several studies support this conclusion. For example, Hadwin and Perner (1991) found that even if virtually all 5-year-olds could appreciate a story character's mistaken expectation, it was only at 6 years of age that a significant majority made correct attributions of surprise, consistent with the story character's misplaced expectation about what was about to happen. Bradmetz and Schneider (1999) examined children's understanding of the Little Red Riding Hood story. Younger children often realized that Little Red Riding Hood did not know that a wolf was waiting for her inside her grandmother's cottage. Yet they would still claim that she was afraid—and they often invoked the wolf to explain her fear: "Because the wolf wants to eat her." Older children were more likely to respond correctly by attributing a positive emotion to her given her mistaken appraisal of what lay in store. De Rosnay and Harris (2002) observed a similar pattern when children watched a video of a child protagonist hearing a knock at the door and mistakenly thinking that her mother is about to enter the room. Younger children frequently erred by identifying the protagonist's emotion as negative, even though they acknowledged that she did not yet know that it was a stranger, and not her mother, who was knocking at the door. Older children, by contrast, realized that the protagonist would be happy to hear the knock at the door, mistakenly taking it to be her mother.

These various studies examined children's ability to figure out what someone else—a story protagonist or a child in a video—is feeling given his or her beliefs. Do children also have trouble in identifying their own belief-based emotions? Bender and his colleagues (Bender, Pons, Harris, & de Rosnay, 2011) interviewed 5½-year-olds and 7-year-olds using a variant of the classic Smarties task. Children were shown a box of Smarties candy and asked to indicate how they felt about getting its contents to eat; needless to say, they almost invariably reported positive feelings. They were then shown that, sadly, the box contained only inedible beads. Next, the beads were returned to the box and children were asked about their initial belief, what they had thought was inside the box, and also about their initial emotion, how they had felt about getting to eat its supposed contents. A considerable proportion of children acknowledged that they had mistakenly thought there were Smarties in the box. Yet they often claimed that they had felt sad about eating the prospective contents. Apparently, these children did not figure out how they had felt by searching their memory and retrieving the positive feelings they had experienced and reported earlier. Their self-report was contaminated by what they discovered later. Apparently, what Birch and Bloom (2007) aptly describe as "the curse of knowledge" applies to children's self-attributions of emotion.

How can we explain the pervasive difficulty of younger children in understanding belief-based emotions? Granted children's early grasp of the link between desire and emotion, it is likely that they attribute positive or negative emotion to someone depending on whether the person in question is approaching an outcome that fits or frustrates his or her desire. Recall that even toddlers acknowledge individual preferences in this fashion (Repacholi & Gopnik, 1997). If so, some kind of inhibitory process would be needed for that outcome-based attribution to be suspended. Realizing that the person is wrongly appraising the impending outcome could, in principle, trigger such an inhibitory process. However, as the above evidence implies, it may fail to do so especially among younger children. It appears that children's attributions become more accurate, not simply because they get better at analyzing the protagonist's mistaken belief, but because they get better at using their analysis of that mistaken belief to override a simpler analysis based only on the perceived desirability—or undesirability—of the impending outcome.

If this interpretation is correct, we might expect children to be more accurate in their attributions of emotion if that override process is made less onerous. Ronfard and Harris (2014) tested this idea by asking children how Little Red Riding Hood would feel, not just when the impending outcome was imminent—for example, as she stood at the door of her grandmother's cottage—but also when she was starting off on her journey to her grandmother. As predicted, children displayed a linear pattern: incorrect attributions of fear to Little Red Riding Hood steadily increased as the override process became more onerous (i.e., as Little Red Riding Hood got closer to the cottage and the impending outcome became more salient). These incorrect attributions increased even though, at each point along her journey, children acknowledged that she knew nothing about the wolf.

Summing up these various findings, we can say that children soon realize that the same situation can elicit different emotions depending on the particular desires that an individual brings to it. They have much more difficulty in realizing that it is someone's belief-based appraisal of an impending situation—accurate or inaccurate—that determines how he or she feels, not the situation itself (Harris, de Rosnay, & Ronfard, 2013).

The Appraisal Process and Transgression

We can learn more about children's developing appreciation of the appraisal process by looking at children's attributions in the context of transgression. In a pioneering study, Nunner-Winkler and Sodian (1988) found a surprising age difference. Four- and 5-year-olds consistently claimed that a story protagonist who had committed a relatively serious transgression (e.g., deliberately lied, or pushed another child, or stolen something) would feel happy. The children justified this by noting that the protagonist had achieved his or her goal—successfully stolen something or pushed another child off the swing. Older children, around the age of 8 years, were more likely to claim that the protagonist would feel bad and in explaining that attribution they referred to the story character's transgression. So, here again we see a shift from a desire- or goal-based attribution of emotion to something more complex.

A plausible explanation for this shift is that older children increasingly expect that a transgression will provoke a bad conscience—they have acquired an understanding of what it means to think about, and feel badly about, a wrongdoing. Still, before focusing in more detail on that interpretation, it is worth considering various alternatives. One possibility is that younger children regard the transgressions as minor. However, a long tradition of research on moral development shows that preschoolers actually think of lying, pushing, and stealing as serious transgressions (Smetana, 1981). Not surprisingly, therefore, Keller, Lourenço, Malti, and Saalbach (2003) could find no age difference in children's castigation of such basic transgressions.

A second possibility is that older children expect the protagonist to feel bad because they are more alert to the risk of punishment. Indeed, being older and arguably expected to "know better," older children might anticipate more severe punishment for such transgressions than younger children. However, children's justifications for their attributions of emotion lend little support to this explanation. They rarely refer to punishment or fear of punishment when explaining why the perpetrator feels bad.

A third possibility is that older children are more likely to interpret the question in terms of the emotion that the perpetrator *should* feel, whereas the younger children focus on what the perpetrator actually *does* feel. However, when Keller et al. (2003) asked children how they themselves would feel after such a transgression—a question format that should presumably help younger children to focus on socially appropriate feelings—the familiar age difference still emerged.

A fourth possibility is that younger children are "happy victimizers." As compared with older children, they are less likely to acknowledge the suffering experienced by the victim of a transgression, and less likely to attribute bad feelings to the person who has caused that distress. However, when Arsenio and Kramer (1992) explicitly asked children of various ages about the feelings of the victim, all age groups acknowledged his or her distress. Indeed, the familiar age difference in the attribution of bad feelings to a wrongdoer emerged even when children were asked about transgressions that did not involve any suffering on the part of a victim. Thus, when Lagattuta (2005) presented children from 4 to 7 years with stories involving a conflict between the protagonist's desire and various nonmoral rules concerning, for example, safety ("Don't run into the street") or nutrition ("Don't eat cookies before dinner"), older children were more likely to acknowledge that the protagonist would feel bad after breaking the rule. Equally important, older children were also more likely to acknowledge that the protagonist would feel good about being a "rightdoer" (i.e., someone who had resisted the temptation to break the rule). Clearly, it is not feasible to explain these age differences in terms of increased empathy for a victim because in neither case was there any victim.

The most plausible explanation of the findings is that, in the course of development, children increasingly conceive of protagonists as engaging in a particular kind of appraisal process. More specifically, younger children are inclined to assume that protagonists focus mainly on their goals and feel happy or sad depending on whether their actions have fulfilled those goals or not. So, for example, a protagonist who wants to steal something and successfully does so will feel good about it. Older children, by contrast, acknowledge that protagonists appraise their actions in terms of their fit with various rules and obligations. They feel good if they have done what they should do and bad if they have done what they ought not to do. In probing children's explanations for the emotion felt by the story characters, Lagattuta (2005) obtained support for this interpretation. Older children were more likely to focus on rules and obligations than younger children. They said, for example, "She feels a little bad because she shouldn't have done that" or "Because his Mom said he had to stay out of the street."

Does this mean that younger children are completely oblivious to rules and obligations in assessing what someone feels? In that case, someone who overtly expresses negative feelings by apologizing for a wrongdoing should be quite puzzling for younger children. Recent findings, however, suggest that, in fact, they are not completely oblivious to the negative feelings that can follow transgression. Smith, Chen, and Harris (2010) gave 4- to 9-year-olds two different stories, one in which the protagonist grabbed something belonging to another child, a bag of marbles, and one in which the protagonist was physically aggressive—pushed another child off the swing. At the end of one story, the protagonist said, "I'm sorry," but at the end of the other, the protagonist was unapologetic. When the protagonist failed to apologize, 4- and 5-year-olds showed the familiar attribution pattern. They expected the transgressor to have positive feelings despite his or her transgression and they explained those feelings in terms of what the transgressor had gained—the opportunity to play with the marbles or to go on the swing. Children's attribution pattern was quite different when the protagonist apologized. They said that the apologetic transgressor would feel bad and in their explanations they called attention to the transgressor's misdeed and its impact on the victim. They also displayed some insight into the impact of an apology on the emotions of the victim, claiming that the victim who received an apology would not feel as bad as the one who received no apology.

These findings offer reassurance to parents who might worry that preschool children think of an apology as a vacuous statement that parents oblige them to make. On the contrary, preschoolers understand that an apology conveys regret on the part of the transgressor and that it will go some way to repair the victim's hurt feelings. By implication, the elicitation of an apology is an effective way to help young children shift their attention away from the dubious goal that they have just achieved to the transgression that they committed in pursuing that goal. This analysis implies that children who are frequently prompted to reflect upon their misdeeds and to apologize for them will be more likely to attribute negative feelings to a wrongdoer—and positive feelings to a rightdoer—than children who are not so prompted. Chinese mothers are more likely than their U.S. counterparts to recall and review past wrongdoings by their children (Wang & Fivush, 2005). In line with these findings, Chen found that 4- to 8-year-old Chinese children growing up in Shanghai were more likely to attribute negative feelings to a wrongdoer, and positive feelings to a rightdoer than their U.S. peers growing up in Boston (Chen, 2009).

Does this developing insight into the link between transgression and bad feelings—into the workings of a guilty conscience—have any impact on children's behavior? More specifically, is there any evidence that children who readily anticipate that wrongdoing will provoke bad feelings in the perpetrator are better able to stop themselves from doing something wrong? Two studies, especially when considered in combination, point to such a link between emotion understanding and behavior. Smith, Blake, and Harris (2013) gave children ranging from 3 to 8 years of age four stickers. Some children were invited to say how many stickers they should give to another child if invited to divide their stickers with him or her. Other children were given two envelopes, one for themselves and one for another child, and invited to divide the four stickers in whatever way they saw fit. Older children, ages 7–8 years, responded consistently to these two invitations. Thus, they said that they should give two of the four stickers to the other child and they actually did so when handed the envelopes. Younger children also said that they should give two stickers. Nevertheless, many of them, especially at 3–4 years, kept all four stickers for themselves. When asked to explain their responses to the question about what they should do, most children, regardless of their age, offered norm-based explanations (e.g., "Then it will be equal") but there was a marked age difference when children explained what they had actually done. Older children again gave mostly norm-based explanations, whereas younger children often gave desire-based explanations (e.g., "It's my favorite color and I want to keep them all"). This pattern is, of course, familiar; it echoes the age difference that we have seen when children think about how a story protagonist will feel after a wrongdoing: Younger children tend to focus on the desires of the protagonist rather than on normative considerations, whereas older children do the reverse. By implication, the older children were likely to act in terms of normative considerations (namely, equal shares for all), whereas younger children could articulate those norms but failed to act on them.

Further analysis also showed that younger children's indifference to the equal sharing norm when actually sharing was not easily explained by a lack of inhibitory control. Children's performance on a standard measure of inhibitory control—the day–night task—improved with age but this improvement did not mediate the link between age and sharing. Earlier work points instead to the likely impact of a growing ability to anticipate the emotional consequences of transgression. Lake, Lane, and Harris (1995) told children a story in which the protagonist took some candy at a friend's house without permission. Children were invited to diagnose how the protagonist felt immediately afterward, as well as later on that day, when the protagonist wondered whether to confess this misdeed to his mother but refrained from doing so. Alongside this attribution task, children were also tested in a resistance-to-temptation paradigm. They could increase their chance of winning a prize if they cheated by peeking while the experimenter was absent. A relationship between children's tendency to cheat and their story attributions was observed. Noncheaters proved to be especially different from cheaters in their responses to a question about how the protagonist felt about not confessing. Noncheaters were more likely to say that the story protagonist felt bad, whereas even after a countersuggestion, cheaters often said that he felt fine. Thus, children who were more alert to the possibility of a guilty conscience were more likely to resist the temptation to cheat.

Taken together, these two studies imply that, as they get older, children increasingly abide by moral norms, not because they have gained any greater knowledge of the norms in question, or because they are better at inhibiting the impulse to transgress, but because they realize that wrongdoing will make them feel bad.

Individual Differences in Understanding Emotion

So far, we have emphasized age differences in children's understanding of emotion. That emphasis reflects a research program that has been dominant for the past 30 years. Investigators have aimed to identify a succession of conceptual insights that children come to master in the course of development (Harris, 1989). However, recently, increasing attention has been paid to individual differences in children's mastery of those insights. Investigators have developed psychometric tools to assess how far children have progressed in their understanding of emotion and to assess how far some children are advanced in their understanding, whereas others lag behind.

Pons, Harris, and de Rosnay (2004) describe a Test of Emotion Comprehension (TEC) composed of nine different components: (1) the recognition of facial expressions of emotion, (2) understanding situational causes, (3) understanding the effect of reminders on emotion, (4) understanding the link between desire and emotion, (5) understanding the link between belief and emotion, (6) understanding the potential discrepancy between felt and expressed emotion, (7) understanding guilt, (8) understanding the regulation of emotion, and (9) understanding mixed or ambivalent emotions. They tested children between 3 and 11 years for their mastery of each component. The main findings were that children displayed a clear improvement with age on each component and the components themselves could be plausibly grouped into three developmental phases. The first period is characterized by the understanding of key public aspects of emotions: their mode of expression, their situational causes, and the effect of reminders. The second period is characterized by mastery of mentalistic aspects of emotion: the role of desires and beliefs and the distinction between felt and expressed emotion. The third period is characterized by an understanding of how the same individual can reflect on a situation in different ways or in terms of different criteria and thereby evoke different feelings, either at the same time or successively. Pons et al. (2004) observed a hierarchical relationship among these three phases. By implication, the understanding of key external aspects of emotion is a prerequisite for understanding the more mentalistic aspects. In turn, understanding these mentalistic aspects is a prerequisite for understanding the impact of reflection on emotion.

Follow-up studies have confirmed that the test has good test–retest reliability over a period of 1–3 months (Pons, Harris, & Doudin, 2002; Tenenbaum, Alfieri, Brooks, & Dunne, 2008). Pons and Harris (2005) examined the scope and stability of individual differences in a longitudinal study of three age groups. Children ages 7, 9, and 11 years were tested at Time 1 and then retested 13 months later at Time 2. More than half of the 7- and 9-year-olds showed gains at retest (although the majority of 11-year-olds remained the same—likely reflecting the absence of challenging components for this older group). Individual differences were marked at both Times 1 and 2 for all three age groups. For example, children in the youngest group varied by as much as six components and children in the two older groups varied by as much as four components. Moreover, when adjacent age groups were compared, the highest-scoring children in the younger group scored higher than the lowest-scoring children in the older group by two to three components depending on which two age groups were compared. Indeed, some of the 7-year-olds had an overall level of emotion understanding that was higher than some of the 11-year-olds. These individual differences remained quite stable over the 13-month period. Thus, despite the gains made by many children in their understanding of emotion, their relative level of understanding at Time 1 was a good predictor of their relative level of understanding at Time 2.

Children's level of understanding can be improved by educational interventions. Pons et al. (2002) administered the TEC to 9-year-olds on two occasions, with an interval of 3 months between each administration. During the interval, children in the experimental group engaged in daily classroom reading and discussion concerning various aspects of emotion, including the origins of particular emotions, the distinction between real and expressed emotion, and strategies for coping with emotion. Control children, by contrast, followed the standard curriculum. Most of the experimental children improved their scores on the TEC, whereas only a minority of control children did so. Strikingly, children's level of understanding at the pretest was correlated with their level of understanding at the posttest, whether they were in the experimental or the control group. By implication, the intervention helped most of the children in the experimental group but it did not eliminate preexisting individual differences in children's relative level of understanding.

Similar results were obtained by Tenenbaum et al. (2008). Following a pretest with the TEC, children ranging from 5 to 8 years listened to vignettes about mixed and hidden emotions and were allocated to one of three groups. They were invited to (1) identify an explanation for the protagonist's emotion that had been mentioned in the story, (2) listen to a similar explanation from the experimenter, or (3) recall aspects of the story not connected to the protagonist's emotion. Children in the first two groups—who had been prompted to think about why the protagonist had displayed mixed feelings or had concealed his or her feelings—showed gains on the TEC in a posttest, whereas children in the third group did not. In line with the findings of Pons et al. (2002), performance at pre- and posttest was correlated for all three groups, again suggesting that an intervention can boost understanding but does not eliminate preexisting individual differences.

Do such marked and stable individual differences in children's understanding of emotion have any impact on their social relationships, especially their relationships with peers? Several studies have explored this possibility. Denham, McKinley, Couchoud, and Holt (1990) tested preschoolers (mean age = 44 months) for their ability to identify a puppet's emotion (of happiness, sadness, anger, or fear) both when the puppet exhibited a prototypical reaction (e.g., fear during a nightmare) and an atypical reaction (e.g., sadness at going to preschool). In addition, using a sociometric measure, children were assessed for their acceptance as a playmate among their peers. Children with higher scores on the emotion test proved to be more popular among their peers, even when the contributions of age and gender were removed. Cassidy, Parke, Butkovsky, and Braungart (1992) obtained very similar results with first-grade children. Children's overall score in an interview about the causes, consequences, and associated expression of emotion was correlated with their popularity. In a longitudinal study of 4- and 5-year-olds, Edwards, Manstead, and MacDonald (1984) found that children who were accurate at identifying facial expressions of emotion proved to be more popular 1–2 years later (even when their initial popularity was taken into account). Finally, in a longitudinal study of somewhat older children, Caputi, Lecce, Pagnin, and Banerjee (2012) found that children's understanding of belief and emotion at 5 years of age was associated with prosocial behavior at 6 years of age, which was in turn related to peer acceptance versus rejection at 7 years of age. By implication, children's understanding of belief and emotion regulates the extent to which they enter into collaborative and sympathetic relationships with their peers—and thereby gain acceptance or face rejection.

However, it would be wrong to draw the conclusion that children with good insight into emotion inevitably have healthy and positive relationships with their peers. As Hughes (2011) emphasizes, children's understanding of mental states, including emotion, is neutral with respect to social behavior. It can lead to either prosocial or antisocial behavior. Consider the following thought-provoking study of bullying carried out by Sutton, Smith, and Swettenham (1999). Bullies are sometimes characterized as awkward children who resort to aggression because of their limited social skills. Yet it is also conceivable that bullying calls for an astute analysis of whom to victimize and how bystanders will react. With this in mind, Sutton et al. (1999) administered a set of stories designed to assess the understanding of emotions and cognitions among 7- to 10-year-olds. Children who were "ringleader" bullies scored higher than several other groups. They scored higher than "follower" bullies (i.e., those who helped or supported the bully) and victims, as well as defenders of the victim.

Summarizing across these studies, the implication is that insight into other children's emotional and mental states is associated with social adroitness. It is linked to popularity and acceptance but it can also be linked to leadership in the context of bullying. It is tempting to assume that a more advanced or precocious understanding of emotion invariably yields positive social outcomes but that assumption is probably too optimistic.

The Origins of Individual Differences

Why do children vary so markedly in their understanding of emotion? One plausible reason is that the development of emotion understanding, indeed the development of children's psychological understanding more broadly, is a reflection of variation in their linguistic competence. In keeping with that possibility, children who are linguistically more advanced are also better able to predict and explain emotions (e.g., Pons, Lawson, Harris, & de Rosnay, 2003). Recent evidence also points to a key role for family conversation. Consider a child whose parent frequently discusses emotions and other psychological states, by drawing out the child's own feelings and desires, by calling attention to the way that his or her actions may have emotional implications for other members of the family, or by elaborating on the thoughts and feelings of story characters. Consider, on the other hand, a parent who is more constrained in talking about such psychological states, whether with respect to the child, or other people. Beyond the contribution that a child's linguistic competence makes to emotion understanding, two such different conversational partners might be expected to have a differential impact on the extent to which the child understands the causes and consequences of emotion.

We know that there is marked variation among families in the frequency with which emotions and other aspects of mental life are discussed. In a pioneering study, Dunn, Brown, and Beardsall (1991) found that some children never made any mention of emotion during an hour-long home visit, whereas others made more than 25 such references; variation among the mothers was equally great. This type of variation in the frequency with which preschool children engage in family discussion about emotions is correlated with their later ability to identify how someone feels. The link has been found over a relatively short period, straddling the third birthday (i.e., from 33 to 40 months; Dunn, Brown, Slomkowski, Tesla, & Youngblade, 1991), as well as a more extended period from 3 to 6 years (Dunn, Brown, & Beardsall, 1991; Brown & Dunn, 1996).

Such correlational data are, of course, open to various interpretations. One possibility is that the correlation reflects some stable attribute of the child that manifests itself both in psychological talk and in sensitivity to emotion. For example, some children may, because of their natural empathy, have a proclivity to both discuss emotions and also to attend to others' feelings. Another possibility is that some caregivers, because of their underlying sensitivity or attunement, may speak more about emotion and thereby engender in the child a heightened awareness of people's emotional lives. Although both of these underlying mechanisms remain plausible, the extant literature strongly suggests that conversational interactions do serve a didactic function, so that the manner in which caregivers speak about psychological states has a direct influence on children's understanding of mind and emotion (de Rosnay & Hughes, 2006).

Evidence that certain kinds of family discussions may prompt children to speak about emotion and increase their understanding and perspective taking comes from various directions. For example, Garner, Jones, Gaddy, and Rennie (1997) found that 3- to 5-year-olds' emotional perspective taking is correlated with family discussions of emotion that focus not simply on what the person feels but rather on *why* someone feels a given emotion. Similarly, Laible (2004) showed that, among 2- to 3-year-olds, emotion understanding was related to mother–child conversations that were high in clarity and stayed on topic, rather than related to references to emotion per se. Taken together, these two studies suggest that children's emotion understanding is cultivated in a conversational environment that encourages them to think about why someone might feel a certain way.

Two recent longitudinal investigations show how the conversational support that mothers offer shifts as their children get older. Taumoepeau and Ruffman (2006, 2008) analyzed structured conversations between mothers and their children while reading psychologically evocative picture books at

15, 24, and 33 months of age. Mothers' utterances were coded for various features of mental state talk (desires, emotions, thoughts, knowledge, etc.), as well as other salient, descriptive, and functional features. Children's vocabulary development was assessed at each age, and measures of mothers' (15 months) and children's (24 and 33 months) emotion understanding were similarly assessed, so that the unique contribution of mothers' conversational input for the development of children's emotion understanding could be determined. The results showed that mothers' mental state discourse uniquely predicted children's later emotion understanding. Nevertheless, the contribution of maternal mental state discourse shifted as children got older—references to desires were important earlier on, whereas references to thoughts and knowledge were more prominent later on. Importantly, at no time did mothers' simple references to emotion directly predict children's emotion understanding, a result that is consistent with studies of mother–child discourse at slightly later ages (Ensor & Hughes, 2008; Ruffman, Slade, & Crowe, 2002). Although this conclusion might seem counterintuitive, it is instructive. The simple identification and labeling of emotion does not seem to help children understand the idiosyncratic appraisal processes that lead to emotions. However, when the thoughts and desires underpinning such appraisal processes are enunciated and emotions are contextualized in terms of their psychological causes, the didactic function of conversational interaction becomes clearer. These data concerning the impact of maternal discourse dovetail nicely with the earlier emphasis on children's developing sensitivity to appraisal processes, and also with the findings from the two educational interventions discussed earlier, which each emphasized the impact of discussion and explanation.

From the evidence presented above, a picture emerges of profound variation in the socialization of emotion understanding via ordinary family conversations. Against this backdrop, it is important to consider the source of such variation more carefully. While direct conversational measures show that mothers' discourse predicts children's psychological understanding, there is little evidence to show that individual differences in children's understanding of mental states predicts maternal discourse. Mothers do adjust their use of psychological terms to their children's developmental level (see Taumoepeau & Ruffman, 2008, for a discussion). Nevertheless, other sources of evidence indicate that a mother's proclivity to think of her child in psychological terms is a relatively stable feature of the caregiver that can be seen in verbal interactions with her preverbal infant (Meins et al., 2002), or indeed when she is simply asked to describe her child (de Rosnay, Pons, Harris, & Morrell, 2004). In each of these two settings, even though the mother was not engaged in conversation with her child, characteristics of her discourse style were nevertheless predictive of the child's understanding of emotion.

Findings such as these suggest that variation in mothers' mental state discourse may depend on how she sees her child as a conversation partner. Ensor and Hughes (2008) used naturalistic observations of family discourse when children were 2, 3, and 4 years of age to examine family discussions of psychological states and the manner in which family members spoke to one another. As they predicted, a relatively high proportion of references to mental states (notably desires, cognitions, and emotions) occurred in the context of connected utterances (i.e., utterances that were semantically related to the interlocutor's previous utterance rather than initiating a new topic or issuing a prescription or insult). Indeed, it was the so-called *connectedness* of the conversational interactions rather than frequency of mental state references that emerged as the best predictor of children's later understanding of mental states, including emotion.

Summarizing across these different studies, it is clear that coherent psychological discourse serves a didactic function for children, supporting and nurturing their developing psychological understanding from early childhood to at least 6 years of age (Harris, de Rosnay, & Pons, 2005; Ruffman et al., 2002). Such conversational interactions occur more often when caregivers are attuned to the child's psychological perspective. Note that these findings are consistent with twin research indicating a large influence of the shared environment on children's understanding of mind and emotion (Hughes et al., 2005).

Conclusions

In this chapter we have examined several interrelated aspects of children's understanding of emotion: their ability to talk about emotions and to understand the way that past emotions can be reactivated; their sensitivity to key components of the appraisal processes that modulate a person's emotional response to a given situation, namely the person's desires, beliefs, and evaluation of their standing in relation to various norms and obligation; and individual differences in emotion understanding, their links with peer relationships, and the key role of family conversation in promoting children's understanding of emotion.

It is conceivable that children's developing understanding of emotion is simply an epiphenomenon of the underlying emotional process. According to this perspective, the understanding of emotion operates at a "meta" level, sealed off from the underlying emotional process that is its subject matter. To take a concrete example, it is possible to assert that the child functions at two separate levels: on one level, there is the child's experience and display of negative feelings after a transgression; at a separate level, there is the child's capacity for attributing, reporting on, and ruminating about such negative feelings. Increased sophistication at this meta level might have few or no repercussions on processing at the former level.

Such a clear-cut separation between levels of processing might simplify our scientific analysis but it probably distorts some fundamental aspects of human emotion. It effectively predicts that a disruption or delay in the development of the understanding of emotion need have no repercussions on the basic emotional processes themselves. Yet, there are several reasons for thinking that such repercussions do exist. First, there is a therapeutic tradition suggesting that when intense emotional experiences are reworked in the context of communication and rumination, they have different sequelae from those that are not. Such reworking need not be in the context of discussion with a trained therapist—it can also occur in the context of a privately written narrative (Pennebaker, 1996). One plausible extrapolation of these findings is that the emotional lives of children who grow up in homes where there is open discussion of emotionally charged encounters will be different from those where such discussion does not occur. They are likely to be prompted to engage in the type of insightful thinking about the causes of their emotions that has been shown to be beneficial for adults' physical and mental health (Pennebaker, Barger, & Tiebout, 1989).

Second, children's capacity for rumination and communication about their emotions dramatically alters the contexts in which they can seek support and reassurance. Attachment theorists have emphasized the way that a caregiver may or may not provide reassurance at moments of distress. Typically, they have focused on those moments when the precipitating factor is fairly easy to discern: the toddler is unnerved by a stranger, distressed by the caregiver's absence, or fretful about the caregiver's imminent departure. In such cases, the toddler's emotion is likely to be expressed via facial, vocal, or bodily cues. However, the emotional horizon of the older child is much larger—he or she can be fearful or distressed about events that might happen in the future or happened in the past. In these cases, signs of distress or worry can be overlooked by caregivers so that children who can articulate their emotional state are better placed to receive reassurance and engage in the kind of causal thinking that has been shown to be helpful for adults (Pennebaker et al., 1989).

Finally, it is likely that children's ability to understand and predict their own emotions affects their decisions about how to act. In its turn, the course of action that they choose will lead to—or avoid—emotionally charged consequences. One example of such self-regulation was discussed earlier. The ability to anticipate negative feelings can serve as a warning signal when a transgression is contemplated (Lake et al., 1995). That warning signal is sufficient to help children to resist temptation and forestall subsequent regret. It is also not difficult to imagine feedback loops in which anticipated emotion can play a disruptive role. Children's ability to anticipate their anxiety (e.g., when facing difficult problems in mathematics) is likely to further undermine their performance unless they are helped to reframe their feelings in a more positive fashion (Maloney & Beilock, 2012). Stated in more general terms, children's insight into their emotional lives does not simply enable them to foresee the inevitable; it also enables them to choose particular actions—actions that have consequences for what they feel.

CHAPTER 17

The Development of Children's Concepts of Emotion

Sherri C. Widen

Imagine a person who has just unexpectedly encountered a snake in the grass: Her eyes widen, she gasps, screams, and runs away. If a young child witnessed this encounter and said the person was *angry*, how should we interpret that response? Is the child wrong or does this response represent the child's current level of emotion concept development? The answer to these questions impact both developmental and emotion psychology. It is also important for parents, teachers, and others who work with children: Children's emotion concepts are related to their empathy and other aspects of emotional intelligence (see Emotional Intelligence, Chapter 30, this volume; Izard et al., 2001), cognitive and linguistic development (Blair, 2002), school readiness (Garner & Waajid, 2008), moral and prosocial understanding (Knafo, Steinberg, & Goldner, 2011), and intervention and therapy assessments (Southam-Gerow & Kendall, 2002). Saying that the child's response in the above example is wrong reflects a different approach to emotion from saying that the child's response represents his or her current level of concept development. This chapter compares these two approaches and the available evidence for each.

The Conceptual Approach: Broad-to-Differentiated Hypothesis

The field of research on emotion has been missing a theory that explains how children's concepts of emotion develop. Based on the basic emotions perspective, a common assumption is that children's concepts of emotion are built on an earlier understanding of facial expressions in terms of specific, discrete emotions (Denham, 1998; Harris, 1993; Izard, 1971, 1994). Indeed, researchers have proposed that, by 6 months of age, infants both produce and recognize facial expressions of basic-level emotions (Haviland & Lelwica, 1987; Walker-Andrews, 2005). In this view, facial expressions are assumed to signal specific emotions that are universally, easily, and perhaps innately recognized (Izard, 1994; Shariff & Tracy, 2011). Facial expressions provide the basis for children's acquisition of other aspects of emotion concepts (causes, consequences, and labels; Denham, 1998; Harris, 1993). Exactly how emotion concepts might be built on a prior understanding of facial expressions has never been described. No specific developmental account has been laid out.

In this chapter, I argue that the evidence is better described by what I call the broad-to-differentiated hypothesis (Widen, 2013). In this data-driven account, emotion concepts are acquired gradually and change over the course of childhood until they approximate the adult taxonomy.[1] Children's initial emotion concepts are broad and valence based (perhaps best described as *feels good* and *feels bad*). Children gradually differentiate within these broad initial concepts by linking the components (e.g., causes, consequences, facial expressions, vocalizations, behaviors) of each specific emotion. This process results in more discrete and complex concepts. Eventually, over the span of several years, the adult taxonomy is acquired. The central question is: What is the basis of this differentiation?

The development of children's emotion concepts is more complex than traditionally assumed. On the broad-to-differentiated view, children's (toddlers through middle childhood) initial valence-based concepts only gradually narrow and come to resemble adult concepts through a process of differentiation. This process of differentiation occurs as children begin to link the different components (e.g., cause, behavior, consequence) of an emotion concept together, which may take several years for some emotions. The basis of these concepts is not the same component for all emotion concepts; instead, it may be different components for different emotions (e.g., threatening behaviors for anger; causes, such as getting what you want, for happiness). Facial expressions are one of the components that are differentiated but are not primary in the process.

Children do not innately or easily understand facial expressions in terms of specific, discrete emotions. Instead, children more easily interpret facial expressions in terms of valence (feels good, feels bad), level of arousal, and other physical information (e.g., gaze direction, whether the person is pouting, gasping; Carroll & Russell, 1996). Attributing a specific emotion to a facial expression alone is possible, but this is a more difficult task. Other components of emotion concepts provide stronger cues to specific emotions. Thus, for most emotions, children more easily attribute a specific emotion to one of these other components than to a facial expression.

Children use all available information to determine how another feels. In a typical situation, "all available information" may include the facial movements, but also the cause, consequence, posture, vocalization, and so on. In laboratory studies, the information also includes the implicit instructions in the task (e.g., forced choice studies provide a short list that limit the emotions that may be attributed; see Widen & Russell, 2015) and so on. Thus, for the child, determining how another feels is a puzzle to solve using the available information. The puzzle's solution varies as the parts of the puzzle vary. As a result, the same facial expression may be interpreted as different emotions in different situations. Adults' interpretation of facial expressions are also influenced by the other parts of the puzzle (Aviezer et al., 2008; Hassin, Aviezer, & Bentin, 2013; Mondloch, 2012; Mondloch, Horner, & Mian, 2013).

Vocabulary and Cognitive Prerequisites

Around 13 months of age, infants begin using words; around 20 months, children begin using emotion words (Bretherton, Fritz, Zahn-Waxler, & Ridgeway, 1986). Children's use of emotion labels in spontaneous conversation follows a developmental progression (Smiley & Huttenlocher, 1989). Initially, children refer to their own emotions. Around 24 months, they also refer to the emotions of others (see Understanding Emotion, Chapter 16, this volume). By 3 years, children's spontaneous conversation suggests that they understand that emotions are internal feelings, distinct from their causes and consequences (Wellman, Harris, Banerjee, & Sinclair, 1995; see also Chapter 16, this volume).

In more structured research contexts, there is evidence of the development of young children's emotion concepts. By 3 years of age, children can both label and generate a cause for some emotions (Balconi & Carrera, 2007; Reichenbach & Masters, 1983; Russell & Widen, 2002a, 2002b; Widen & Russell, 2002, 2004, 2010a, 2010b). They can also give the expected label for happiness, sadness, and anger expressions (Camras & Allison, 1985; Denham & Couchoud, 1990; Harrigan, 1984; Widen & Russell, 2003, 2008c). Thus, by 3 years of age, the linguistic and cognitive prerequisites are in place for children to differentiate emotion concepts and to begin linking the components of a concept. (See Blankson et al., 2013; Porges, 2003; Posner & Rothbart, 2007, for perspectives on the connections between cognitive development and emotion understanding.)

Development of Emotion Concepts

Valence-Based Discrimination

Studies with infants and toddlers demonstrate that emotion concepts are initially valence based. Before the age of 10 months, infants make appropriate emotional and behavioral responses to positive and negative facial expressions (Caron, Caron, & Myers, 1985; Haviland & Lelwica, 1987) but do not respond differently to discrete negative emotions. In the social referencing paradigm, infants 10 months of age and older can use the valence of the caregiver's facial expressions to guide their own behavior (e.g., Klinnert, Emde, Butterfield, & Campos, 1986). When shown a positive expression, infants approach, and when shown a negative one, they withdraw. But, such studies rarely compare different negative expressions and thus do not provide evidence that infants can either discriminate or recognize specific emotions from facial expressions.

Two-year-olds have begun to use emotion labels such as "happy" and "mad," but their understanding of these labels is systematically different from adults'. For example, these children may label a number of different faces as "angry," but their label use is not random. Instead, responses that are incorrect by adult standards prove to be systematic: Children are more likely to use "angry" for expressions that have the same valence and similar levels of arousal (e.g., the disgust and sad expressions) than for expressions that are dissimilar on these dimensions (happiness expression). The unbiased hit rate (Wagner, 1992), which accounts for response biases, can be revealing of what label use may represent. The unbiased hit rate was applied to 2-year-olds' (aggregated from five studies, N = 94; Widen & Russell, 2003, 2008a, 2010a, 2010b) use of angry for each of six facial expressions. They used angry at above chance levels for the anger, sadness, and disgust expressions but did not do so for the fear, surprise, or happiness expressions.

Valence-based categories also emerge when children are not asked to produce any labels. For example, on a categorization task, the emotion category was presented as a box into which only people who felt a particular emotion could go (Russell & Widen, 2002a). Children decided whether each facial expression should go in the box or out. This task had low verbal demands—the child could respond by pointing—and children understood the task. Yet, children's responses revealed that they did not have a discrete concept of anger. Instead, when asked to include only the angry people, 2-year-olds were as likely to include the sadness, fear, and disgust expressions as the anger ones, but they excluded the happiness expressions. Two-year-olds show the same pattern when asked to select the angry faces in an array of facial expressions: They were equally likely to select all the negative expressions but unlikely to select the happy ones (Bullock & Russell, 1985). Thus, across tasks, 2-year-olds have broad, valence-based emotion concepts.

A question that has not yet been empirically addressed is how these young children differentiate facial expressions. On what basis do children who include all the negative facial expressions in the angry category decide which facial expressions to include (Bullock & Russell, 1985; Russell & Widen, 2002a)? Perhaps children attend to the full configuration of the facial expression or to a specific feature (such as the brow furrow, or lack of smile) common to these varied negative expressions.

Differentiation: From Broad to Differentiated Concepts

In this section, evidence related to children's understanding of facial expressions is explored to compare the basic emotions perspective and the broad-to-differentiated hypothesis. Then, the process of differentiation from children's initial valence-based concepts to more adult-like specific concepts is addressed.

"Correct" and "Incorrect" Responses

Gradually, older children's interpretation of faces becomes more discrete (e.g., Denham & Couchoud, 1990; Massarani, Gosselin, Montembeault, Gagnon, & Suurland, 2011; Vicari, Reilly, Pasqualetti, Vizzotto, & Caltagirone, 2000) as their concepts come to resemble adults'. To illustrate this gradual change, data from 11 studies in which children freely labeled facial expressions (Widen, Pochedly, & Russell, 2013; Widen & Russell, 2002, 2003, Study 2, Study 3, 2008a, 2008b, 2010a, 2010b, Study 1, Study 2, 2010c, 2013b) were aggregated. As shown in Figure 17.1, children used the expected label at an early age for happiness, sadness, and anger expressions; children's use of the expected label increased only gradually for surprise, fear, and disgust expressions. As illustrated in Table 17.1, other researchers find the same general pattern with the free-labeling task (Bisson, 2013; Harrigan, 1984; Markham & Adams, 1992; Markham & Wang, 1996; Michalson & Lewis, 1995; Nelson, Hudspeth, & Russell, 2013; Vicari et al., 2000).

Although young preschoolers label some facial expressions "correctly," just what that correctness represents is a big question. The basic emotions perspective assumes that young children recognize the angry face as *angry*, the scared face as *scared*, and so on. This recognition has also been extended to infants, who are assumed to recognize facial expressions within the first half year of life (e.g., D'Entremont & Muir, 1999; Haviland & Lelwica, 1987; Izard, 1971; Walker-Andrews, 2005). According to Izard (1994), "Infants discriminate between positive and negative expressions by about 3 months and among negative expressions by 6 or

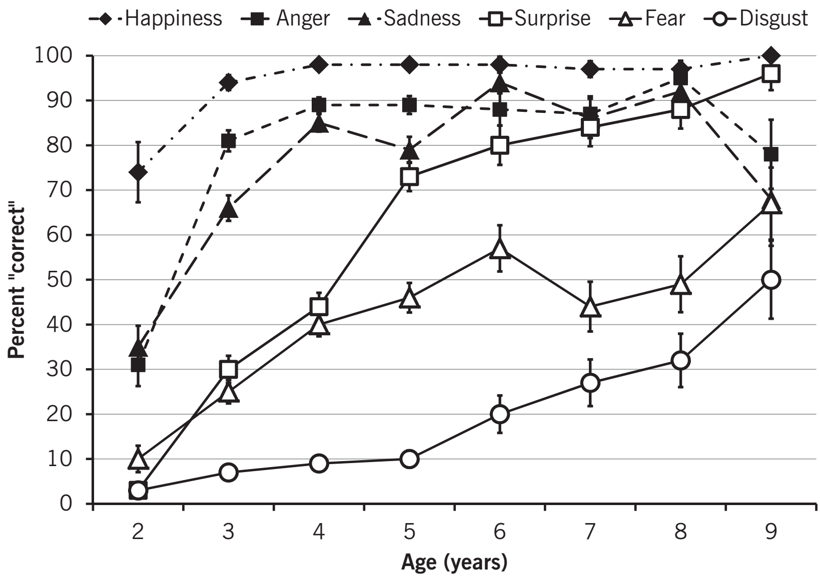

FIGURE 17.1. Children used the expected ("correct") labels (with standard errors) for the happiness, anger, and sadness expressions from an early age but for each of the other facial expressions use of the "correct" label increased gradually with age. Data from 11 studies were aggregated (Widen et al., 2013; Widen & Russell, 2002, 2003, Study 2, Study 3, 2008a, 2008b, 2010a, 2010b, Study 1, Study 2, 2010c, 2012b). The sample sizes for each age group were 2 years (n = 94), 3 years (*n* = 229), 4 years (*n* = 299), 5 years (*n* = 209), 6 years (*n* = 74), 7 years (*n* = 66), 8 years (*n* = 61), 9 years (*n* = 33).

7 months" (p. 292). And, it has also been proposed that "prior to the onset of language, the primary means by which infants can communicate with others in their environment, including caregivers, is by 'reading' faces" (Leppanen & Nelson, 2006, p. 38)—that is, by recognizing another's identity and emotions. The assumption that recognition is in place early is consistent with the assumption that facial expressions evolved to express specific, discrete emotions.

Alternatively, "correctness" in children 3 years and older may represent a different understanding of emotion than it does in adults, that is, young children's emotion concepts are systematically different from adults (Widen & Russell, 2003, 2008a, 2010a, 2010b). As children gradually begin to differentiate the negative concept into discrete negative emotions (e.g., Denham & Couchoud, 1990; Izard, 1971; Massarani et al., 2011; Roberson, Kikutani, Doge, Whitaker, & Majid, 2012; Vicari et al., 2000), one challenge is to determine how to analyze their responses.

Participants—both adults and children—tend to use some emotion terms more than others (Wagner, 1992). When children (2–10 years) were asked to freely label facial expressions or emotion stories, they used "happy," "sad," and "angry" most frequently, both "correctly" and "incorrectly" (Massarani et al., 2011; Widen & Russell, 2003, 2008a, 2010b, 2011). Thus, the high percentage of "correct" responses for the happiness, sadness, and anger expressions becomes suspect, especially for the younger children whose implicit definition of these labels is broadest and who are least likely to use other emotion labels. How many of these responses were genuinely correct, and how many were a happy accident of children's tendency to use these labels more frequently? Conversely, children used "scared," "surprised," and "disgusted" correctly less frequently but were unlikely to use these labels incorrectly. Use of the unbiased hit rate (Wagner, 1992) can ameliorate these response biases.

Focusing only on children's correct responses omits a large percentage of their responses, especially for fear, surprise, and disgust facial stimuli—and for other emotions such as embarrassment, shame, pride, and so on. Children are not silent when they do not give the expected response. For example, in one study, all of the children's (2–5 years) incorrect responses on a free-labeling task were coded as feeling versus nonfeeling words (Widen & Russell, 2008a): 75% were feeling words

TABLE 17.1. Percentages of Children Who "Correctly" Free Labeled Each of Six Basic-Level Facial Expressions in Nine Datasets

Study	Ages in years (*n*)	Facial expression					
		Happiness	Sadness	Anger	Fear	Surprise	Disgust
Harrigan (1984)	3–12 (96)	94	83	78	59	39	46

Note. The task given the children was free labeling photographs of facial expressions.

[a]Australian sample.

[b]French Canadian sample, tested in French.

[c]Widen and Russell (2013b) is a database of 11 free labeling studies from our lab: Widen et al. (2013); Widen and Russell (2002, 2003, Study 2, Study 3, 2008a, 2008b, 2010a, 2010b, Study 1, Study 2, 2010c, 2012b).

that were incorrect for the target category. Ignoring incorrect responses also implicitly assumes the basic emotion perspective that facial expressions signal specific emotions and are easily, universally, and perhaps even innately, recognized. In dismissing children's "errors," the opportunity to explore and observe the development of their emotion concepts is missed.

There are other response formats that can be used to measure children's understanding of facial expressions. One of the most commonly used is choice from array (Bullock & Russell, 1984, 1985; Harrigan, 1984; Izard, 1971; Michalson & Lewis, 1995; Nelson & Russell, 2016; Widen & Naab, 2012; Widen & Russell, 2008b). In the choice-from-array task, children are given a label and asked to select the matching expression from an array of facial expressions. Thus, this task has no production demands and children are provided with both the label and the facial expressions. Indeed, studies that compared free labeling and choice from array have found that children are more likely to associate the emotion label with the target facial expression in choice from array than free labeling (Harrigan, 1984; Izard, 1971; Michalson & Lewis, 1995).

Unfortunately, choice from array suffers substantive problems. First, the choice-from-array task lacks face validity. Children are given a concept and asked to find a matching face. In their daily lives, it is unlikely that children seek out people who look sad or scared. Thus, tasks like free labeling ask the more important question of how children interpret an expression when they see it. Second, children can solve this task through a process of elimination. Asked to find the person who is scared, children who can reliably label the happiness, sadness, and anger faces can readily rule these faces out of the array, and they likely also associate the disgust face with anger (see Widen, 2013; Widen & Russell, 2015). Thus, children are left with only the fear and surprise faces to decide between—assuming all six faces are presented in the array. Indeed, children's performance increases as the size of the array decreases (Widen & Russell, 2013a), supporting the suggestion that they are using a process of elimination. Further evidence comes from a series of studies in which children (2–10 years) matched a nonsense emotion label to a nonsense facial expression in an array (Nelson & Russell, 2016). Children's performance for the nonsense label and face was as high as it was for the "real" emotions in the array. The nonsense match could only have been made through a process of elimination. This finding raises questions about children's performance on choice from array in general.

Differentiation of Emotion Concepts

Children's emotion concepts and their understanding of various emotion cues (facial expressions, emotion stories, labels, etc.) gradually undergo a differentiation process and their initial broad concepts become more discrete and adult-like. Only by examining all of children's responses—both correct and incorrect—did the systematic nature of this process become evident. This broad-to-differentiated pattern accounts for at least 80% of children in each sample, both for different cues to emotion and on different tasks (Widen & Russell, 2003, 2008a, 2010a, 2010b).

The differentiation pattern for how children label facial expressions was originally based on data from three studies (Widen & Russell, 2003). Here, the pattern is illustrated with the aggregated data from 10 studies and 1,050 children (2–9 years; Widen & Russell, 2002, 2003, 2008a, 2008b, 2010b, 2010c, 2015). On the free-labeling task, children at Labeling Level 0 (n = 32) use no emotion labels. Children at Labeling Level 1 (n = 15) use only one label ("happy"). Children at Labeling Level 2 (n = 58) use two labels, adding either "angry" or "sad." Children at Labeling Level 3 (n = 141) use all three labels ("happy," "sad," and "angry"). Children at Labeling Level 4 (n = 327) add "scared" or "surprised." Children at Labeling Level 5 (n = 191) use all five labels ("happy," "sad," "angry," "scared," and "surprised"). Children at Labeling Level 6 (n = 92) add "disgusted" and use all six target labels. Of the 1,050 children in this aggregated sample, 82% used one of these combinations. Age increased from a mean of 2 years, 6 months, at Labeling Level 0 to 6 years, 2 months, at Labeling Level 6. This pattern has also been supported in French Canadian children who were tested in French (Massarani et al., 2011).

Regardless of how few or how many emotion concepts/labels children have, they use them to account for the entire emotion domain. For example, at Labeling Level 2, children's only negative emotion label is "angry" (or "sad"), but children's implicit definition of the label is different from adults' and includes all negative emotions. Young preschoolers' (2–4 years, N = 148; Widen & Russell, 2010b) differentiation of this negative emotion concept beginning at Labeling Level 2 is shown in Figure 17.2. At this labeling level, children's modal label for all four negative facial expressions was "angry" (Figure 17.2A). For these children, the implicit definition of angry was broad and may be closer to feels bad. At Labeling Level 3, children are a little older, have more experience, and differentiate the broad negative concept into two. Now, angry is narrower and is used for the anger and disgust faces, and sad is used for the sadness and fear faces. Children's implicit definitions of angry and sad are still broader than adults'. At Labeling Level 4, sad becomes narrower and is used modally only for the sadness face, and scared is used for the fear face. (Surprise stimuli were not used in this study, so there was no Labeling Level 5.) At Labeling Level 6, disgusted is also added, though infrequently in this age range. As

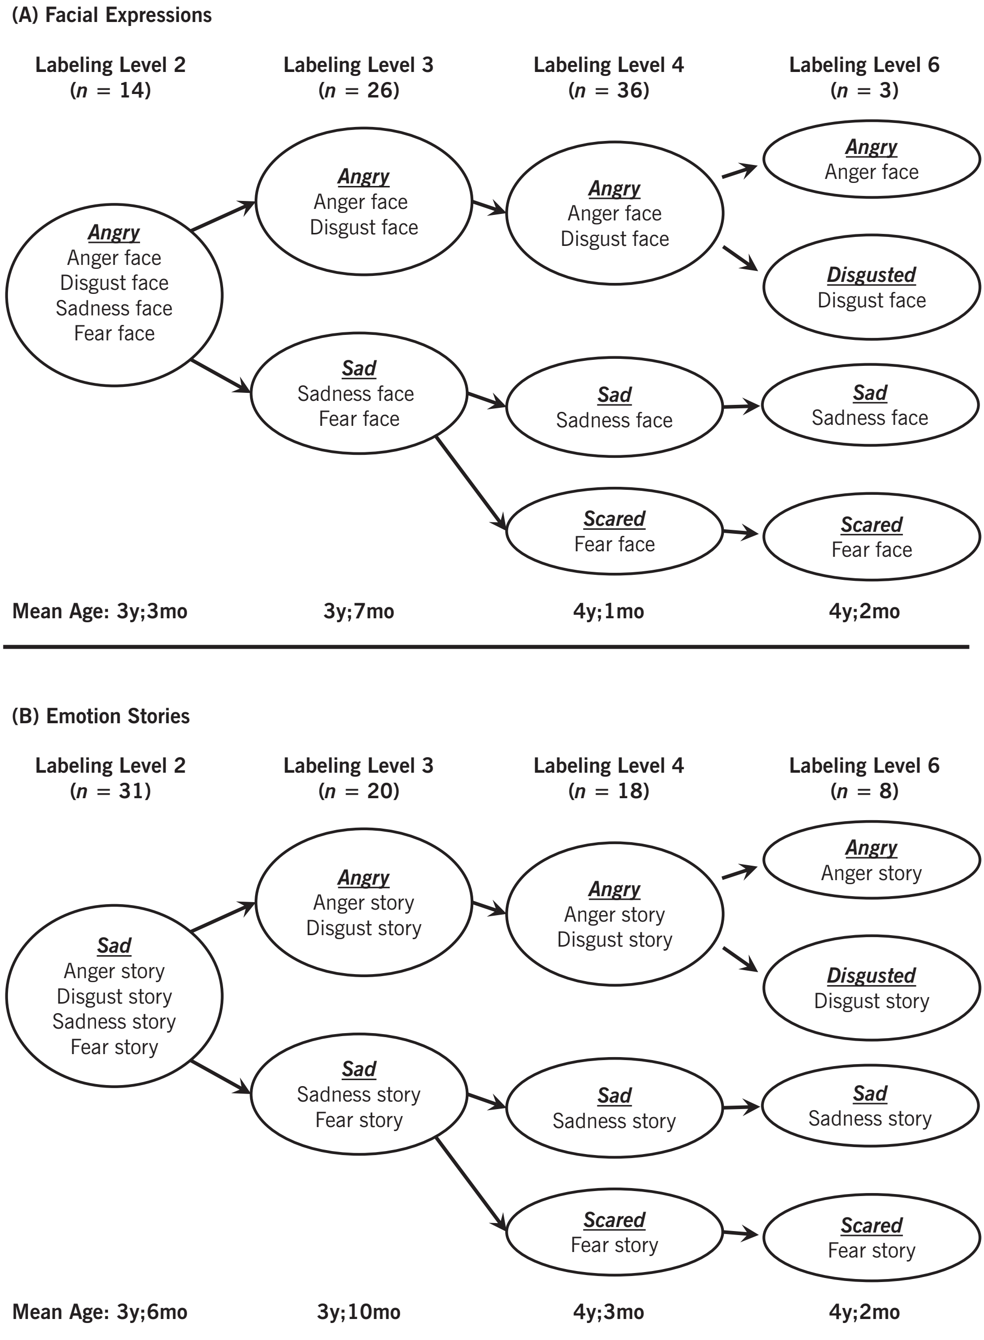

FIGURE 17.2. Differentiation of the broad negative emotion concept beginning at Labeling Level 2. The modal label that was used for each (A) face or (B) story at each labeling level. Data were aggregated from two studies (Widen & Russell, 2010b, Study 1, Study 2) that included 148 children between the ages of 2 and 4 years. There were no surprise facial expressions or stories in these studies so there was no Labeling Level 5.

additional concepts and labels are acquired, children's implicit definitions of angry and sad become narrower, gradually coming to resemble the adult definitions. Although children's use of "angry," "sad," and "scared"—and by corollary, their corresponding concepts—appear discrete around the age of 50 months in Figure 17.2A, this appearance is an artifact of the set of facial expressions that were tested. When a wider array of facial expressions were tested, older children (up to 10 years) used "angry" modally for contempt and disgust faces and "sad" modally for embarrassment and compassionate faces (Widen & Russell, 2010a). This pattern of differentiation also occurs in French Canadian children (5–10 years) who freely labeled basic-level facial expressions (Massarani et al., 2011). Palestinian children show the broad-to-differentiated pattern although their emotion concepts narrow at a later age than do American children's (Kayyal, Widen, & Russell, 2013).

The broad-to-differentiated pattern was first identified in children's free-labeling responses to facial expressions, but it also occurs with other stimuli. Children's differentiation of both facial expressions and brief emotion stories (each describing the cause and behavioral consequence of an emotion) shows the same pattern but also some differences (Russell & Widen, 2002b; Widen & Russell, 2010b). One difference was the modal label at Labeling Level 2: For negative facial expressions, it was "angry" (Figure 17.2A). As Figure 17.2B illustrates, for negative emotion stories, it was "sad." After Labeling Level 2, the differentiation pattern for this set of faces and stories was the same. A second difference was the average age at the lower labeling levels: On average, children were 2–3 months older for stories than for facial expressions at Labeling Levels 2, 3, and 4 (see Figure 17.2). However, when older children (4–10 years) were tested with a wider array of emotions (basic-level emotions and contempt, embarrassment, compassion, and shame), children differentiated stories earlier than facial expressions (Widen & Russell, 2010a). Taken together, the evidence supports the broad-to-differentiated hypothesis: Children's emotion concepts are initially broad and valence based and narrow only gradually as children acquire additional emotion concepts and an adult-like taxonomy.

The Basis of Differentiation

Of course, an emotion concept is complex and includes more than a label, facial expression, and even a cause and consequence. An emotion concept can be thought of as a script (Fehr & Russell, 1984; Chapter 16, this volume; Lewis, 1989). A mature emotion script is composed of a list of component events linked in a temporal and causal order, including prototypical causes, facial expressions, vocalizations, behaviors, consequences, a label(s), subjective experience, and so on. For example, sadness is caused by a personally relevant loss and the associated behavior is crying. Observation of these components can also serve to identify an emotion in another.

How do children move from a two-concept, valence-based system to full scripts for differentiated specific emotion concepts? On the broad-to-differentiated hypothesis, each emotion concept develops gradually, as components are added individually. A concept does not emerge fully formed. For example, to differentiate fear from the broad negative emotion concept, children might begin by adding causal components related to threat or consequence components related to flight. (See Lewis, 1989, for a discussion of cultural differences in emotion scripts.)

No one component is the basis for all scripts. Rather, any component (cause, consequence, behavior, etc.) may be the basis of each script. The cues that are initially tied to the two early concepts (positive and negative) are unknown but may be identified empirically. The cues could be behaviors (laughing and clapping vs. yelling and hitting), facial expressions (smiling vs. not smiling), or a primitive theory of mind (when people get what they want, they feel good; when they don't get what they want, they feel bad), or another component. For example, referential understanding studies test infants' (9–18 months) understanding of the connection between a person's emotional displays and his or her intentions and desires. Infants looked longer when a person's behavior did not match his or her emotional display (e.g., sadness, happiness; Barna & Legerstee, 2005; Phillips, Wellman, & Spelke, 2002). Another study showed that by 18 months, toddlers understood that someone's emotion (pleasure vs. disgust) indicated the food she preferred and wanted more of even when the toddlers themselves did not prefer that food (Repacholi & Gopnik, 1997). Theory-of-mind studies found that 2-year-olds could attribute emotions based on desire. They understood that "Bill who wants a bunny and finds one will be happy whereas Mary who wants a kitty and finds a bunny—the exact same bunny that Bill found—will be sad"; Wellman, 1995, p. 302).

They could not make parallel attributions based on beliefs. But each of these studies compared happiness and only one negative emotion. Thus, they do not speak to the question of if or when infants' and toddlers' specific, discrete emotion concepts begin to develop. They do provide some hints as to the components that may provide the bases of toddlers' positive and negative valence concepts.

One question is how children differentiate the broad negative emotion concept into multiple negative concepts (as illustrated in Figure 17.2). The basis of differentiation is unlikely to be the same component for all emotion concepts. By isolating the components of a script, those that children associate with specific emotions can be identified. Components children identify more strongly with a particular emotion are assumed to be those they acquired earlier.

The basic emotions perspective predicts that faces are the basis of children's emotion scripts. If so, children should associate the expected emotion with facial expressions earlier than with other components of emotion concepts. For example, on a storytelling task, 3- and 4-year-olds should be more likely to generate causes that adult judges recognize as the target emotion for facial expressions (e.g., fear face) than for labels (e.g., "scared") or consequences (e.g., "It made Danny scream. He ran away as fast as he could. Danny kept looking back to see if he was being followed. He just wanted to get home where he was safe"; Widen & Russell, 2004). Instead, an overall *face inferiority effect* was found: Children were least likely to generate recognizable causes for facial expressions. This effect was strongest for fear and disgust. The face inferiority effect is robust across a wide age range (3–10 years) and variety of tasks (generate causes, free labeling, categorization; Balconi & Carrera, 2007; Reichenbach & Masters, 1983; Russell & Widen, 2002a, 2002b; Widen & Russell, 2002, 2004, 2010a, 2010b).

One possible objection to findings of a face inferiority effect is that these studies used posed photographs. In daily experience, emotional expressions are dynamic. Thus, it has been proposed that children might be more likely to associate videos of dynamic expressions of emotion with expected labels than they do photographs (Caron et al., 1985; Eibl-Eibesfeldt, 1970; Flavell, 1985; Fogel, 1983; Vieillard & Guidetti, 2009). There are only four studies that have compared children's understanding of photographs and videos of emotion expressions (Leime, Neto, Alves, & Torro-Alves, 2013; Nelson et al., 2013; Nelson & Russell, 2011a, 2011b; Widen & Russell, 2015). None of these free-labeling studies found an overall advantage for videos over photographs. And two found that children were more likely to label the *photographs* of anger and disgust faces "correctly" than the corresponding videos (Nelson et al., 2013; Nelson & Russell, 2011b).

Tasks that compare children's understanding of emotion labels versus facial expressions have found a *label superiority effect*—children are more likely to give the expected response for the label than the facial expression (Bruce et al., 2000; Camras & Allison, 1985; Russell, 1990; Russell & Widen, 2002a, 2002b; Widen & Russell, 2004, 2010a). For example, children (4–10 years) freely labeled facial expressions and, separately, brief stories for anger, fear, surprise, disgust, compassion, embarrassment, shame, and contempt (Widen & Russell, 2010a). An overall label superiority effect was found, and this effect was also significant for five of the eight emotions (fear, disgust, compassion, embarrassment, and shame).

A strong label superiority effect has been found for disgust (Camras & Allison, 1985; Russell & Widen, 2002a, 2002b; Widen & Russell, 2004, 2010a; see Widen & Russell, 2013a, for a review of children's understanding disgust). Children are more likely to use "disgusted" (or a close synonym) for a disgust story than the corresponding facial expression. Indeed, the disgust face is one of the last components to be added to children's disgust concept; until then, they associate the disgust face with anger (Widen & Russell, 2013a). Once children have linked the facial expression to their disgust concept, as demonstrated in free labeling, they are also less likely to associate it with anger on other tasks (e.g., the box task; Widen & Russell, 2008a, 2008b). The label superiority effect supports research demonstrating the power of labels in children's acquisition of concepts more generally (Gelman, 2003; Gentner & Goldin-Meadow, 2003), the constitutive role of language in emotion perception (Lindquist, Barrett, Bliss-Moreau, & Russell, 2006; Lindquist & Gendron, 2013), and the differences in how languages and cultures divide the emotion domain (de Mendoza, Fernández-Dols, Parrott, & Carrera, 2010; Kayyal & Russell, 2013; Russell & Sato, 1995; Wierzbicka, 2009).

Conclusion

The central question of this chapter was how children's concepts of emotion develop. The evidence supports the broad-to-differentiated hypothesis: Children's emotion concepts undergo gradual development from broad, valence-based concepts to more specific, discrete concepts through a process of differentiation. Differentiation may begin when children notice that not all "feels bad" feelings are the same and is achieved by linking the components of an emotion concept together until children acquire the adult taxonomy—moving from feels bad to anger, fear, embarrassment, and so on, each with its own script. At all levels of development, children have a systematic way of interpreting the emotion domain, but acquiring adult-like emotion concepts is a years-long process.

At the outset, I observed the absence of a detailed theory of the development of children's concepts of emotion. Research that focuses only on children's "correct" responses in emotion tasks implicitly assumes that children's emotion concepts are the same as adults'. It also implicitly assumes that their "incorrect" responses are meaningless. I proposed an alternate approach—the broad-to-differentiated hypothesis—that describes the development of children's emotion concepts by analyzing both correct and incorrect responses and looked at how these responses change with age. Other alternatives are also possible and should be explored.

Acknowledgments

Thanks to Nicole Trauffer, Mary Kayyal, and Catalina Torrente for their feedback on an earlier version of this chapter.

Note

1. In their final adult form, emotion concepts vary as a function of language and culture (see Kayyal & Russell, 2013; de Mendoza, Fernández-Dols, Parrott, & Carrera, 2010; Mesquita & Frijda, 1992; Russell, 1991; Wierzbicka, 2009). However, this aspect of emotion concept development is not the focus of this chapter.

CHAPTER 18

Emotion and Aging

Mara Mather and Allison Ponzio

Emotions depend on a complex circuitry of brain regions interacting with neurotransmitter systems and stress and sex hormones. They are shaped by experience and current circumstances. Feedback loops and self-directed control mechanisms regulate emotions and help curtail how long they last and how intense they get. All of these basic mechanisms and contextual factors change in normal aging and so it is not surprising that emotional experience and processes change with age as well. The changes are not what one might initially predict, however. With aging come health challenges, physical declines, and the loss of friends and family because of illness and death. Furthermore, prefrontal control processes that help regulate behavior, attention, and memory deteriorate, which should make it more difficult to regulate negative emotion. Despite these constraints and challenges, emotional well-being does not tend to decline in normal aging. Why do older adults not revert back to the emotional intelligence of teenagers, a time when their frontal lobes were not yet functioning at full capacity? The surprising lack of decline in emotional function makes aging a fascinating test case for understanding the mechanisms of emotional well-being. In this chapter, we review some key issues regarding emotion and aging: How emotional well-being is maintained across the lifespan, how aging affects specific emotions, how emotions predict longevity, the age-related positivity effect in attention and memory, which aspects of emotion regulation processes are influenced by aging, changes in arousal and stress response processes during aging, interoceptive declines in aging, changes in recognizing the emotions of others, shifts in the causes of depression and anxiety, how dementia affects emotion, and potential cultural differences in emotion and aging.

Emotional Well-Being

As we review below, emotional functioning holds up remarkably well in normal aging. Given the limitations and biases of memory (e.g., Kennedy, Mather, & Carstensen, 2004; Levine & Safer, 2002; Redelmeier, Katz, & Kahneman, 2003), emotional well-being should ideally be assessed in the moment, with enough moments sampled over time to estimate an average. One landmark study used experience sampling methods to assess frequency and intensity of 19 emotions across a 1-week period in a representative sample of healthy adults, and repeated the assessment across three waves of data collection each 5 years apart (Carstensen et al., 2011). Emotional well-being was defined by subtracting the average frequency of negative emotions experienced from the average frequency of positive emotions experienced. At each wave, the balance of positive to negative emotional experience increased into the late 60s and then stopped increasing. The same pattern was seen within individuals who were assessed at multiple waves. In contrast, the intensity of experienced emotions did not vary based on age.

A similar age-related increase in ratios of positive to negative affect was found in a survey of over 300,000 people in the United States (Stone, Schwartz, Broderick, & Deaton, 2010). Respondents were asked, "Did you experience the following feelings during a lot of the day yesterday?" about enjoyment, happiness, stress, worry, anger, and sadness. From ages 50 to 70, positive emotions increased and negative emotions decreased with age. Before and after those ages, patterns differed across specific emotions, but the older cohorts overall had a higher positive-relative-to-negative emotional experience than the younger ones. Other studies in the United States show similar increases in emotional well-being with age (Charles, Reynolds, & Gatz, 2001; Gross et al., 1997; Mroczek & Kolarz, 1998). Such increases in emotional well-being across adulthood are intriguing. Even with aging-related hardships, older adults generally are satisfied with old age and experience relatively high levels of emotional well-being and decreases in negative affect (Grühn, Smith, & Baltes, 2005).

Specific Emotions

In the following sections, we move from general well-being to focus on the trajectories of some specific emotions—namely, happiness, anger, sadness, and regret.

Happiness

When he drafted the U.S. Declaration of Independence, Thomas Jefferson wrote that all men have the right to life, liberty, and the pursuit of happiness (Boyd, 1950). After mostly neglecting the topic, in recent years both economists and psychologists developed a stronger appreciation of the importance of happiness (e.g., Frey & Stutzer, 2010; Seligman, 2012). Happiness predicts success in many domains (Lyubomirsky, King, & Diener, 2005) and can help people develop resilience to challenging and shifting circumstances (Cohn, Fredrickson, Brown, Mikels, & Conway, 2009).

A widespread belief is that people become less happy as they get older—but this belief conflicts with happiness self-reports. For instance, in one study, both younger and older adults estimated significant decline in happiness with age, although in fact the younger group was less happy than the older group (Figure 18.1; Lacey, Smith, & Ubel, 2006). In cross-sectional studies, happiness increases with age among cohorts in their mid-50s to mid-70s, then stabilizes or declines slightly in late life (Mroczek & Kolarz, 1998; Stone et al., 2010).

One question is how much happiness declines in very late life (after age 85). One perspective is that although things look good for the "young old" (in Western cultures, this often refers to those in their 60s and 70s), things are so bleak among the oldest old that "living longer seems to be a major

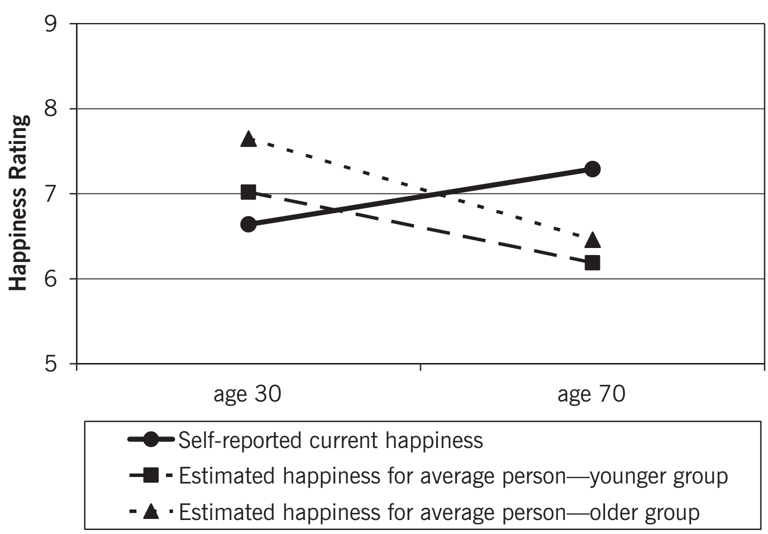

FIGURE 18.1. Current happiness self-reports versus happiness estimates for the average person, for ages 30 and 70. From Lacey, Smith, and Ubel (2006). Copyright 2006 by. Reprinted by permission.

risk factor for human dignity" (Baltes & Smith, 2003, p. 128). Baltes and Smith argue that aspects of emotion and well-being that show no decline in the young old show prominent decline among the oldest old. Part of their pessimism about this phase in life is that Alzheimer's disease is common among the oldest old. They state, "It may be a sad commentary, but dying before reaching the oldest ages is currently the only way to avoid succumbing to Alzheimer-type dementia!" (p. 129).

Indeed, in the face of physical dysfunction (e.g., dementia or other age-related chronic disease), it is natural to expect dramatic increases in depression. Yet, counter to this expectation, a population-based sample of German centenarians indicated as much happiness as representative middle-age and older Germans (Jopp & Rott, 2006). This counters the notion that happiness declines precipitously in the oldest old and is a striking finding given that 80% of the centenarians surveyed needed nursing care.

Anger

In contrast with happiness, anger can be hazardous to one's health (Suinn, 2001; Williams, 2012). Anger is especially likely to trigger and exacerbate cardiovascular disease, the leading cause of death in the United States (Heidenreich et al., 2011). People who generally have poor anger control are more likely to develop cardiovascular disease in the next 10–15 years (Haukkala, Konttinen, Laatikainen, Kawachi, & Uutela, 2010) and outbursts of anger increase the likelihood of an acute cardiovascular event in the next 2 hours (Mostofsky, Penner, & Mittleman, 2014).

The frequency of self-reported anger increases during young adulthood but then decreases steadily until old age (Kunzmann, Richter, & Schmukle, 2013; Kunzmann & Thomas, 2014; Stone et al., 2010). When specifically asked about interpersonal tensions, older adults report experiencing less anger and using more loyalty strategies such as doing nothing and fewer anger exit strategies, such as yelling, than younger adults (Birditt & Fingerman, 2003, 2005; Birditt, Fingerman, & Almeida, 2005; Blanchard-Fields & Coats, 2008). More generally, in representative samples in both the United States and Japan, there was stability in positive interactions and decreases in negative interactions in close relationships (Akiyama, Antonucci, Takahashi, & Langfahl, 2003).

Older adults also respond to triggers with less anger than younger adults in laboratory studies. When confronted with a recorded conversation of two people ostensibly talking about them, older adults reported less anger but equal levels of sadness compared with younger adults, and their comments seemed less negative to raters (Charles & Carstensen, 2008). Compared with younger adults, older adults showed decreased visual cortex-evoked potentials in response to angry but not to sad or happy faces (Mienaltowski, Corballis, Blanchard-Fields, Parks, & Hilimire, 2011), a finding that may relate to older adults interpreting a protagonist in a videotape as less angry than younger adults do (Charles, Carstensen, & McFall, 2001). These decreases in anger as people age may be critical for survival, given that anger increases the risk of cardiovascular events and that rates of cardiovascular disease are so high among older adults (among people free of cardiovascular disease at age 50, the lifetime risk to develop it was 52% for men and 39% for women; Lloyd-Jones et al., 2010).

Sadness

Losses trigger sadness (Bowlby, 1998). Losing a loved one is the most obvious example, but loss of social roles, places, or things can all lead to sadness. Older adults tend to have older peer groups and spouses, making them susceptible to loss of close loved ones. They also have a lifetime of accumulated roles, familiar places, and things that are all at risk of loss, while they suffer age-related declines in some physical and mental abilities. And they are closer to the end of their own lives. Thus, among the biggest emotional challenges older adults face is how to cope with loss, both past and future, and these challenges seem likely to lead to increases in sadness.

Although some studies show increases in older age, others show no change in sadness. Self-reported everyday sadness shows an almost flat profile across age groups, with studies showing either no age differences (Kunzmann & Thomas, 2014), a midlife small bump that decreases in later life (Stone et al., 2010), or a flat profile across most of adulthood with an increase among those in their late 70s and 80s (Kunzmann et al., 2013). When reporting on emotional reactions to interpersonal conflict, participants show no significant age differences in reported sadness (Birditt & Fingerman, 2003). In the lab, there are no age differences in sadness elicited by conversations involving disparaging comments about the participant (Charles & Carstensen, 2008), or by a film clip about a boy mourning his father's death (Tsai, Levenson, & Carstensen, 2000), but older adults felt more sadness than younger adults after watching other film clips involving themes of death or Alzheimer's disease (Kunzmann & Gruhn, 2005; Seider, Shiota, Whalen, & Levenson, 2011).

Thus, while some (but not all) studies suggest that sadness is a more accessible emotion for older adults, there is less of an increase in sadness than might be expected given the losses associated with aging. This discrepancy between circumstances and reactions is particularly striking in a longitudinal study in which German participants ages 58–81 estimated perceived deficits in performance and losses in abilities and also rated how contented they were with themselves and their present functional state in the respective domains (Rothermund & Brandstädter, 2003). Perceived losses and deficits increased significantly with age, but contentment with performance did not decline.

Regret

Regret involves sadness or remorse over past acts. Having a longer life to look back on means that there are more things to regret and also potentially fewer opportunities to address the regrets via new behaviors. Surprisingly, given their longer lives and increased opportunities for regrets, older adults are less likely than younger adults to report regrets. For instance, nearly 4,000 Dutch and German adults 40–85 years old were asked to complete the sentence, "When looking back on my past life, I regret . . ." (Timmer, Westerhof, & Dittmann-Kohli, 2005); the likelihood of reporting nothing to regret increased with age. In addition, among 825 Swedish adults between 18 and 85 years old, self-reported frequency of regret decreased with age, along with the intensity and duration of everyday regrets (Västfjäll, Peters, & Bjälkebring, 2011; see also Bjälkebring, Västfjäll, & Johansson, 2013).

Even when regrets are induced in the laboratory as part of risky gamble choices and so younger and older adults have the same temporal distance from their choices, there are age differences in how much people focus on potential or past regrets. For instance, when asked why they made the choices they did in a risky gamble situation, older adults were more focused on receiving some positive reward and cared less about avoiding potential regret than younger adults (Mather, Mazar, Gorlick, Lighthall, & Ariely, 2012). In another study, feedback about missed chances on one risky-choice trial predicted risk-taking behavior on the next trial in healthy younger and depressed older adults (suggesting their choices were modulated by regret), but not in healthy older adults (Brassen, Gamer, Peters, Gluth, & Büchel, 2012). In addition, the healthy younger and depressed older adults showed decreased brain activity in reward-processing regions when shown their missed opportunities, whereas healthy older adults did not. In contrast, only the healthy older adults showed more anterior cingulate activation during presentation of missed opportunities relative to trials without a missed chance, potentially reflecting cognitive control efforts to disengage from regret.

An increased likelihood of resolving regrets among older adults was also seen in a study of 455 caregivers of terminally ill patients, when interviewed 6 months after their loved ones died (Torges, Stewart, & Nolen-Hoeksema, 2008). The likelihood the caregivers had resolved their regrets increased linearly with age, and regret resolution predicted lower depressive symptoms and higher well-being 18 months after their loved one's death.

The most effective strategies for defusing regrets may shift with age. In one study, older adults experienced less regret when they felt little control over the event, whereas younger adults felt less regret when they felt high levels of control (Wrosch & Heckhausen, 2002). The authors argued that low attributions of control could be an adaptive strategy when feeling that there is little time left for active attempts to change regrettable behavior. In another study, older adults' lower levels of regret were mediated both by postdecision reappraisal ("I try to reevaluate the decision") and by predecision avoidance ("Delay the decision"; Bjälkebring et al., 2013). Other studies also suggest older adults are more likely to avoid decisions to postpone negative affect and regret (Mather, 2006). Thus, research suggests that older adults use various strategies including decision avoidance as well as more cognitively engaging strategies to defuse regret and that, with decreasing time left in life to change regrettable things, older adults may be better off if they attribute less self-control to themselves about the things they regret.

Emotions Predict Longevity

People who experience relatively more positive than negative emotions in their everyday lives live longer (Carstensen et al., 2011; Diener & Chan, 2011). Subjective well-being consistently predicts longevity among those who are healthy, albeit with a weaker relationship with longevity among those suffering from a disease (Diener & Chan, 2011). For instance, positive emotional content in nuns' early life autobiographies predicted longevity six decades later (Danner, Snowdon, & Friesen, 2001). Likewise, baseball players who smiled authentically (moving muscles both around the mouth and eyes) in their photos in the 1952 *Baseball Register* were half as likely to die in any subsequent year compared with nonsmilers (Figure 18.2; Abel & Kruger, 2010).

In addition to predicting mortality, negative emotions are associated with physical health in late life. For instance, among older adults, higher levels of intense life regrets are associated with more cortisol secretion and health problems (Wrosch, Bauer, Miller, & Lupien, 2007).

One question the survival effects raise is how much the decrease in negative affect among older cohorts results from the happiest people surviving the longest. So far, no studies have tackled the question of how much of the variance in cohort comparison studies is related to survival effects. Longitudinal studies, however, show emotional well-being increases within individuals across adulthood (Carstensen, Pasupathi, Mayr, & Nesselroade, 2000; Carstensen et al., 2011; Charles, Reynolds, et al., 2001) indicating that it is not just a matter of all the people who are chronically unhappy dying off; instead, across the adult lifespan emotional experience tends to improve.

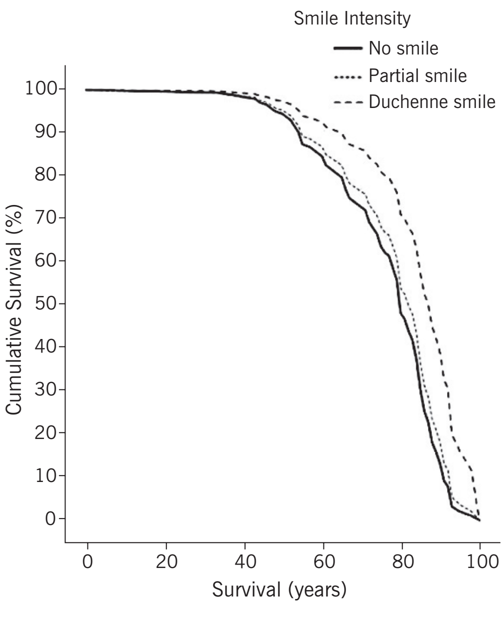

FIGURE 18.2. Percentage of Major League Baseball player's cumulative survival based on photographed smile intensity. The curves represent the probability of survival as predicted by a history of no smile in pictures, partial smile in pictures, or full (otherwise known as Duchenne) smile in pictures. From Abel and Kruger (2010). Copyright 2010 by. Reprinted by permission.

Another question these findings raise is: If negative emotions are associated with shorter and less healthy lives, why do we even have them? According to functionalist theories of emotion, all emotions have some adaptive benefits (Farb, Chapman, & Anderson, 2013; Keltner & Haidt, 1999; Levenson, 1999). For instance, sadness and depression can focus and enhance analysis of social problems and signal to partners the need to help or make concessions (Watson & Andrews, 2002). Depression also facilitates disengagement from unattainable goals (Wrosch & Miller, 2009). Anger, in contrast, promotes readiness to take action and persistence (Frijda, Kuipers, & ter Schure, 1989; Lench & Levine, 2008).

The adaptations of specific emotions may change with age. For instance, goal disengagement may play a more important role for older adults as they perceive diminishing opportunities to undo the consequences of their regrets (Wrosch, Bauer, & Scheier, 2005). Consistent with the idea that certain negative emotions may promote well-being most at certain life phases, the relationship between participants' negative emotions in response to a thematically ambiguous film and their subjective well-being depended on age, with anger responses associated with higher well-being for middle age but not younger or older adults, and sadness responses associated with higher well-being for older but not the other groups (Haase, Seider, Shiota, & Levenson, 2012).

Age-Related Positivity Effect

In the research reviewed thus far, a picture emerges of late life as a time of surprising emotional resilience, with well-maintained positive emotions and somewhat decreased negative emotions. It turns out that there is also an age-related positivity effect in attention and memory (Mather & Carstensen, 2005). For example, in one study where younger, middle-age, and older adults completed a recall test of positive negative and neutral pictures, the ratio of positive to negative images recalled increased with the age of the participant (Figure 18.3; Charles, Mather, & Carstensen, 2003).

Similar age-by-valence interactions have emerged in other studies as well. A meta-analysis of over 100 studies using both positive and negative stimuli and testing both younger and older participants found that, compared with younger adults, older adults were significantly more likely to favor positive over negative information in attention and memory (Reed, Chan, & Mikels, 2014).

What are the mechanisms underlying this striking pattern? One obvious possibility is that it is just a side effect of older adults being in a better mood and showing mood-congruent memory and attention. Current mood and negative emotion levels fail to account for the positivity effect, however (Charles et al., 2003; Kennedy et al., 2004; Mather & Carstensen, 2003; Mather & Knight, 2005). Given everything we know about the neural, cognitive, and physical declines associated with aging, another obvious explanation is that older adults' positivity effect is a serendipitous side effect of some sort of decline. For instance, perhaps the amygdala, a brain region attuned to negative potentially threatening information, declines more than other brain regions and so leads to this pattern (Cacioppo, Berntson, Bechara, Tranel, & Hawkley, 2011).

Contrary to this aging-brain model, however, older adults show intact threat detection advantages in visual search (Leclerc & Kensinger, 2008; Mather & Knight, 2006) and less structural decline in the amygdala than in most of the rest of the brain (Mather, in press; Nashiro, Sakaki, & Mather, 2012). And although older adults show less amygdala activity in response to negative stimuli than do younger adults, this does not seem to be due to decline but instead to what they are most attuned to, as they show more amygdala response to positive than to negative stimuli (Leclerc & Kensinger, 2011; Mather et al., 2004; Waldinger, Kensinger, & Schulz, 2011). Another problem for the decline story is that the positivity effect is stronger in older adults who do well on tests of cognitive control than in those who do poorly (Mather & Knight, 2005; Petrican, Moscovitch, & Schimmack, 2008) and emerges in visual search tasks that require controlled attentional processes, but not in those that require only automatic processes (Hahn, Carlson, Singer, & Gronlund, 2006). When presented with stimuli while engaged in a task that taps cognitive control resources, older adults no longer show a positivity effect (Knight et al., 2007; Mather & Knight, 2005). Thus, cognitive control mechanisms seem to promote older adults' positivity in attention and memory. Indeed, the effect size of the positivity effect is larger when participants are free to process stimuli as they choose

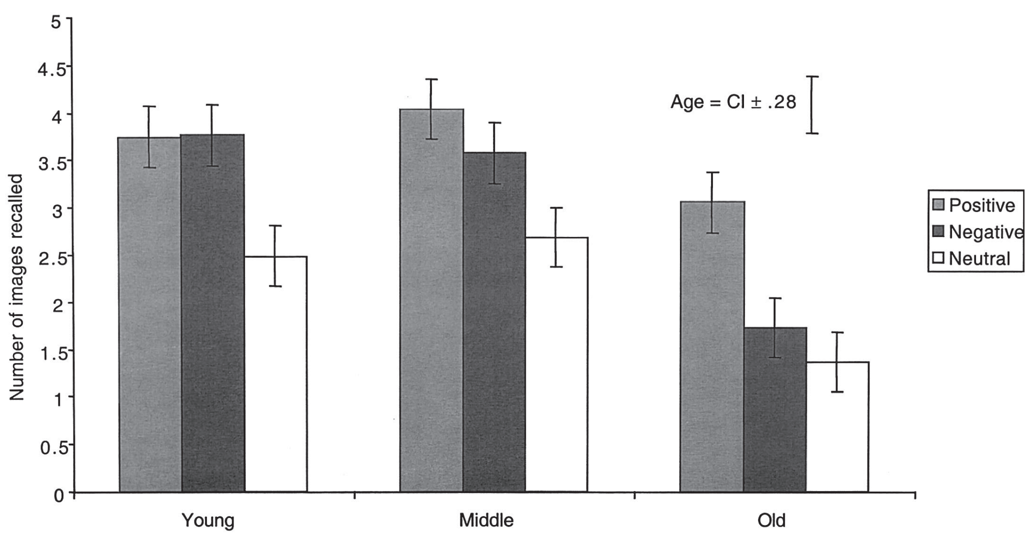

FIGURE 18.3. Number of positive, negative, and neutral images recalled for younger adults, middle-age adults, and older adults. From Charles, Mather, and Carstensen (2003). Copyright 2003 by. Reprinted by permission.

rather than being constrained by specific task instructions (Reed et al., 2014).

Furthermore, in functional magnetic resonance imaging studies older adults show more prefrontal activity while processing emotional than neutral stimuli, compared with younger adults (Mather, 2012), suggesting they are engaging prefrontal control processes to help guide the way they process emotional information. In particular, for older adults with strong positivity biases in attention, prefrontal control processes appear to downregulate amygdala responses to negative stimuli (Sakaki, Nga, & Mather, 2013). Likewise, anterior cingulate activation is related to a positivity bias and emotional stability in successful aging (Brassen, Gamer, & Buchel, 2011).

In summary, these findings reveal a surprising answer to the question of the mechanisms leading to older adults' positivity effect. Instead of being associated with age-related decline in brain regions that detect and respond to negative information, older adults' positivity effect is associated with prefrontal control mechanisms that help people direct their own attention and memory processes. This is not yet a complete answer, however. Cognitive control processes decline more than almost all other cognitive processes in normal aging, so why would older adults use these resources more than younger adults to guide their processing of emotional stimuli?

One potential answer is offered by a lifespan theory of how time perspective can influence motivation (Carstensen, Isaacowitz, & Charles, 1999). According to socioemotional selectivity theory, time horizons shape the ways in which people prioritize and set goals. When people view their time as expansive, they spend more time investing in their future, acquiring new knowledge, looking for novelty, and expanding their time horizons. Alternatively, when people view their time as being limited, they often direct their attention to more emotionally meaningful endeavors, including the desire to have emotionally fulfilling relationships and feeling socially connected (Carstensen, 2006). This more limited time perspective among older adults may account for their greater focus on regulating emotions, a better emotional well-being profile, and their positivity effect (Barber, Opitz, Martins, Sakaki, & Mather, in press; Carstensen, Mikels, & Mather, 2006; Reed & Carstensen, 2012). In addition, in terms of the question about how older adults could rely more than younger adults on cognitive control resources to direct attention and memory when processing emotional stimuli, insofar as older adults chronically focus more on emotion regulation goals than younger adults do, older adults should also recruit cognitive control processes more in the service of emotional goals than do younger adults, even if they have diminished cognitive control resources overall (Kryla-Lighthall & Mather, 2009).

Emotion Regulation

Given the findings covered so far about how the balance of positive to negative affect improves with age, an obvious assumption is that older adults get better at regulating their emotions. Consistent with this possibility, older adults give themselves higher ratings than younger adults in response to the question, "Overall, how much control would you say you have over your emotions?" (Gross et al., 1997). In addition, older adults are less likely to ruminate on negative emotions (McConatha & Huba, 1999). Life experience might also help people become expert emotion regulators (e.g., Blanchard-Fields, 2007), just as it seems to increase their social expertise (Hess & Kotter-Grühn, 2011). Yet laboratory studies that compare younger and older adults' performance when they are instructed to regulate in response to emotional stimuli reveal no consistent age advantages for either younger or older adults (see Mather, 2012, for a review). Instead, where age differences are more likely to emerge is in which regulation strategies people tend to use. Older people are more likely to report using suppression and less likely to report using reappraisal, rumination, and active coping than younger adults (Nolen-Hoeksema & Aldao, 2011; Marquez-Gonzalez, de Troconiz, Cerrato, & Baltar, 2008; but see John & Gross, 2004). Older adults also report prioritizing avoiding emotional situations more than do younger adults (Lawton, Kleban, Rajagopal, & Dean, 1992). This pattern of age differences is more challenging to investigate using laboratory methods, as what needs to be measured are people's habitual modes of processing rather than their skill at any one type of processing.

A recent framework explains why younger and older adults spontaneously select different strategies to regulate their emotions. The framework—selection, optimization, and compensation with emotion regulation (Urry & Gross, 2010)—follows previous theoretical thinking (Baltes & Baltes, 1990) that by sticking to three core tenets (selection, optimization, and compensation), successful living can be achieved at any stage of life. Selection requires an individual to assess his or her own realistic capabilities and make realistic goals. Optimization requires time, practice, and effort to achieve the set goals. And finally, compensation involves increasing effort or acquiring help to overcome losses. Applying these principles to emotion regulation strategies (Opitz, Gross, & Urry, 2012), available cognitive resources may influence strategy selection. Younger people may be more likely to use regulation strategies that require heavy cognitive control involvement, such as reappraisal. In contrast, older adults may rely more heavily on social support and situation selection (Sims & Carstensen, 2014).

Emotion and Physiology

Arousal

Common aging ailments like peripheral neuropathy and cataracts can impact arousal responses, including skin conductance and pupil dilation. As people age, their arteries become less plastic and cardiac muscles become weaker, resulting in greater peripheral resistance and poorer blood circulation efficiency (Lakatta, 1990). These changes in the cardiovascular system influence some psychophysiological measures of arousal, like blood pressure and heartbeat. Aging also causes changes in the electrodermal system, resulting in a decrease in the quantity of sweat glands, the amount of sweat produced (Porges & Fox, 1986), and the accuracy with which we may be able to measure skin conductance. Thus, not surprisingly, age-related decreases on measures such as heartbeat interval, skin conductance, respiration period, ear pulse transmission, and systolic blood pressure have been found in people's responses to emotional cues (Kunzmann, Kupperbusch, & Levenson, 2005; Levenson, Friesen, Ekman, & Carstensen, 1991; Tsai et al., 2000; but see Denburg, Buchanan, Tranel, & Adolphs, 2003; Neiss, Leigland, Carlson, & Janowsky, 2009, for studies finding no significant age differences for skin conductance).

In a longitudinal clinical–pathological cohort study, researchers found that a higher density of noradrenergic neurons in the locus coeruleus, a structure in the pons important for physiological responses to arousal, was predictive of a slower rate of cognitive decline (Wilson et al., 2013). This suggests that there is a relationship between the integrity of emotional arousal processes and cognitive performance during late life (Watson et al., 2006). One intriguing possibility is that, via noradrenaline's neuroprotective effects, experiencing novel, arousing events throughout life by having an engaging career and social life maintains brain function (and builds "cognitive reserve") even as neuropathology increases (Robertson, 2013).

Stress

Cortisol, a hormone responsible for stress regulation, on average shows a different diurnal rhythm in younger and older people. Although both younger and older people experience a peak (and subsequent slow decline) in the hormone after waking, older adults never reach the same lowest level as younger adults (Van Cauter, Leproult, & Kupfer, 1996). Since older adults never reach the same low cortisol levels achieved by younger adults, mean daily cortisol levels increase 20–50% from age 20 to 80 (Van Cauter et al., 1996; see also Nicolson, Storms, Ponds, & Sulon, 1997). In another study that examined subgroups, 50% of older adults in the sample maintained typical cycles, while most of the rest of the sample had daily cycles that varied substantially from day to day (Ice, Katz-Stein, Himes, & Kane, 2004). This indicates that, while day-to-day variation may increase, normal diurnal rhythms of cortisol can be maintained in late life.

Younger and older adults show similar cortisol responses to acute physical stressors such as holding a hand in ice water (Mather, Gorlick, & Lighthall, 2009; Lighthall, Gorlick, Schoeke, Frank, & Mather, 2013) and to the Trier Social Stress Test, an acute social stressors test (Kudielka, Buske-Kirschbaum, Hellhammer, & Kirschbaum, 2004; Rohleder, Kudielka, Hellhammer, Wolf, & Kirschbaum, 2002). One study, looking at adrenaline and noradrenaline (hormones responsible for the fight-or-flight response) effects on psychophysiological responses in older men, found that, after experiencing a psychosocial stressor, blood pressure and adrenaline levels increased steadily in both middle-age and older men, but were slower to return to normal levels in the older men (Faucheux, Bourliere, Baulon, & Dupuis, 1981). A meta-analysis that included studies using pharmacological challenges found that, on average, older adults (and especially women) showed greater cortisol responses to challenge (Otte et al., 2005). So, in general, older adults' cortisol response to acute stress is as strong or stronger than that of younger adults.

According to strength and vulnerability integration (SAVI) theory, in order to understand how age, stress, and affective experience interact, the context of daily life needs to be understood (Charles & Piazza, 2009; Charles, 2010). When older adults avoid or reduce exposure to emotional distress, they often respond better than younger adults. But when older adults experience high levels of sustained emotional arousal, age-related advantages in emotional well-being are diminished, and older adults have greater difficulties returning to homeostasis (see Charles & Luong, 2013, for a review). The theory claims that there are three instances that make people unable to avoid stressors or reduce exposure to caustic events: social isolation (see Ong, Rothstein, & Uchino, 2012), neurological dysregulation (see Kryla-Lighthall & Mather, 2009, for review), and exposure to chronic and unpredictable stressors and inevitable stressor overload (see Piazza, Charles, Stawski, & Almeida, 2013).

Interoception

Since the work of William James and Carl Lange (Lange & James, 1922), research in the field of emotion has recognized the key role of body sensations in emotion. Signals from brain regions that track body sensations such as heartbeats, breath, digestion processes, and skin flushing help shape our emotional experience (Barrett, Quigley, Bliss-Moreau, & Aronson, 2004; Critchley, Wiens, Rotshtein, Ohman, & Dolan, 2004; Damasio, 1999). With age, people are less able to detect visceral sensations such as gastric distension, rectal distension, esophageal pain, and their own heartbeat (Khalsa, Rudrauf, & Tranel, 2009; Lagier et al., 1999; Lasch, Castell, & Castell, 1997; Rayner, MacIntosh, Chapman, & Horowitz, 2000). The as-yet-unanswered question in the field is how these changes influence emotional experience and general well-being. Even just the simple question of whether these interoceptive sensation declines correlate with emotional experience has not been addressed and is an important question for future research.

Recognizing Others' Emotional Facial Expressions

Other people are the most likely trigger as well as object of emotions for almost all humans (Oatley, 2004). What would life be like if we could not detect the emotions of others? Without this skill, it would be much more challenging to fulfill social goals such as cooperating, forming a new relationship, showing affection, seeking help, deferring to others, and fighting. Emotions are conveyed in many ways, but faces are often the most specific and clear signal of emotions.

Recognition of some emotions is more impaired by aging than others (see Isaacowitz & Stanley, 2011; Ruffman, Henry, Livingstone, & Phillips, 2008, for reviews). Older adults are typically worse than younger adults at recognizing fear and sadness. They also sometimes are worse at recognizing angry expressions. They typically are as good as or better than younger adults, however, at recognizing disgusted expressions. Older adults also show age equivalence, smaller deficits, or even advantages in recognizing happy and surprised facial expressions.

Older adults' maintained ability to identify facial expressions of disgust is particularly striking because disgust is one of the emotions younger adults find most difficult to identify (Ruffman et al., 2008). Disgust recognition seems to depend in particular on the insula (Adolphs, Tranel, & Damasio, 2003; Calder, Keane, Manes, Antoun, & Young, 2000). Thus, one possibility is that the insula maintains its influence over face-processing networks more effectively with age than other brain regions that are more important for other types of facial emotions, such as the ventral striatum or amygdala (Adolphs et al., 2005; Calder, Keane, Lawrence, & Manes, 2004). For instance, while encoding fearful faces, younger adults showed more amygdala and hippocampal activation than older adults, while older adults showed more insular cortex and right superior frontal gyrus activity (Fischer, Nyberg, & Backman, 2010). Neither age difference was apparent during encoding of neutral faces. Likewise, another study found that older adults showed greater insula activity than younger adults during rating emotional expressions (Keightley, Chiew, Winocur, & Grady, 2007). Thus, shifts in the brain regions most likely to contribute to face processing may contribute to which types of facial expressions are most likely to be recognized.

Another possibility is that age-related shifts in which emotions are easiest to identify result from changes in which facial features are noticed most. When viewing faces, older adults fixate less on the eyes than younger adults do, and more on the mouth and nose (Firestone, Turk-Browne, & Ryan, 2007; Murphy & Isaacowitz, 2010; Sullivan, Ruffman, & Hutton, 2007; Wong, Cronin-Golomb, & Neargarder, 2005), especially when the faces have already been seen recently (Heisz & Ryan, 2011). In addition, older adults are less likely than younger adults to follow the eye gaze cues of younger adults (Slessor, Phillips, & Bull, 2008).

Clinical Issues

Depression

Contrary to common perception, rates of depression in older adults are lower than in younger adults (Blazer, 2003; Hasin, Goodwin, Stinson, & Grant, 2005). But older adults' symptoms of depression may be more harmful than younger adults' symptoms (Fiske, Wetherell, & Gatz, 2009). Depression at older ages is associated with decreased cognitive, physical, and social functioning; increased risk of morbidity; increased risk of suicide; increased self-neglect; and increased mortality (Blazer, 2003). Clinical presentation at old age is the sum of a lifetime of social, environmental, and physiological risk and protective factors (Fiske et al., 2009). Depression is also associated with increased frailty (Mezuk, Edwards, Lohman, Choi, & Lapane, 2012). Stressful life events have been associated with an increased risk of depression at all ages (Nolen-Hoeksema & Ahrens, 2002), though the types of events would likely differ for younger and older people. Precipitating events in later life include financial difficulties, a new illness or disability, a family member with a new illness or disability, retirement, or change in living situation (Fiske et al., 2009). Older adults who experience socioeconomic disadvantage are more likely to have higher rates of depression (Mojtabai & Olfson, 2004). Several age-related diseases lead to an increased risk for depression, including cardiovascular disease (Carney & Freedland, 2003) and diabetes (Li, Ford, Strine, & Mokdad, 2008). Depression in older people can present as either a lifetime illness with repeated depressive symptoms across the lifespan, or solely as a late-life condition. Differences in depression in late life as compared with early in life exist in etiology, prognosis, and lived experiences (Fiske et al., 2009). There are some important differences between early and late onset. Those with early onset of depression are more likely to have a family history of depression, suggesting a possible genetic influence (Heun, Papassotiropoulos, Jessen, Maier, & Breitner, 2001). Older adults with late-onset depression are more likely to have vascular risk factors, experience disruption in cognitive functioning, and are more likely to develop dementia (Hickie et al., 2005; Schweitzer, Tuckwell, O'Brien, & Ames, 2002).

Depressed older adults often present with more physical than emotional symptoms (Büchtemann, Luppa, Bramesfeld, & Riedel-Heller, 2012). Older adults with depression are less likely to endorse dysphoria (a state of unease or general dissatisfaction with life) and feelings of worthlessness or guilt. Older adults with late-onset depression display sleep disturbances, fatigue, psychomotor retardation, loss of interest in living, and hopelessness about the future, more so than younger adults or older adults who had early-onset depression (Fiske et al., 2009). Depressed older adults are also more likely to complain about poor memory and concentration (Christensen, Jorm, MacKinnon, Korten, Jacomb, et al., 1999).

Anxiety

Anxiety symptoms are likely twice as prevalent as depression symptoms in older people (Singleton, Bumpstead, O'Brien, Lee, & Meltzer, 2003) and a mix of anxiety and depression is common (Wetherell, Maser, & Balkom, 2005). Depression and anxiety often present together and have similar risk profiles (Vink, Aartsen, & Schoevers, 2008). Though anxiety is a common psychological symptom at any age, it has several older-age specific facets (Wolitzky-Taylor, Castriotta, Lenze, Stanley, & Craske, 2010). Anxiety related to fear of falling and anxiety comorbid to other illnesses are most common in older ages. Fear of falling has a strong relationship with limiting physical and social activity, and therefore has an impact on independence and mobility. Anxiety also predicts limited activity independent of depression (Norton et al., 2012). Poor balance and reduced activity levels make individuals fear falling and its serious health outcomes, such as hip fractures (Cumming, Salkeld, Thomas, & Szonyi, 2000). Sometimes referred to as "postfall syndrome," this disorder has been cited as the most common anxiety reported in older people (Howland et al., 1993). Anxiety can often be comorbid to other diseases. In a community dwelling group of older adults with cardiovascular diseases, subthreshold anxiety was found to be highly prevalent, suggesting that anxiety could be comorbid with high blood pressure and depression (Grenier et al., 2012). A review indicated that there was a relationship between anxiety and menopause. Specifically, menopause was linked to both vasomotor symptoms and panic disorder (Bryant, Judd, & Hickey, 2012).

Dementia and Alzheimer's Disease

Alzheimer's disease and other dementias impair thinking and reasoning and increase in prevalence with age (Corrada, Brookmeyer, Paganini-Hill, Berlau, & Kawas, 2010). Population-based studies that surveyed centenarians estimated 51% in Denmark had dementia (Andersen-Ranberg, Vasegaard, & Jeune, 2001) and 70% in Japan (Asada et al., 1996). While normal aging has the biggest impact on fronto-striatal brain systems, Alzheimer's disease targets medial temporal lobes and cortical networks involving the posterior cingulate and retrosplenial cortex (Buckner, 2004). These different trajectories are also apparent for emotions, which fare worse in Alzheimer's disease than in normal aging. A community-based sample study of dementia found that apathy was the most common emotional symptom, followed by depression and agitation or aggression (Lyketsos et al., 2000). Both depression and Alzheimer's disease involve chronic inflammation and hyperactivation of the hypothalamic–pituitary–adrenal axis (Caraci, Copani, Nicoletti, & Drago, 2010). The aggression and other psychiatric symptoms sometimes seen with Alzheimer's disease have been linked to damage to the serotonergic and dopaminergic systems in the brain (Katz et al., 1999; Assal & Cummings, 2002).

Cultural Caveats in How Age Relates to Emotion

One limitation of this review is that the majority of age-related comparisons in emotion and associated processes have been conducted in English-speaking countries. It is unclear if there are similar age associations elsewhere or if there are cultural differences. One study suggests that culture can have a significant impact on how emotional well-being differs across age cohorts (Steptoe, Deaton, & Stone, 2015). While English-speaking wealthy countries showed the general pattern of increasing emotional well-being with age, regions such as the former Soviet Union and Eastern European satellites showed a decreasing ratio of positive-to-negative emotional ratings, and other regions such as Africa and Latin American regions showed few age differences or mixed patterns. Differences in these cross-sectional trends across countries may be the result of societal upheavals in some regions of the world that deprive older adults of security and economic resources. Further research is needed to better understand cultural factors influencing well-being, ideally, longitudinal studies that involve experience sampling.

Only a few studies examining how valence influences emotional attention or memory have been run in non-Western samples (Reed et al., 2014), however, among those there were significant positive effect age × valence interactions among Koreans (Ko, Lee, Yoon, Kwon, & Mather, 2011; Kwon, Scheibe, Samanez-Larkin, & Tsai, 2009) and Hong Kong Chinese (Fung, Isaacowitz, Lu, & Li, 2010; but see Fung et al., 2008), suggesting that the shift toward remembering positive relatively better than negative information occurs in Asian as well as Western cultures.

Do individuals within a culture take on more of their culture's values over time? If so, this would predict that cultural differences would be most pronounced among older cohorts. Indeed, there are some initial findings suggesting that social values and personality traits such as optimism differ most across cultures among older cohorts (Fung, 2013). But cultural differences are sometimes most pronounced among the younger cohorts (Fung & You, 2011; Ko et al., 2011). Whereas younger Koreans versus Americans show the expected cultural difference in which Asians integrate the emotional context more when rating the emotion of a foreground face, older Koreans versus Americans do not show any differences in context integration (Ko et al., 2011). Thus, emotional differences across cultures are likely influenced by factors other than a deepening identification with one's culture over time.

Conclusion

Whether addressing the topics of discrete emotions, psychophysiological arousal, or emotion regulation, it is clear that in terms of aging, the results are not always what people initially assume. Even though people believe that they will get less happy with age, older adults tend to self-report being more happy and less angry then their younger adult counterparts. As they age, people are more likely to lose those they care about, yet they do not necessarily become sadder with time. After a lifetime of learning from emotion regulation successes and failures, older adults report feeling more in control of their own emotions. Older adults may experience declines in systems important for *feeling* emotion (i.e., electrodermal and cardiovascular systems) but some measures of psychophysiological arousal show similar results between younger and older people. Depression is less frequent in later than earlier adulthood and depression that starts at older ages is associated with a lifetime of stressful experiences, a decrease in social networks, and an increase in comorbidities, and differs from depression at younger ages. Older people are often anxious about falling and comorbidities—things younger people worry little about. In general, emotion is a domain in which older adults fare surprisingly well especially considering declines in cognitive and physical domains. Current theoretical models have helped explain some of the age differences in emotional processes, but more research is needed to see which (if any) of the theoretical frameworks outlined above can be ruled out or further supported.

CHAPTER 19

The Interplay of Motivation and Emotion

View from Adulthood and Old Age

Molly Sands, Nhi Ngo, and Derek M. Isaacowitz

In this chapter, we consider the relationship between emotion and motivation, with a particular focus on how this relationship changes across the lifespan. Emotion and motivation have generally been considered by psychologists to be distinct constructs, although they have much in common (Lazarus, 1991). For instance, both emotion and motivation are thought to play an important role in directing thoughts and behaviors (Bradley & Lang, 2000; Pessoa, 2009). Emotion can facilitate motivation and help define desired goals, while failure or success in motivated goal pursuit can also cause emotional responses. Below, we focus specifically on how various motivational processes may influence emotion by examining key research findings, and the theoretical frameworks used to interpret them, in the context of lifespan development.

Over the past several decades, cross-sectional and longitudinal research has revealed age-related differences in various types of emotional processes, including affective experience, emotion regulation, and emotion perception (Charles, Reynolds, & Gatz, 2001; Stanley & Isaacowitz, 2014). Since chronological age alone does not adequately explain changes in emotional processes across the lifespan (Wohlwill, 1970) there has been a strong interest in understanding and explaining the underlying mechanisms that drive these age differences in emotional processes. Prominent theories of socioemotional development have proposed that changes in motivation result in changes in these emotional processes, so it is important to examine how these motivational theories can explain, or fail to explain, age differences in emotion. In this chapter, we assess empirical evidence of age differences in emotional processes through the lenses of two motivational models of lifespan development: (1) the selection, optimization, and compensation (SOC) metatheory; and (2) socioemotional selectivity theory (SST). Conceptually, these theories are consistent in offering motivational accounts for age differences in emotion. However, each theory ascribes these changes to different mechanisms that may help us understand emotions in the context of aging. This is not meant to be an exhaustive list of lifespan motivational theories. Instead, we have selected the models that are most frequently linked to findings in the extant literature on emotion.

These two prominent theoretical orientations have guided research questions and provided a framework for interpreting empirical results in the emotion regulation and emotion perception literature. In the remainder of this chapter, we first present key empirical findings and review the primary motivational accounts used to explain them. We then evaluate how effectively they explain the current state of findings in the areas of emotion regulation and emotion perception, two of the most studied emotional processes in aging.

Empirical Evidence for Age Differences in Emotional Processes

Age Differences in Affective Experience

Aging has been associated with stability, and in some cases improvements, in affective well-being (Carstensen, Pasupathi, Mayr, & Nesselroade, 2000). Initially, this may seem counterintuitive considering age-related losses in cognitive function, physical performance, and control over the environment (Salthouse, Atkinson, & Berish, 2003; Perera, Mody, Woodman, & Studenski, 2006). However, in general, older adults have been found to maintain higher levels of positive affect and subjective well-being and have lower levels of negative affect (Charles et al., 2001; Kunzmann, Little, & Smith, 2000). Since positive and negative affect appear to be separate dimensions rather than opposite ends of a bipolar scale (Bradburn, 1969), we gain the best understanding of age-related changes in well-being by examining positive and negative affect separately.

Older adults report less frequent and less intense experiences of negative emotions than their younger counterparts (Diener, Sandvik, & Larsen, 1985). Cross-sectional data also suggest that negative affect consistently declines from adolescence until about 60 years of age, but then plateaus or slightly increases (Carstensen et al., 2000; Diener & Suh, 1998). Analyses of the Berlin Aging Study data revealed that when factors such as personality and cognitive function were controlled for, advanced age did not account for changes in negative affect, suggesting that contextual changes also explain age differences in affective experience in very old age (Isaacowitz & Smith, 2003). Cumulatively, these findings suggest that individuals exhibit relatively stable levels of negative affect, with a slow decline throughout the lifespan until very late life, in which negative affect typically increases (Charles et al., 2001).

Positive affect, however, exhibits a less clear pattern of age differences, with some studies finding slight decreases and others indicating stability or even increases throughout the lifespan. In two longitudinal studies of lifespan samples, positive affect slightly decreased, especially for people in late life (Charles et al., 2001; Stacey & Gatz, 1991). Mroczek and Kolarz (1998) found increases in positive affect in a lifespan sample that were best modeled by a quadratic curve. These findings suggested that the trajectory of change in positive affect differs by gender but consistently increased with age and only decreased in very late life. A longitudinal experience sampling study revealed that age is associated with more frequent experiences of positive affect, greater emotional stability, and increases in the co-occurrence of positive and negative emotions (Carstensen et al., 2011). In contrast, another experience sampling study found no age differences in the frequency or intensity of positive emotions in a sample ranging from 18 to 94 years of age (Carstensen et al., 2000). Overall, it seems affective well-being improves throughout the lifespan, with declines in negative affect and relative stability of positive affect, until very old age.

Age Differences in Emotion Regulation

Findings of age differences in affective experience raise questions about the effects of aging on emotion regulation—the processes by which people impact or alter their emotional experiences. There are a number of ways in which individuals can regulate their emotions throughout the lifespan, but much of the research in this area has been guided by the process model of emotion regulation (Gross & Thompson, 2007) and thus focuses on the strategies proposed by this framework. In this framework, antecedent strategies occur early in the emotion generative process, and include situation selection, situation modification, attentional deployment, and cognitive change. Later, response modification strategies, such as expressive suppression, are available.

Older adults have been found to effectively utilize antecedent emotion regulation strategies, especially those that minimize engagement with negative stimuli. In a laboratory study of choices of affective materials, older adults with high emotional self-efficacy choose to spend less time interacting with negative stimuli than younger adults with the same beliefs (Rovenpor, Skogsberg, & Isaacowitz, 2013), though no main effect of age was found in that study or a series of follow-up studies (Isaacowitz, Livingstone, Harris, & Marcotte, 2015). Additionally, older adults exhibit a preference for close, emotionally rewarding social partners. As people age, there is a reduction in the total number of social partners they engage with (Carstensen, 1992; Fung, Carstensen, & Lang, 2001). Early interpretations of this finding posited that older adults experienced a decrease in social partners due to physical challenges or declining resources; however, the reductions in social networks begin long before these age-related losses (Carstensen, 1992). As the number of social partners people engage with declines, they actually report closer, more satisfying emotional relationships with this relatively smaller number of individuals (Fung et al., 2001). The selection of social partners is not a direct measure of situation selection as a regulatory strategy, but suggests that older adults may shape their environment in ways that promote positive emotions.

Numerous studies have also shown that older adults remember and attend to a higher ratio of positive compared with negative information, a phenomenon termed the "age-related positivity effect," which has often been interpreted as information processing in the service of emotion regulatory goals (Isaacowitz & Blanchard-Fields, 2012; Mather & Carstensen, 2005). In memory recall tasks, older adults show a reduction in memory for negative stimuli (Charles, Mather, & Carstensen, 2003). Additionally, in a recognition task younger adults were better able to identify negative images while older adults did not differ in recognition of positive and negative stimuli (Charles et al., 2003). However, when participants of all ages were primed to focus on their current emotional state, instead of memory accuracy, they were more likely to display positivity effects, suggesting that positive biases in memory are motivated by emotion regulatory goals (Kennedy, Mather, & Carstensen, 2004).

Studies of visual attention to emotional stimuli have also found evidence of positivity effects, which have primarily been interpreted as support for motivational accounts. In order to determine if positivity effects in memory are also related to age differences in attentional patterns, we examined visual attention to emotional faces using eye tracking in older and younger adults and in fact, the results of these studies were consistent with positivity effects in memory (Isaacowitz, 2006). In a subsequent eye-tracking study, we examined older and younger adults' gaze patterns while viewing emotional faces and again found that older adults fixated significantly less on angry and fearful faces and significantly more on happy facial expressions (Isaacowitz, Wadlinger, Goren, & Wilson, 2006). To determine if these findings were related to motivation for older adults to feel good, and not simply mood-congruent gaze patterns, we conducted another study that accounted for baseline mood. If younger adults started the task in a negative mood, they exhibited mood-congruent looking patterns by attending more to negative stimuli, but if older adults started the task in a negative mood, they attended most to happy faces; they did not display valence preferences when in a positive or neutral mood (Isaacowitz, Toner, Goren, & Wilson, 2008). However, positive looking patterns only seem to help older adults with good attentional abilities regulate their moods (Isaacowitz, Toner, & Neupert, 2009; Noh, Lohani, & Isaacowitz, 2011). In sum, these findings suggest that as people age they use and benefit more from attentional strategies, which allow them to engage less with negative emotional content, and potentially improve negative moods.

Age differences in the use of cognitive change as an emotion regulation strategy indicate, however, that younger adults may rely more on cognitive regulatory strategies. Shiota and Levenson (2009) found that detached reappraisal (adopting an unemotional, objective attitude) was most effective for younger adults, whereas positive reappraisal (focusing on the positive aspects) led to the best emotional outcomes and lower levels of physiological reactivity for older adults in response to negative film clips. In another laboratory study, younger and older adults were asked to perform a cognitive load task while down-regulating from a negative emotional state; mood recovery was assessed over time. Younger adults under cognitive load had more difficulty regulating their emotions than older adults under cognitive load, suggesting that they may inherently rely more on cognitive forms of regulation (Scheibe & Blanchard-Fields, 2009). Cumulatively, the results of these studies suggest that older adults may be using different mechanisms to regulate their emotions than younger adults, which in turn may impact the use and effectiveness of various emotion regulation strategies.

Age Differences in Emotion Perception

Although affective experience and some forms of emotion regulation appear to improve with age, the trajectory is the opposite for the perception of emotion in others. A meta-analytic review (Ruffman, Henry, Livingston, & Phillips, 2008), a theoretical review (Isaacowitz & Stanley, 2011), and a detailed, tabulated summary of past findings (Isaacowitz et al., 2007) all concluded that older adults have more difficulty than younger adults in identifying facial expressions, especially those of negative emotions. Ruffman and colleagues (2008) analyzed 28 datasets from 15 published studies and found that older adults have more difficulty than younger adults in identifying at least some of the basic emotions across a number of modalities (faces, voices, bodies/contexts, and face–voice matching). Older adults perform worse than younger adults in identifying most negative facial expressions, specifically of fear, sadness, and anger (Calder et al., 2003; Keightley, Winocur, Burianova, Hongwanishkul, & Grady, 2006; Orgeta & Phillips, 2008; Phillips, MacLean, & Allen, 2002; Ruffman et al., 2008; Sullivan & Ruffman, 2004a; Wong, Cronin-Golomb, & Neargarder, 2005). The exception of this pattern is the disgusted face, which older adults identify as consistently (Orgeta & Phillips, 2008; Phillips et al., 2002) or better than younger adults (Calder et al., 2003; Suzuki, Hoshino, Shigemasu, & Kawamura, 2007; Wong et al., 2005). The age-associated deficit also does not extend to happy and surprised faces (Murphy & Isaacowitz, 2010; Orgeta & Phillips, 2008; Phillips et al., 2002; Sullivan & Ruffman, 2004a).

There are a few possible nonmotivational accounts of the age-associated deficit in emotion perception that have been tested in the literature. First, older adults' response biases for certain emotions can lead to decreased accuracy in other emotions. Older adults were found to have a response bias for disgust, fear (Isaacowitz et al., 2007; Sasson et al., 2010), neutral, sadness, and anger labels for facial expressions (Sasson et al., 2010) and happiness, sadness, and surprise labels for words (Isaacowitz et al., 2007). While not directly calculating response biases, Ebner, He, and Johnson (2011) found that older adults mistake angry faces for disgusted, while younger adults did not show this pattern. It remains to be seen why older adults prefer certain labels over others, although their response biases might not necessarily be related to their emotion perception difficulty. Age differences in accuracy remain even after controlling for emotion-specific response biases (Isaacowitz et al., 2007; Sasson et al., 2010), indicating that older adults' decreased accuracy has roots beyond their tendency to choose particular emotion labels.

As aging comes with various declines in cognitive functioning, emotion perception deficits in older adults can be a consequence or a specific manifestation of general cognitive and perceptual decline. Age differences were reduced when cognitive measures were statistically controlled for (Orgeta & Phillips, 2008), and low-functioning older adults were more impaired at anger perception than high-functioning older adults (Krendl & Ambady, 2010), suggesting there is at least some overlap between general cognitive ability and emotion perception. However, in several studies, cognitive functioning accounted for the age differences in perception of only some facial expressions (Sullivan & Ruffman, 2004b; Suzuki & Akiyama, 2013; Murphy & Isaacowitz, 2010). Besides standard cognitive measures used in those studies, other measures of cognitive ability such as face processing and processing speed (Orgeta & Phillips, 2008; Sullivan & Ruffman, 2004b) also did not explain age differences in emotion perception. Age differences in emotion perception ability might be related to decline in general cognitive functioning, but is not entirely caused by cognitive decline in old age.

Aging also comes with changes in the structural and functional properties of the brain (e.g., Raz et al., 2005), which poses the question of whether these changes can lead to changes in emotion perception abilities. Most of the studies that look at age differences in neural activity related to facial expressions had participants passively view the stimuli without making explicit categorization. It is therefore still unknown how patterns of neural activity are associated with deficits in older adults' ability to label emotional facial expressions (see Isaacowitz & Stanley, 2011). The few studies that explored age differences in neural activity while participants identified facial expressions have yielded mixed results (Ebner, Johnson, Fischer, 2012; Williams et al., 2006). Another possible cause for the emotion perception deficit is older adults' attentional patterns. Older adults focus more on the lower half of the face when identifying facial expressions, a gaze pattern associated with lower accuracy in emotion identification (Sullivan, Ruffman, & Hutton, 2007; Wong et al., 2005). However, when different measures of fixation were controlled for, age differences were still significant for some facial expressions (Murphy & Isaacowitz, 2010).

In summary, older adults are consistently less accurate than younger adults in emotion identification tasks partly due to their response biases to a select few emotion labels, decline in general cognitive ability, and preference to look at the lower half of the face. However, none of these factors have fully explained the age-associated deficit in emotion perception, as age differences in accuracy still remain after controlling for these factors.

Motivational Models of Lifespan Development

Selection, Optimization, and Compensation

The SOC metatheory posits that successful human development is characterized by the maximization of gains and minimization of losses (Baltes & Baltes, 1990; Freund & Baltes, 2000). In this framework, developmental regulation of gains and losses consists of three processes: selection, optimization, and compensation. SOC aims to capture changes in the dynamics of these three processes across the lifespan and their consequences for successful development across different domains of functioning. In the domain of personal goals, SOC has proved to be particularly useful for understanding motivational changes across the lifespan.

The first assumption of the SOC model is that developmental trajectories contain both growth (gains) and decline (losses), and that these trajectories are present at all stages of development. For example, children gain new knowledge but lose the ability to speak a foreign language at native level after the age of 12; older adults may learn new things even as their health is in decline. Individuals are also thought to have constrained resources at any point in their lifespan, although they are especially more limited in old age than earlier in life (Baltes, 1997). The ratio of gains to losses thus becomes less positive with age, which motivates older individuals to utilize resources to avoid losses in order to maintain a desired level of functioning, as opposed to allocating these resources toward growth. Freedom from age-related social expectations allows older adults to be less constrained in their goal selection and pursuit, yet they are more limited in terms of resources to shape their environment according to their goals. Selection of goals and goal domains, optimization of remaining resources, and compensation for losses of resources for goal attainment are thus crucial in old age.

Selection involves reducing the numerous domains of functioning to those with available or attainable resources, as resources become more limited with increasing age. Focusing on a few select domains can increase the likelihood of successful goal achievement for older adults whose resources become more constrained (Freund & Baltes, 1998). Selection is only the first step in achieving goals. Individuals must engage in goal-relevant actions and invest resources to improve performance in the selected domains and attain goals. This process is called *optimization*. Optimization to achieve growth-related goals is especially important in old age, when the focus is primarily on losses (Freund & Baltes, 2000). When faced with losses in means to attain goals, individuals *compensate* in order to maintain a given level of functioning. Optimization means are used to successfully attain goals, whereas compensation is used to prevent losses, which has greater value than gains (Freund, 2006). Compensation is therefore important in old age due to declines in cognitive and physical functioning. To compensate for a loss in goal-related means, individuals can substitute by drawing on unused but functioning and equivalent means, or by acquiring new means.

Evidence for SOC comes most prominently from studies in aging, where changes in SOC correspond to the expected human development trajectory. Younger adults, who have more opportunities for growth, focus on optimization, whereas older adults, due to their increasing losses, focus on compensation. This pattern has been found in several self-report studies when participants were asked to rate the focus of their goals (e.g., Ebner, Freund, & Baltes, 2006; Heckhausen, 1997), although the results are not consistent across all studies (Freund & Baltes, 1998, 2002; Ogilvie, Rose, & Heppen, 2001). Results are clearer with behavioral studies. In an experiment where participants, after being trained, engaged in a dual-task paradigm that required both sensorimotor skills (walking) and cognitive resources (memory), older adults suffered from greater dual-task cost in the memory domain, but not the walking component. When both tasks increased in difficulty, older adults chose to employ external aids for walking but not for memory. This result indicates that older adults engaged in loss-based selection and compensation for the domain that they deemed both more important and prone to less loss (Li, Lindenberger, Freund, & Baltes, 2001).

Another study using behavioral measures found similar results (Freund, 2006). In two experiments, older adults spent more time on a task in which they were instructed to compensate for a loss, whereas younger adults persisted more on another task in which they were instructed to strive to do better (optimize). This pattern held even when controlling for differences in performance levels, and when the instructions changed into descriptions of difficulty, as opposed to the original ones focusing on gains and losses. The SOC metatheory provides a useful account of how the selection of developmentally relevant goals and an individual's ability to optimize resources and compensate for losses contributes to goal attainment and successful aging.

Applications to Emotion Regulation

Urry and Gross (2010) applied the SOC metatheory specifically to age differences in emotion regulation (selection, optimization, and compensation—emotion regulation [SOC-ER]). In this model, they propose that changes in resources may be important determinants of the emotion regulation strategies people use. SOC-ER posits that older adults compensate for losses in resources by selecting and optimizing strategies that rely on resources that improve or remain stable as they age in order to continue to effectively regulate their emotions. Older adults do not appear to experience deficits in their abilities to regulate their emotions, in fact, findings about affective experience suggest they may even have improved regulatory abilities (Charles et al., 2001. Older adults often report higher levels of affective well-being and it is likely that they are optimizing their emotion regulation efforts to attain these positive emotional outcomes.

Specifically, the SOC-ER model proposes that older adults rely on antecedent emotion regulation strategies, such as attentional deployment and situation selection, which draw primarily on experience with emotions and less on cognitive resources that decline with age. For instance, older adults have better emotional outcomes when they use regulatory strategies that rely on social support, a resource known to improve with age, rather than working memory capacity, a resource known to decline as people age (Opitz, Gross, & Urry, 2012). The positivity effect, which seems to be influenced by motivated differences in attention, also provides support for this framework. Older adults benefit from attentional deployment but only when they have good attentional abilities, suggesting that selecting strategies that rely on available resources, and perhaps compensate for losses, is particularly important for successful emotion regulation as people age (Isaacowitz et al., 2009; Noh et al., 2011). However, it is also important to consider to what extent individuals' preferences for these strategies have been differentiated from their effectiveness at regulating mood in empirical research to truly understand how these resource-based changes influence emotion regulation outcomes (Isaacowitz & Blanchard-Fields, 2012).

Applications to Emotion Perception

The applications of the SOC framework to findings about age deficits in emotion perception have been more limited than in emotion regulation. Explanations have primarily focused on abilities, with the assumption that older adults' decreased accuracy is related to a decline in some aspect of functioning, such as cognitive functioning, gaze patterns, or neural activity. Few studies have examined the possibility that it is not ability that changes across the lifespan, but motivation related to emotion perception that does.

It is possible that age differences in emotion perception are not motivated only by emotional goals, but also social cognitive goals. In this domain, older adults have demonstrated selective engagement, such that they select to engage only when stimuli are meaningful or relevant in some way, a phenomenon termed the "selective engagement hypothesis" (Hess, 2006, 2014). This hypothesis posits that older adults utilize SOC-type strategies to achieve their desired level of social cognitive functioning, by being selective in which goals they pursue. In addition, older adults optimize and compensate using their social expertise, which is accumulated knowledge over the lifespan about social situations (Hess, 2006). Selectivity in social cognition is demonstrated through enhanced performance for stimuli that have higher personal relevance or meaningfulness in older adults (e.g., Hess, Rosenberg, & Waters, 2001).

The selective engagement hypothesis can be helpful in explaining the age-associated emotion deficit, especially in light of studies that found no age differences in emotion perception using dynamic stimuli and stimuli embedded in information-rich context (Richter, Dietzel, & Kunzmann, 2011; Murphy, Lerhreld, & Isaacowitz, 2010; Noh & Isaacowitz, 2013). From the perspective of the selective engagement hypothesis, if older adults are motivated to preserve their cognitive resources and engage only in relevant, meaningful tasks, they may not perform well in emotion perception tasks in which stimuli are less relevant, unrealistic, and challenging. In real life, people, particularly older adults, do not often have to decode emotions through static and isolated images. The experience of doing so in a laboratory setting might thus appear highly contrived and consequently less motivating to older adults.

Stimuli and tasks that are low in ecological validity also put older adults at a disadvantage. In real-life social interactions, older adults might be using other cues from the environment as well as their social expertise to decode emotions. Social expertise—or social knowledge developed from experience over time—improves with age and can be used as a source of optimization and compensation in social cognitive functioning. Depriving older adults of these sources of environmental and personal resources can impede older adults from performing well.

In addition to being unrealistic, targets used in emotion perception tasks may be less relevant to older adults because they are faces of strangers. In real life, older adults interact with their small and tight social network, and rarely with strangers. Perceived closeness can therefore motivate older adults in emotion perception. In fact, increasing perceived closeness by telling participants that the targets had similar interests to theirs significantly enhanced emotion identification accuracy for older adults, and only marginally so for younger adults (Zhang, Fung, Stanley, Isaacowitz, & Ho, 2013). Additionally, the age differences in emotion perception were reduced for close social partners (Stanley & Isaacowitz, 2014).

Thus far, we have seen that while SOC-based motivational explanations of lifespan emotion perception findings present promising alternatives to cognitive-based accounts, very few studies have looked into SOC strategies as part of the mechanism behind the age-associated emotion perception deficit. It is worthwhile for future research to incorporate SOC into their investigation of lifespan emotion perception, as changes in motivation in late adulthood can impact emotion perception performance beyond the consequences of decline in ability or cognitive functioning.

Socioemotional Selectivity Theory

SST posits that as people age, they are motivated to prioritize emotional goals, due to a limited future time perspective (Carstensen, Isaacowitz, & Charles, 1999). There are two primary categories of social goals that individuals are motivated to pursue: knowledge acquisition and emotionally relevant goals. At any point in development, resources for goal pursuit are limited, and therefore, people can pursue only a limited number of goals simultaneously (Baltes, 1997). Because age and time left in life are inextricably linked, most of the research on SST has focused on age-related changes in emotional goals. Younger adults, for whom time seems expansive, tend to prioritize future-oriented goals such as knowledge acquisition. In these earlier phases of development, social behavior such as interacting with novel social partners and attending to negative emotional information provides important information that may play a crucial role in human functioning. As people age, however, their sense of time left in life becomes more limited, making emotionally meaningful goals more salient and motivating them to select socially relevant prohedonic goals.

Although shifts in goals are age related, SST posits that it is time perspective, and not age itself, that motivates individuals to prioritize positive emotions. Laboratory studies in which time perspective is not associated with age, or is experimentally manipulated, have found similar effects of limited time perspective on social partner selection. In one study, same-age participants who differed in their HIV status were asked to select from a series of social partners who would provide either a novel experience that might lead to knowledge acquisition, or an experience likely to be more emotionally meaningful. HIV-positive, symptomatic participants whose time perspective was the most limited, showed the same preference for close, emotionally rewarding social partners as older adults did in the same task, supporting the idea that it is time perspective, not chronological age, that motivates individuals to preferentially pursue prohedonic goals (Carstensen & Fredrickson, 1998). Similar effects of time perspective have been found in groups that are experiencing the "end of an era." For instance, college seniors also display preferences for close emotional partners while students with more time left in their current social environment show more interest in novel social interactions (Fredrickson, 1995). By examining the motivational role of time perspective in groups other than older adults, researchers have identified time perspective as an underlying mechanism that motivates changes in socially relevant goals. Individuals' social goals motivate their behavior and in turn influence emotional processes, such as emotion regulation and emotion perception.

Applications to Emotion Regulation

In the domain of emotion regulation, SST posits that prohedonic goals motivate older adults to regulate their emotions in ways that allow them to avoid experiencing negative emotions and ultimately maintain high levels of positive affect. SST is consistent with SOC in that the model considers selection of certain goals to be adaptive, especially in the social domain. These age differences in emotional goals have been evident in multiple domains, including preferences for social partners and cognitive processing of emotional stimuli.

One of the key ways SST has been applied is to explain age differences in affective experience as the result of preferences for emotion regulation strategies that are motivated by older adults' desire to feel good. The strength and vulnerability integration (SAVI) model (Charles, 2010) builds upon the SST framework by outlining the strengths and challenges associated with aging, and discussing their implications for emotion regulation. SAVI suggests that older adults attain their positive emotional goals by relying on emotion regulation strategies that become more effective, or at least maintain their effectiveness, with age. On the one hand, increased knowledge and experience with emotions is a major strength of aging. Older adults may be better able to interpret emotional cues and utilize prior experience to achieve their affective goals. On the other hand, older adults experience declines in cognitive and physiological flexibility, which may make it more difficult to down-regulate from high arousal, negative emotional states.

Emotion regulation strategies in which older adults are able to avoid or limit engagement with negative emotional content, are likely increasingly effective with age, since older adults seem to be better able to predict the emotional outcomes of situations but less equipped to down-regulate after experiencing a full-blown emotional response. Older adults selectively invest resources in emotionally rewarding relationships, which may also aid in emotion regulation and help them to compensate for losses in physical and cognitive resources that could negatively impact emotional outcomes (Fung et al., 2001). For instance, familiar partners can enhance memory by providing contextual clues and can utilize knowledge about physical ailments to help older adults compensate, thus enhancing emotional well-being (Baltes & Carstensen, 1996).

The SST framework has also guided much of the research about age differences in the cognitive processing of emotional information. According to SST, positivity effects (i.e., more positive patterns of memory and attention) are self-regulatory processes that align with older adults' emotional goals. Though cognitive resources decline with age, cognitive processing of emotional materials may remain somewhat stable, yet older adults display a preference for positive emotional information (Carstensen & Mikels, 2005). Positivity effects, particularly in attention, have also been associated with better moods in older adults, suggesting they serve regulatory functions, especially for older adults with good attentional abilities (Isaacowitz, 2012; Isaacowitz & Blanchard-Fields, 2012).

Generally, SST explains age differences in affective experience and regulation as motivated by changes in goals, which influence these emotional processes. This framework has been a major contributor to the literature and has driven much of the research in the area of aging and emotion. It aligns with the SOC framework by considering social goal selection as a key facet of motivation and proposing that some of the ways older adults attain prohedonic goals rely on optimization of emotion regulation and compensatory strategies. However, SST assumes that these chronically activated emotional goals guide most facets of older adults' behavior and research is limited about circumstances in which contrahedonic goals might be beneficial to older adults.

Applications to Emotion Perception

Age-associated deficits in emotion perception have been found mostly in facial expressions of negative emotions, whereas perception of expressions of positive or neutral emotions appears intact with age (Ruffman et al., 2008). It is possible that this deficit is caused by older adults' prioritization of prohedonic goals, and consequently preferential processing of positive stimuli and avoidance of negative ones (Cartensen & Mikels, 2005). Older adults are less likely to report anger in an angry–happy face blend (Bucks, Garner, Tarrant, Bradley, & Mogg, 2008), and demonstrate automatic response biases for happy over neutral, and neutral over fearful responses to low-intensity facial expressions (Johnson & Whiting, 2013). Reduced activity in the medial frontal cortex in response to fearful faces, and increased activity for happy faces in older adults indicates a discrepancy in controlled processing for positive and negative facial expressions (Williams et al., 2006), with negative facial expressions requiring more regulation efforts to avoid negative emotions. These findings could be interpreted as supporting motivated positivity effects in older adults' emotion perception.

Alternatively, this difference in processing efforts may stem from the levels of difficulty of identifying different facial expressions (Isaacowitz & Stanley, 2011). In the majority of experiments on age differences in emotion perception, happiness is the only positive emotion presented to the participants, or the only positive response option. In contrast, there is a range of negative emotions in stimuli and response options that might be more challenging to distinguish. Older and younger adults' equivalent performance on positive emotions therefore can be a result of a ceiling effect, as older adults still perform worse than younger adults in identifying positive facial expressions when the task becomes more difficult (Isaacowitz et al., 2007; Orgeta, 2010). Furthermore, age differences in perception of negative emotions are not uniform across studies, with older adults exhibiting difficulty for some emotions, but not others. Older adults' motivation to avoid negative emotions, therefore, cannot fully explain why the deficit varies across negative facial expressions, but are more pronounced for only some.

Contributions of Motivational Accounts

The models reviewed above overlap in a few critical ways. First, these frameworks propose that motivation is central to understanding age differences in emotional processes. They also both conceptualize successful aging as the ability to effectively pursue goals that enhance well-being, not as the absence of age-related decline in some domains. In addition, they both acknowledge shifting resources throughout the lifespan as people pursue social goals.

In the domains of emotional experience and emotion regulation, although each of these motivational accounts of development can provide interpretations of the empirical findings, some have been applied to specific findings more than others. For instance, the majority of the research on positivity effects has been from the conceptual perspective of SST, whereas emotion regulation is frequently linked to SOC through the SOC-ER model. An open question is whether these models simply have more explanatory power for findings they are applied to, or if research in these areas has thus far not adequately interpreted findings using alternative accounts. It is important for motivational models to be tested against one another, as well as against alternative nonmotivational accounts of lifespan development to determine which aspects of these findings can be explained by various predictors.

In the emotion perception literature, findings of an age-associated deficit in identification of isolated and contextualized facial expressions suggest that there is a change in the emotion perception process in older age. However, instead of conceptualizing this change as a decline in the ability to identify facial expression, it is more appropriate to think of this change as a shift in the utilization of alternate resources, which may be partly involuntary due to loss of primary cognitive or perceptual resources, and partly voluntary due to motivation to optimize and compensate to maintain a normal level of functioning. In other words, older adults are both obliged and motivated to rely more on external cues from the target of perception and the environment that both they (the perceiver) and the target are in to identify facial expressions. Older adults thus are at a disadvantage in the traditional lab-based emotion perception tasks. Motivational accounts can facilitate holistic considerations of the internal cues from the perceiver (how motivated the perceiver is to decode the target's emotion) as well as the external cues from the target (how relevant, familiar, or contextualized the target is) and the environment (what other cues besides the target are available). Therefore, the differences between emotion perception deficits due to ability, and those due to motivation, need to be further explored.

Avenues for Future Research

In reviewing the key empirical findings about lifespan emotional development and applying the most prominent lifespan motivational theories to them, we found that age-related changes in motivation may plausibly influence both emotion regulation and perception, and could lead to age differences in these emotional processes. At the same time, the individual studies that the larger body of research comprises have typically followed from, and thus only tested, one of the several possible motivational models (e.g., studies that investigate SST only as a possible explanation). In addition to SOC, there are other models that try to delineate motivation in aging across different domains. One such model is the motivational theory of lifespan development, which specifically focuses on the role of primary and secondary control in goal pursuit, and provides a compelling framework for interpreting findings about age differences in the affective consequences of goal selection, engagement, and disengagement. However, there has been a lack of empirical research about emotion regulation and perception conducted in the context of this theory, and so it has been less informative about age differences in these emotional processes (Heckhausen, Wrosch, & Schulz, 2010).

In order to fully understand these emotional processes and the potential role of motivation underlying them, it is critical that researchers focus on empirically testing motivational models in comparison to one another, in paradigms that do not simply aim to affirm or reject one model. It is also possible that these models could be integrated into an overarching framework to more adequately explain the role of motivation in emotion regulation and perception throughout the lifespan. In the domain of emotion regulation, motivational models provide compelling accounts for many of the empirical findings. However, the extent to which these various models uniquely contribute to our understanding of emotional processing throughout development remains unclear. The SOC-ER framework provides a comprehensive model for understanding age-related changes in emotion regulation. Nevertheless, the model is contingent on cognitive decline and other shifting resources, accounting for age-related variability in emotion regulation. In order to empirically test its validity, it will be critical to isolate changes in resources (such as cognitive function) and determine if these are sufficient to produce patterns consistent with age differences in emotion regulation. SST has successfully identified time perspective as a variable that accounts for differences in emotional goals. The theory is particularly effective at explaining positivity effects and changes in social environments throughout the lifespan. Though SST has been supported by substantial descriptive evidence of age-related positivity effects, Isaacowitz and Blanchard-Fields (2012) address the distinction between studying age differences in how emotional information is processed and understanding the downstream consequences of these differences. In order to understand how processing of emotional information influences emotional experience, we must assess positivity effects' real-time outcomes for mood (e.g., Isaacowitz et al., 2008).

There are still many open questions about affective experience and emotion regulation, and how these processes dynamically change throughout the lifespan. For instance, findings about the lifespan trajectory of affective experience have been somewhat contradictory. Therefore, it may be important to consider alternative explanations, or more nuanced versions of motivational models as potential explanations. There is also a need to better identify in which contexts older and younger adults rely on differential emotion regulation strategies to obtain a more nuanced understanding of factors that motivate these age differences.

Alternative theories, such as nonmotivational models, may also explain key age differences in emotion. The aging brain model proposes that structural changes in key emotion-generative brain areas, such as decreased volume of the amygdala, lead to fewer experiences of negative affect. Structural and functional changes in the brain are important to consider especially when interpreting age differences in emotional experience and emotion regulation (Cacioppo, Berntson, Bechara, Tranel, & Hawkley, 2011). However, age-related changes in positive affect seem to vary and are not entirely consistent with the idea that diminished brain activity leads to diminished affective experiences (Urry & Gross, 2010). Alternatively, some empirical results suggest that older adults experience greater sensitivity in amygdala responses. For instance, younger adults experience greater increases in amygdala activity than older adults in response to negative, but not positive images (Mather et al., 2004). In response to negative images, older adults also experience less activity in a parietal brain region, suggesting that positivity effects may also exist in low-level processing of emotional stimuli. We should also consider that differences in neural response during affective experiences could be the result of emotion regulation to pursue prohedonic goals (Samanez-Larkin & Carstensen, 2011). Additionally, in the domain of emotion perception, differences in task engagement and stimuli salience may also be evident in brain activity. In response to facial stimuli, older adults exhibit lower levels of amygdala activity, which is often interpreted as dysfunction in this brain region. However, behavioral studies provide support for the idea that processing of emotional stimuli remains intact and thus decreased amygdala activity may instead be related to decreased salience of the stimuli (Samanez-Larkin & Carstensen, 2011).

Another nonmotivational framework, dynamic integration theory (DIT) attempts to resolve the discrepancy between improvements in well-being, which are often attributed to enhanced regulatory ability, and emotion regulation challenges associated with age-related cognitive decline (Labouvie-Vief, 2003). To integrate these findings, DIT proposes a dynamic relationship between emotion and cognition that allows individuals to coordinate optimization, which relies on preconscious experience and is somewhat automatic, and differentiation, which requires more elaborative cognitive processing. As people age, they maintain higher levels of well-being if they are able to successfully integrate and balance these processes of optimization and differentiation. Older adults may sacrifice differentiation for optimization, suggesting that age-related differences in affective experience (and perhaps regulation) may be compensatory strategies.

Blanchard-Fields (2007) offers another nonmotivational account of aging that centers on expertise. In a series of everyday problem-solving tasks, older adults displayed a wider range of problem-solving strategies and used them effectively to regulate emotion and strategically solve problems (Blanchard-Fields, 2007). In this account, experience and the flexible use of context-appropriate strategies lead to successful emotion regulation and positive affective outcomes. Future studies will need to ascertain methods for testing among these approaches that may sometimes make only subtly different predictions, at least about observable outcomes.

Though motivational accounts have been employed to test predictions and interpret results regarding emotion regulation, only a few studies have attempted to directly investigate the role of motivation, specifically SST (e.g., Williams et al., 2006) and SOC (selective engagement; Zhang et al., 2013), in emotion perception. As discussed above, the potential of motivational theories in emotion perception and aging has not been fully explored. For example, while SST is compelling in explaining why older adults' deficit in emotion categorization applies to only negative faces, one critique of this account is that positive emotion in most emotion perception studies has an unfair advantage: The only positive facial expression being tested or the only positive response option is happy. Only one study so far with younger and older adults has used alluring faces along with happy faces to examine emotion perception abilities, and found a linear decrease in emotion perception ability with age for both positive and negative emotions (Lambrecht, Kreifelts, & Wildgruber, 2012).

Similarly, despite the focus on goals of motivation models, most studies have yet to explicitly investigate older adults' specific goals in emotion perception, making it difficult to apply the principles of SOC to evaluate the effect of motivational processes on emotion perception outcomes. Selective engagement is thought to play a role in task engagement and subsequent performance in emotion perception, but this effect has not yet been adequately applied to the study of age differences in emotion perception. In daily life, we interact more with dynamic facial expressions than static ones, and it is possible that static images of strangers' posed facial expressions are neither familiar nor relevant to older adults.

Motivation to process context is another approach that merits further consideration. Older adults' use of context in cognitive tasks stems from both a motivation to compensate for loss in cognitive abilities, and an involuntary yield to external control of cognitive functioning due to a decline in internal control (Lindenberger & Mayr, 2014), although little is known about the extent to which this hypothesis applies to emotion perception. Only one study so far has addressed this question (Ngo & Isaacowitz, 2015) but future research can investigate whether context processing in emotion perception is a result of changes in cognitive functioning or motivation, or a combination of both.

In addition to considering effects of motivation on context processing, there are a few other models that have not yet been evaluated in emotion perception but may suggest new venues for research that should be further explored. For instance, despite being similar to younger adults in avoidance goals (Nikitin & Freund, 2011), older adults' approach and avoidance goals might affect their performance on negative facial expressions, especially when not all negative emotions promote avoidance (Hutcherson & Gross, 2011). Additionally, the regulatory fit framework posits that individuals engage more with tasks that align with their goals, which then influences judgments and task performance (Higgins, 2005). This theory echoes the predictions of SOC and selective engagement as discussed above. It is possible that within the laboratory environment the means for older adults to succeed in emotion perception are not adequately available. If this is the case, older adults may not be able to reach their goals, leading to decreased task engagement (Higgins, 2000, 2005). Motivational models, and alternative theories, should be considered when interpreting empirical findings in the emotion perception literature.

Conclusion

Motivational models are prominent in the study of emotion and aging, and these models have generated important findings across the research areas of emotional experience, emotion regulation, and emotion perception. At the same time, there is much work to be done in order to align motivational theories with descriptive data about similarities and differences in emotion-relevant processes across adulthood and old age. In particular, studies that test motivational theories against each other rather than only affirming one particular model, and studies that test motivational against nonmotivational theories, will be critical in advancing the field. Only by clearly understanding the limits of motivational influences on emotion across adulthood can we fully appreciate the important role motivational processes can and do play in emotion from younger adulthood into old age.

CHAPTER 20

EMOTIONAL DEVELOPMENT IN ADOLESCENCE

Leah H. Somerville

Adolescence is a phase of the lifespan marked by dynamically changing emotional experiences, which are multiply determined by sociocultural, psychological, and neurobiological factors. Though adolescence follows childhood and precedes adulthood, it is not the case that adolescents' emotional behavior is a straightforward hybrid of earlier and younger ages. On the contrary, the emotional experiences and behaviors of adolescents are demonstrably unique. Adolescents' emotional experiences are robust and variable, emotional cues can strongly "trip up" their self-regulatory capacity, and certain contexts—most prominently, social contexts—powerfully shape adolescents' emotional experiences.

In this chapter, I highlight descriptive and empirical research that begins to characterize how adolescents' emotional experiences and behaviors are unique and the neurodevelopmental mechanisms that contribute to adolescents' unique emotions. In the first section of this chapter I consider the unique emotional landscape adolescents face, and their phenomenological experience of emotion. In the second section, I address what emotional subprocesses are dynamically changing through adolescence by highlighting empirical work that is capable of teasing apart different "ingredients" of affective experiences. In the third section, I propose a key role for brain development in "tipping" adolescents toward emotional reactivity in certain contexts.

The Emotional Landscape of Adolescence

What Is Adolescence, and How Do We Study Adolescents' Emotional Lives?

Adolescence is defined of a phase of the lifespan that begins around the transition into physical puberty and ends when an individual reaches adult-like levels of independence. As such, there are no particular ages that accurately encompass this phase of the lifespan for all individuals, and the boundary even within an individual is fuzzy at best. The earliest indicators of physical puberty occur around 10 years of age for girls and 11½ years of age for boys (Herman-Giddens et al., 1997; Herman-Giddens, Wang, & Koch, 2001), though there is substantial variability in age of onset. Whereas 18 years of age constitutes the legal definition of adulthood in the United States, the psychological endpoint of adolescence is thought to be the achievement of adult levels of independence and self-regulatory competence. The attributes that mark the achievement of the adult transition are highly dependent on culture (Arnett, 2012; Schlegel & Barry, 1991).

It should be acknowledged that research findings presented in this chapter define "adolescence" in different ways, a reflection of the struggle to place precise boundaries around this phase of the lifespan. A simple strategy is to operationalize adolescence as "the teen years" of 13–17, though scientists commonly voice the limitations of this approach and call for more sophisticated metrics that incorporate sex, hormonal changes, and other variables (Crone & Dahl, 2012). Another way of sidestepping this issue is to avoid categorical age comparisons altogether, instead measuring a wide range of ages and testing continuous linear and nonlinear models of age-related differences on the variables of interest (e.g., Somerville et al., 2013). Many research findings subdivide early and late adolescent phases given the heterogeneity of this phase of the lifespan, with pubertal hormonal being most prominent in "early" adolescence (approximately 12–14 years) and stressful transitions to independence more common in "late" adolescence (approximately 15–18 years). That said, the field is not yet sufficiently refined so as to pinpoint "early" and "late" changes in adolescent emotional processes.

Emotions have been defined as coordinated responses to salient environmental inputs that manifest at multiple levels (e.g., Scherer, 2005), including *affect* (subjective experiences of valence and arousal), *physiology* (arousal and stress responses via the peripheral nervous system), *expression* (facial, verbal, or action tendency), and in *appraisals* (cognitive evaluation of significance to self). In recent years, the coordinated nature of emotional reactions has been subject to intense debate (Barrett, 2006; Mauss, Levenson, McCarter, Wilhelm, & Gross, 2005). Indeed, developmental changes in the degree of coordination itself could serve as a key mechanism underlying emotional development from childhood to adulthood. However, scant attention has been given to this issue thus far. As such, this chapter addresses the emotional challenges faced by adolescents, what is known about the development of different emotional subprocesses, the capacity to *regulate* (or alter emotional reactions once they are evoked), and the *modulatory influence* of emotion on concurrent information processing, without assuming anything about their coordination or lack thereof.

Concurrent Emotional Challenges in Adolescence

A primary feature of the adolescent transition is the need to navigate an environment that demands increasingly complex decision making and independent self-regulation. While adolescents function with more independence than they did during childhood, they must also take on more responsibilities at home, school, and in their social relationships (Larson, 2001; Spear, 2000). Yet they have a relatively shallow experience base to draw from in making independent choices, resulting in trial-and-error style navigation through complex decisions. In many cultures, concerns with academic and personal achievement become salient during this time of life as individuals face life-altering decisions concerning future educational and occupational goals (Csikszentmihalyi & Larson, 1984). Physical changes such as growth spurts, pubertal hormonal surges (Forbes & Dahl, 2010; Sisk & Zehr, 2005), and shifts in endogenous sleep patterns that "mismatch" the modern world (Peper & Dahl, 2013) are common in adolescence and can be experienced as quite stressful (Spear, 2000). Psychosocial models of adolescent development refer to these simultaneous domains of change as representing a "pileup" of emotional stressors (Petersen, 1988), highlighting the challenge adolescents face in managing concurrently changing bodies, relationships, and responsibilities.

A critical domain of change in adolescents' daily experiences is in the social realm, as adolescents strive to identify with increasingly complex and salient social groups (Pfeifer & Peake, 2012; Somerville, 2013). Adolescents spend less time with their family members than children do and more time with their peers (Barnes, Hoffman, Welte, Farrell, & Dintcheff, 2007). Family interactions are generally less warm and more prone to conflict compared with childhood (Smetana, 1995), a pattern that typically resolves into the transition out of adolescence (Steinberg, 1990). A large meta-analysis demonstrated that affective intensity is a key factor in adolescent family conflict: When family conflict occurs, it is accompanied by more intense affect in midadolescence relative to both early and late adolescence (Laursen, Coy, & Collins, 1998).

At the same time, peer groups become larger and more complex, and adolescents spend more time interacting with peers both digitally and in person (Barnes et al., 2007; Larson, 2001; Lenhart, Ling, Campbell, & Purcell, 2010) compared with childhood and adulthood. This rise in peer interaction is not unique to humans. For example, "adolescent"-age rats display a preference for social interaction (Douglas, Varlinskaya, & Speak, 2004) and spend more time engaged in social play than adult rats (Primus & Kellogg, 1989). While peer relationships become increasingly important and time-consuming in adolescence, they also tend to be unstable. Social networks fluctuate rapidly in adolescence (Cairns, Leung, Buchanan, & Cairns, 1995), thus instances of social acceptance and rejection become commonplace (Cairns et al., 1995; Wang, Iannotti, & Nansel, 2009).

Adolescents' Reported Affect

The previous section implies that adolescents' day-to-day environment is uncertain and stressful. Although the unique challenges faced by adolescents are very real, their daily reports of affect are far less extreme than the classic "storm-and-stress" stereotype (Hall, 1904) would suggest. Experience sampling studies show that adolescents report their daily affect as overall more positive than negative (as in younger and older ages; Larson, Moneta, Richards, & Wilson, 2002; Weinstein, Mermelstein, Hankin, Hedeker, & Flay, 2007). However, the frequency of positive affect over a given week reduces from early- to midadolescence (Larson et al., 2002; Weinstein et al., 2007) while the frequency of negative affect sharply rises from preadolescence to midadolescence (Larson et al., 2002). Furthermore, adolescents' daily affect fluctuates more in midadolescence compared with preadolescence (Rutter, Graham, Chadwick, & Yule, 1976), as indicated by greater cross-measurement variance in experience sampling over a 1-week period (Larson et al., 2002).

The social context is highly evocative of emotion during adolescence, with concern over social evaluation rising sharply from childhood (Westenberg, Drewes, Goedhart, Siebelink, & Treffers, 2004). Adolescents more frequently interpret themselves as being the target of social evaluation (leading to such phenomena as the *imaginary audience*; Elkind & Bowen, 1979), and reported daily self-conscious emotion reaches peak levels (Rankin, Lane, Gibbons, & Gerrard, 2004). As such, social feedback and perceived instances of social evaluation are thought to be a potent antecedent to both positive and negative affect in adolescence (Somerville, 2013), a possibility that is explored in detail in the next section.

During adolescence, emotional disturbances (e.g., Kring, 2008) also manifest in rapidly rising incidence of psychopathology. Epidemiological studies indicate that over half of lifetime cases of mood, anxiety, conduct, and substance abuse disorders are identified by midadolescence, and adolescence is the most common stage of development to initially present with depression and anxiety disorders (Beesdo, Knappe, & Pine, 2009; Burke, Burke, Regier, & Rae, 1990; Costello, Mustillo, Erkanli, Keeler, & Angold, 2003; Kandel & Davies, 1982; Kessler et al., 2005). Furthermore, individuals who show an onset of clinical and subclinical symptoms of psychopathology in adolescence have greater severity and chronicity of psychopathology across the lifespan (Hofstra, van der Ende, & Verhulst, 2002; Pine, Cohen, Gurley, Brook, & Ma, 1998).

Subclinical emotional disturbances are alarmingly common in adolescence as well. The Youth Risk Behavior Survey (YRBS; Eaton et al., 2008), a large-scale survey of health risk behaviors in adolescents, found that in the prior year, more than one in four adolescents (27.3%) had experienced significant symptoms of depression for at least 2 weeks, to the point that it interfered with his or her everyday functioning. Because adolescence represents a unique phase of simultaneous vulnerability for emotional disturbance and developmental malleability to intervention and training, clinical science has taken a keen interest in leveraging the plasticity of neurodevelopmental and behavioral change to target adolescent-specific interventions that could ultimately improve lifelong health (see Steinberg et al., 2006, for further discussion).

The Development of Emotional Subprocesses in Adolescence

At any given moment, an emotional state is a product of the psychological and physiological processes that generate an emotional response, and that contextualize, regulate, or otherwise alter such responses. Metaphorically speaking, is the emotional "temperature" of adolescence higher due to differences in "heating" (emotional reactivity), "cooling" (regulation), or both? When emotional reactivity and regulatory demands come into conflict, which ultimately guides behaviors and choices? A new wave of experimental research has begun to tease apart the developmental changes in emotional subprocesses that contribute to these behavioral tendencies. Together, these studies suggest that under some contexts, adolescents evoke exaggerated emotional reactivity patterns, which are paired with a still-maturing regulatory capacity. These behavioral patterns are paralleled by dynamic trajectories of brain development through this stage of life. Overall, this work supports the notion that dynamic interactions among emotional subprocesses give rise to unique emotional response profiles in adolescence.

Emotional Reactivity

How do adolescents react to emotional provocation? For the few studies that measure "pure" emotional reactivity (in the absence of competing or regulatory demands), the emerging answer appears to be "It depends what the provocation is, and how you measure it." Self-report studies have probed whether subjective affect (such as the strength of negative affect) differs in children, adolescents, and adults in response to passively viewing negative International Affective Picture System (IAPS) pictures (Lang, Bradley, & Cuthbert, 2008). The results of multiple studies have demonstrated that affective self-report measures of "reactivity" to negative images are comparable when comparing adolescents with individuals of older and younger ages (McRae et al., 2012; Silvers et al., 2012).

These findings contrast with measurements of adolescents' affective reactions within the social context. As stated earlier, social relations take on prime importance during adolescence. In response to laboratory manipulations designed to deliver supposedly genuine social acceptance and rejection cues, adolescents experience a greater drop in self-reported mood and greater increase in anxiety than adults do when excluded from a virtual ball-tossing game with a supposed peer (Sebastian, Viding, Williams, & Blakemore, 2010), and a greater self-reported increase in mood when receiving socially accepting feedback from a desirable peer (Guyer, Choate, Pine, & Nelson, 2012). Further, Silk and colleagues (2012) used eye tracking—an indirect measure of salience processing—to target implicit emotional and motivational responses to being accepted or rejected by peers for an online chat. Although all participants (9–17 years) showed a pupil difference to rejecting compared with accepting trials, this response was exaggerated in older adolescents. Further, heightened pupillary responses to rejecting social feedback predicted less connectedness in participants' real-life social relationships. Thus, new evidence is mounting to suggest that receiving social feedback elicits exaggerated positive and negative affective reactions in adolescents.

A related issue is whether the simple act of *being evaluated* is sufficient to generate strong emotional reactions in adolescents. Adolescents who underwent the Trier Social Stress Test (a laboratory-based social evaluative battery) experienced a greater release of cortisol (a potent stress hormone and index of hypothalamic–pituitary–adrenal [HPA] axis reactivity) compared with adults and preadolescents (Gunnar, Wewerka, Frenn, Long, & Griggs, 2009). Further, social conditions sufficient to evoke strong emotion in adolescents are quite minimal; a recent study (Somerville et al., 2013) demonstrated that merely being looked at by a peer yielded a rise in self-conscious affect (peaking at age 16) and autonomic nervous system arousal (peaking at age 14) as measured by skin conductance response (Dawson, Schell, & Filion, 2001). These findings indicate that the social environment is a potent emotional context for adolescents, who show exaggerated subjective affect and biological markers of affective response to overt feedback and even to simply being evaluated. This work is highly relevant to translational goals of determining the causes of, and potential interventions for, links among ostracism, symptoms of depression, and risk of suicide, particularly among adolescent girls (Hall-Lande, Eisenberg, Christenson, & Neumark-Sztainer, 2007; Lewinsohn et al., 1994).

Emotion Regulation

Classic research from cognitive development suggests that cognitive regulatory capacity continues to improve from childhood to adulthood in a progressive fashion (Davidson, Amso, Anderson, & Diamond, 2006; De Luca et al., 2003; Huizinga, Dolan, & van der Molen, 2006). Given that emotion regulation scaffolds on cognitive regulation, one might expect that from childhood through adolescence and into adulthood, the capacity to effectively engage emotion regulation continues to improve, a topic of recent study.

Reappraisal is a form of emotion regulation whereby an individual attempts to alter the meaning of an emotional cue through cognitive reinterpretation. Greater reductions in negative affect are observed after reappraisal than other emotion regulation techniques (Gross, 1998, 2002), indicating that reappraisal is a particularly effective form of emotion regulation. Reappraisal relies on numerous, complex cognitive processes, including working memory, abstract reasoning, and response selection (Ochsner & Gross, 2005). This has led scientists to speculate that reappraisal ability might be a late-developing psychological capability that contributes to adolescents' emotional reactivity (Silvers et al., 2012). Indeed, though adolescents make use of this regulation technique more effectively than children (Williams & McGillicuddy-De Lisi, 1999), they utilize reappraisal strategies in their daily lives less frequently than adults do (Garnefski, Legerstee, Kraaij, Van Den Kommer, & Teerds, 2002).

Silvers and colleagues (2012) asked 10- to 22-year-old participants to view negatively valenced images and reappraise their reaction to them so as to reduce their negative impact. Results showed robust age differences in the efficacy of reappraisal in reducing negative affect relative to a passive viewing condition, with increasing age predicting greater regulatory success. This finding is consistent with results of a similar study undertaken in the functional magnetic resonance imaging (fMRI) environment (McRae et al., 2012). Intriguingly, adolescents' reappraisal capacity was selectively worse for images depicting negative social interactions and social suffering (Silvers et al., 2012). This reduction was not observed for younger or older ages, suggesting that reappraisal might be especially challenged by potent social cues during adolescence.

Influence of Emotion on Cognition

Emotional content can modulate numerous cognitive processes, including memory, attention, and cognitive control. Experimental approaches in the cognitive tradition test the extent to which emotional cues modulate cognitive processes (e.g., cognition–emotion interactions) with differential strength across developmental stage. Taken together, this work demonstrates that adolescents' cognitive capacity is especially perturbed by emotional information, though the outcome of cognition–emotion interactions depends heavily on the context in which emotional cues are introduced.

We all know how difficult it is to ignore emotional cues: Imagine trying to focus on reading at a café while a patron is laughing or crying at a neighboring table. In this scenario, the presence of emotional cues captures attentional resources (Easterbrook, 1959; Fox, Russo, Bowles, & Dutton, 2001), selectively interrupting performance on a separate task. How capable are adolescents of disengaging from irrelevant emotional information to complete a primary task?

Cohen-Gilbert and Thomas (2013) asked children, adolescents, and adults to complete a go/no-go task where participants viewed rapidly presented target cues, and were to respond with a button press to a frequent go target, and withhold that response from a rare no-go target. For some trials, the screen backgrounds incidentally depicted arousing positive and negative images, while in others the background depicted a scrambled image. Task performance in the scrambled condition steadily improved across adolescence, consistent with the notion that behavioral regulation continues to improve during this time of life. However, task performance was disproportionally impaired in early adolescents (13- to 14-year-olds) when negative images served as backgrounds, relative to other ages and relative to their own performance on the neutral background trials. Similarly, adolescents show exaggerated response slowing while making physical judgments of faces posing fear relative to no expression (Monk et al., 2003), while detecting fearful relative to neutral target stimuli (Hare et al., 2008), and in a flanker task with fearful face distractors (Grose-Fifer, Rodrigues, Hoover, & Zottoli, 2013). These findings suggest that emotional distractors (in this case, negatively valenced ones) can inordinately disrupt performance on simple cognitive tasks in adolescence more than in earlier and later ages.

A related but distinct form of cognitive–emotion interaction entails placing the emotional content as the *target* of control. The emotional go/no-go task quantifies the relative influence of emotional content on the capacity to flexibly approach and withhold behavioral responses (Tottenham, Hare, & Casey, 2011). Of particular interest are differential commission rates (failing to withhold a response) depending on the emotional qualities of the stimulus. Are adolescents less capable of stopping themselves when a stimulus holds affective value? A study comparing children, adolescents, and adults found that adolescents were selectively worse than both children and adults at withholding a response toward emotionally arousing happy faces relative to emotionally neutral faces (Somerville, Hare, & Casey, 2011;, see Figure 20.1). Preliminary findings also show that emotion-impaired impulse control in adolescents might also be evident for fearful facial expressions (Dreyfuss, Caudle, Drysdale, Johnston, Cohen, et al., 2014), suggesting that it is perhaps the arousal value (rather than positive valence per se) that interferes with adolescents' reduced regulatory capacity.

These findings indicate that emotional content is particularly disruptive to cognitive performance when emotional information is (1) a distractor, or (2) the target of regulatory demand. However, an intriguing line of research suggests that adolescents' sensitivity to affectively salient cues can be "flipped" to selectively *improve* regulatory capacity in adolescents—that is, the promise of an affec-

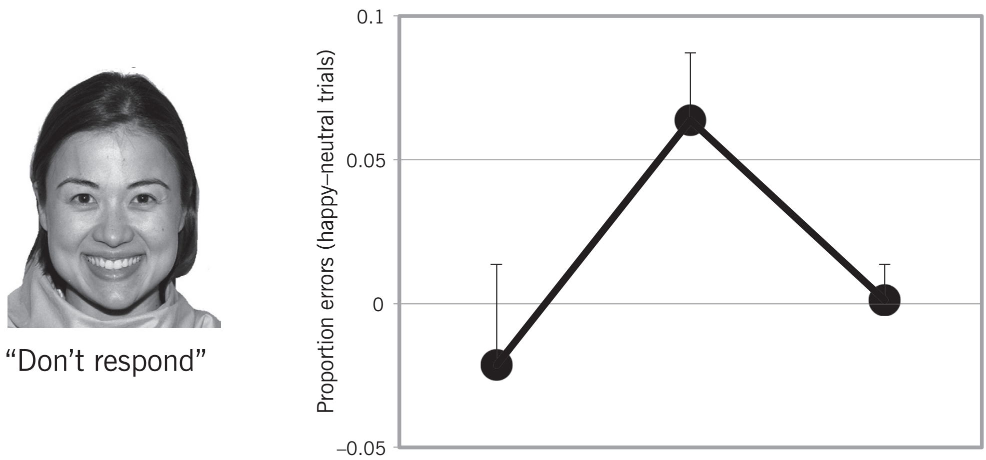

FIGURE 20.1. (*Left*) Sample "emotion no-go" trial from emotional go/no-go task. Participants view faces depicting emotional or neutral expressions and are instructed at the beginning of a task block to respond to ("go"), or withhold a response from ("no-go"), a face stimuli depending on the expression. (*Right*) False-alarm rates for emotional relative to neutral no-go trials. Adolescents were selectively impaired at withholding a response to arousing, happy faces relative to neutral faces as compared with children and adults.

tively salient *outcome* (such as monetary reward) results in a greater boost of cognitive regulation in adolescents than adults (Geier, Terwilliger, Teslovich, Velanova, & Luna, 2010; Hardin, Pine, & Ernst, 2009; Jazbec et al., 2006; Kohls, Petzler, Hepertz-Dahlmann, & Konrad, 2009; Padmanabhan, Geier, Ordaz, Teslovich, & Luna, 2011; see Somerville & Casey, 2010, for further discussion of this issue).

These findings underscore the notion that interactions between regulatory demands and affective/motivational load are highly context dependent. Overall, adolescents' regulatory capacity is especially swayed by emotional content. This can result in selectively disrupted or improved performance, depending on the contextual positioning of the affective information—as distractor, target, or outcome.

Decisions and Risk

A final line of work in this domain concerns whether emotional factors modulate adolescents' decision making. This research is motivated by alarming health statistics indicating that the top four causes of adolescent mortality are preventable (Eaton et al., 2008), and partially result from the dire outcomes of suboptimal decision making (Casey & Caudle, 2013; Steinberg, 2004). In particular, adolescents engage in significantly more risky driving, illicit drug use, criminal acts, and unsafe sexual behavior than children and adults (National Research Council, 2007; Substance Abuse and Mental Health Services Administration, 2007).

Intriguingly, adolescent risky decision making does not appear to be a product of lacking information about risk, poorly estimating risk, or lacking the capacity to make calculated decisions involving risk (Reyna & Farley, 2006). Further, although adolescents experience more freedom and less supervision by parents, risky decision making cannot solely be explained by greater access to risk-enabling situations, as an orientation toward risk can also be elicited in controlled laboratory settings and in animal models. Thus, researchers have sought more nuanced psychological explanations for adolescents' propensity toward risk. This work has indicated that emotional factors, including a motivation toward arousing and novel experiences, paired with contextual factors, play a key role in the uptick of risky behavior in adolescence (Albert, Chein, & Steinberg, 2013).

Sensation Seeking

Sensation seeking is a key psychological variable that plays an important role in adolescent risk taking. Sensation seeking is defined as the motivation to seek out complex, novel, and arousing experiences; adolescents endorse greater sensation-seeking motivation than adults do (Zuckerman, Eysenck, & Eysenck, 1978). Animal models of adolescence support this conception. A variety of behavioral indices of novelty seeking and risk-taking behavior reveal that "adolescent"-age rodents exhibit greater novelty seeking, reduced behavioral markers of anxiety to novelty, greater willingness to engage in "extreme" behavior, and more risky actions in navigation-based assays such as the elevated plus maze (see Laviola, Macri, Morley-Fletcher, & Adriani, 2003, for a review). Orientation toward novelty seeking could represent an advantageous mode of interacting with the environment during adolescence from an evolutionary perspective, given the heightened demands on adolescents to find novel territories, mates, and resources (Doremus-Fitzwater, Varlinskaya, & Spear, 2010; Ellis et al., 2012; Spear, 2000).

In addition to sensation seeking, one can examine the extent to which adolescents utilize emotionally relevant information (concerning the gain and loss of resources) in decision making. Cauffman and colleagues (2010) used the Iowa Gambling Task to quantify approach- and avoidance-based decision making in children, adolescents, and young adults. Using experimenter feedback to learn to approach "good" decks of cards (positive feedback) and avoid "bad" decks (negative feedback), experimenters measured participants' tendency to make decisions based on seeking reward and avoiding punishment. They found that levels of approach toward potential reward took on a curvilinear function, with the maximal sensitivity to positive feedback occurring during the adolescent years. In contrast, use of negative feedback to avoid negative outcomes strengthened with age in a linear fashion, not showing full maturity until the adult years. These findings suggest that adolescents have a disproportionate approach orientation, paired with a still-maturing avoidance orientation, which could strongly propel adolescents toward risky choices.

Decision Making in Affectively Charged Contexts

Recent work has highlighted the selectivity of risky behavior in adolescents. Though adolescents display an orientation toward novelty and sensation seeking, adolescents do not reveal these tendencies in all situations, leading some studies to find no evidence for risky decision making in adolescents (e.g., Van Leijenhorst, Westenberg, & Crone, 2008). This has led scientists to identify the particular contexts in which adolescents' decision-making capacity is swayed toward risk, focusing on (1) arousing or exciting contexts and (2) social contexts.

One task that can capture decision making in affectively "hot" relative to "cold" contexts is the Columbia Card Task, a risky decision-making task in which participants make odds-based gambling decisions in cold contexts that are designed to encourage deliberative decision making, or hot contexts with high emotional arousal (Figner, Mackinlay, Wilkening, & Weber, 2009). Adolescents showed greater risky decision making than children and adults, but selectively in the arousing hot context (Figner et al., 2009). Within the hot contexts, adolescents tended to disregard the information about the odds of gain and loss and report greater reliance on "gut-level" and "excitement" cues to shape their choices (ultimately impairing their performance more than younger and older ages). These findings and others (Burnett, Bault, Coricelli, & Blakemore, 2010; van Duijvenvoorde, Jansen, Visser, & Huizenga, 2010) support the notion that contexts with heightened arousal or salience selectively push adolescents' decision making toward riskiness. This conclusion mirrors adolescent risk taking in the real world, which often occurs in thrilling, exciting contexts (Casey & Caudle, 2013).

The social context can also propel adolescents' decision making in the direction of risk. Adolescents are more likely to make dangerous moves behind the wheel of a car in the presence of peers (Simons-Morton, Lerner, & Singer, 2005), and crime statistics indicate that adolescents are more prone to deviant behavior when with others than when alone (Zimring, 1998). The tendency to engage in risky choices in social contexts is also observed in the laboratory using simulated driving tasks (Chein, Albert, O'Brien, Uckert, & Steinberg, 2011; Gardner & Steinberg, 2005) and delay discounting tasks (O'Brien, Albert, Chein, & Steinberg, 2011; Weigard, Chein, Albert, Smith, & Steinberg, 2014; see Albert et al., 2013, for further discussion). There are many potential mechanisms underlying peer influence, including enhanced desire for impression management, peers introducing a "cognitive load," the capacity for peers to shift orientation toward reward (e.g., Chein et al., 2011), and heightened physiological and emotional arousal around peers and in contexts of peer evaluation (e.g., Somerville et al., 2013). Though the phenomenon of peer influence on adolescent risk taking is evident, more work is needed to clarify the underlying psychological mechanisms of peer influence.

Individual Differences Stratify during Adolescence: The Case of Developmental Timing

Though emotional responses are subject to individual differences at all points in the lifespan, variability seems to be particularly pronounced during adolescence. To take one example, a recent paper reported scatter plots for 9- to 22-year-olds' subjective, physiological, and neural reactivity patterns to being looked at by a supposed peer (Somerville et al., 2013). In all three graphs, the response variability stratifies during the adolescent years relative to earlier and younger ages. Why might this be? One critical factor is developmental timing, as age is a limited proxy for actual developmental stage. The onset of physical puberty varies across individuals as much as 4–5 years, with females tending to initiate puberty earlier than males. Widespread hormonal and neurodevelopmental changes underlying physical puberty sensitize physiological reactivity to stressors (Gunnar et al., 2009; Romeo, 2010), suggesting that some aspects of affective responding are more dependent on pubertal-dependent mechanisms than age-dependent mechanisms. In addition, early puberty can become an antecedent to emotional difficulties, as early puberty in females (relative to one's peers) predicts psychosocial difficulties during adolescence, risk for psychopathology, and delinquent behavior (Ge, Rand, & Elder, 1996). Therefore, developmental timing interacts with emotional functioning in complex ways during adolescence. Fortunately, the field is experiencing a surge of interest in teasing apart age- or experience-dependent mechanisms from pubertal-dependent mechanisms of adolescent emotional development (e.g., Crone & Dahl, 2012), which will lead to a more complete understanding of sources of variability in adolescent emotional response.

Neurodevelopmental Mechanisms of Adolescent Emotional Behavior

What role does the developing brain play in shaping adolescents' emotional experiences? In recent years, research has begun to uncover the unique biological contributions to adolescent emotional behavior. Key properties of brain development through adolescence (and hormonal fluctuations that influence brain function) are thought to play a mediating role in adolescents' propensity for frequent and intense emotional reactions, and for the influence of emotion on cognitive and decision-making behavior.

This theoretical framework stems from neurobiological models of the neural circuits that subserve valuation and regulation signals. In the past two decades, advances in neuroscientific tools have enabled a precise characterization of the neural systems that subserve affective processes, regulatory processes, and interactions between them that ultimately shape affective and behavioral outcomes. As such, measurements of brain development and brain function can offer insight into the constituent and interacting roles of emotion-generative and emotion regulatory processes in shaping adolescent emotional behavior.

Though the human brain reaches 95% of its adult size by middle childhood, the structure and function of the brain continue to change dynamically throughout adolescence and young adulthood. A key principle of neurodevelopment is that functionally distinct neural systems reach maturity in a staggered fashion. For instance, sensory and motor circuits undergo rapid development in infancy and toddlerhood, supporting the key environmental demands of this time of life (navigation, perception, learning), whereas other networks, including circuitry that supports inhibitory control and abstract reasoning, undergo major developmental refinement at a much later point (Casey, Galvan, & Hare, 2005).

This principle of staggered emergence of neurocircuitry can partially account for adolescents' propensity to emotional reactivity relative to both younger and older ages (Somerville & Casey, 2010; Somerville, Jones, & Casey, 2010). On one hand, brain circuitry that supports emotional and cognitive regulation is thought to be among the "final frontiers" of neurodevelopment, and continues to develop linearly throughout adolescence into early adulthood. On the other hand, brain circuitry that supports emotion- (and motivation-) generative processes is (1) largely structurally mature; and (2) functionally sensitized, due in part to pubertal modulation of neurotransmitter systems that affect brain function uniquely in adolescence (Figure 20.2). The combination of sensitized emotion-generative and intermediate emotion regulatory processes is thought to represent a developmentally normative "imbalance" within neural systems that could lead to a heightened influence of emotional processes on affective behavior and decisions. This

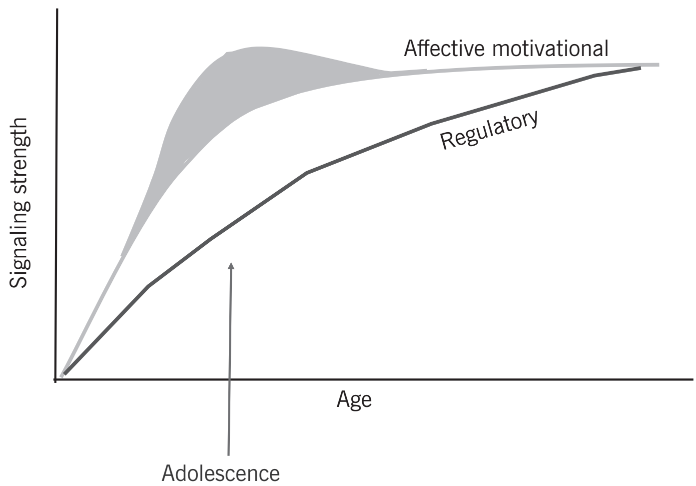

FIGURE 20.2. Cartoon diagram of "staggered emergence" hypothesis of adolescent emotional sensitivity. Early maturation of subcortical limbic regions such as the amygdala and ventral striatum (gray line) and functional sensitization (gray shaded area), combined with late maturation of regulatory strength subserved by the prefrontal cortex (black line), predicts a nonlinear enhancement in affectively driven behavior during adolescence.

framework distinguishes adolescents' brain function from both *adults*, who have mature regulatory capacity and less sensitized emotion-generative function, and *children*, who lack mature regulatory capacity but do not have such strong input from emotion-generative circuitry.

Similar versions of this framework have been put forth by various research teams (Ernst, Pine, & Hardin, 2006; Geier & Luna, 2009; Somerville et al., 2010; Steinberg, 2008; see Casey, 2015, for a discussion of differences among models). Though criticized for oversimplicity (Crone & Dahl, 2012) and for somewhat inexact neural hypothesis (Pfeifer & Allen, 2012), the staggered emergence or "imbalance" framework has received support from rodent, primate, and human data and presently represents a dominant viewpoint among the neurodevelopmental community.

Complex emotional behavior relies on interactions across a widespread network of brain structures (Lindquist, Wager, Kober, Bliss-Moreau, & Barrett, 2012). Due to the youth of the field, developmental models currently lack a comprehensive understanding of the full-scale network interactions that change across adolescence. A more common (albeit limited) approach thus far has been to pinpoint the structural or functional differences across development in particular subparts of emotion networks. As such, this discussion is inherently limited in addressing large-scale, network-based neurodevelopment (though it should be noted that domains of cognitive development have incorporated a sophisticated network-based developmental approach (Fair et al., 2007; Schlaggar et al., 2002). The next section briefly introduces three brain structures whose dynamic interactions are thought to uniquely influence the interaction among emotional, motivated, and regulatory behaviors in adolescence.

The Ventral Striatum

One critical player in this circuitry is the ventral striatum, a portion of the basal ganglia that contains the nucleus accumbens (NAc). The NAc contributes to decision-making behavior by signaling the anticipation and attainment of rewards, and serves to influence motivated behavior via connections with the prefrontal cortex (Cardinal, Parkinson, Hall, & Everitt, 2002; Delgado, 2007; Schultz, 2006).

Numerous studies have examined neural activity in response to the receipt or loss of monetary incentive or prizes. These studies show that the magnitude of neural response in the ventral striatum is exaggerated in adolescents as compared with children and adults (Cohen et al., 2010; Ernst et al., 2005; Galvan et al., 2006; Van Leijenhorst et al., 2010), and after pubertal onset relative to just before (Pfeifer et al., 2011). There is strong evidence from animal models to suggest that signals of the dopaminergic neurotransmitter system are sensitized in adolescence, a finding that specifies a key mechanism underlying the functional sensitization of the ventral striatum during this phase of life (see Spear, 2000; Ernst, Romeo, & Andersen, 2009, for a review).

The Prefrontal Cortex

Second, the prefrontal cortex has been implicated in wide-serving cognitive functions, including the implementation of cognitive control, regulation of emotion, decision making, and complex cognition (Casey et al., 2005; Miller & Cohen, 2001; Ochsner & Gross, 2005). Regions of the prefrontal cortex continue to reach structural and functional maturity throughout the adolescent years (Shaw, Kabani, Lerch, Eckstrand, Lenroot, et al., 2008; Somerville et al., 2011), and the connections between subcortical and cortical structures continue to strengthen (e.g., Asato, Terwilliger, Woo, & Luna, 2010; Liston, Watts, Tottenham, Davidson, Niogi, et al., 2006). As such, the final frontal maturational events that take place during adolescence are thought to limit the strength and efficiency of regulatory behavior, including emotion regulation. Brain imaging studies have shown that less robust regulatory signaling from the prefrontal cortex in adolescents parallels worse performance on a number of inhibitory control tasks, supporting the idea that functional maturity of the prefrontal cortex is a key factor in the ability to exert cognitive (and likely emotional) control (Luna et al., 2001; Rubia et al., 2006).

The Amygdala

Finally, the amygdaloid complex, bilateral clusters of nuclei situated in the medial temporal lobe, plays a critical role in processing information of biological significance (Aggleton, 2000; Davis & Whalen, 2001; LeDoux, 2000), including emotionally evocative stimuli, potential threats, and cues depicting the emotional states of conspecifics. A growing number of studies are reporting that the amygdala response to salient information is exaggerated in adolescents relative to children (Hare et al., 2008) and adults (Guyer, Monk, McClure-Tone, Nelson, Roberson-Nay, et al., 2008; Hare et al., 2008; Monk et al., 2003; Williams, Brown, Palmer, Liddell, Kemp, et al., 2006; see Somerville, Fani, & McClure-Tone, 2011, for a review). Further, these effects are influenced by pubertal development. Longitudinal investigations have demonstrated that the amygdala and prefrontal cortex response while viewing sad facial expressions (but not other expressions) is significantly greater after pubertal onset than just prior (Moore, Pfeifer, Masten, Mazziotta, Iacoboni, et al., 2012). Together, these studies suggest that emotionally salient stimuli recruit a stronger amygdala response in adolescents, perhaps reflecting their social communication value during a time of life characterized by social reorientation (Crone & Dahl, 2012; Nelson, Leibenluft, McClure, & Pine, 2005). However, rodent research is mixed with regard to how amygdala function differs in adolescence relative to childhood and adulthood (see Spear, 2011, for an alternative view).

From the Brain Back to Emotional Behavior

Based on the available evidence, it is clear that adolescent brain function is unique in its combination of (1) exaggerated incentive-based responding in the ventral striatum, (2) intermediate regulatory capacity via the continually developing prefrontal cortex, and (3) a possibly exaggerated amygdala response to affectively salient cues. What are the consequences of the functional "imbalance" just described for adolescents' emotional experiences and behavior? Returning to the temperature metaphor, one possibility is a combination of both "overheating" and "undercooling."

Risk-taking behavior is thought to emerge, in part, due to the capacity for strong-signaling regions of the striatum that code motivation and learning about potential rewards to "override" regulatory capacity in adolescence. In other words, the adolescent brain is thought to deliver a motivational push toward novel, exciting, and potentially rewarding situations. Such an explanation is bolstered by experimental studies simultaneously measuring behavioral performance and brain activity. For instance, failing to withhold a button response to arousing happy faces in adolescence was paralleled by exaggerated ventral striatal responding and exaggerated striatocortical functional connectivity (Somerville et al., 2011). In addition, adolescents demonstrated unique patterns of interactions between the ventral striatum and prefrontal cortex while "working for a reward" (Geier et al., 2010), and correlational evidence links ventral striatal reactivity to a monetary reward and a tendency to take risks in the real world (Galvan, Hare, Voss, Glover, & Casey, 2007). Ventral striatal responding is also exaggerated in adolescents while making risky decisions around peers compared with making similar decisions when alone (Chein et al., 2011), suggesting that arousing peer contexts might trigger a hyperreactive incentive–motivation system and promote risky decisions.

Studies involving the processing of aversive stimuli suggest that adolescents' proneness to emotional interference might arise from exaggerated salience-detection responses. For instance, Hare and colleagues (2008) demonstrated that the amygdala response to fearful faces was exaggerated in adolescents relative to children and adults, and predicted an exaggerated response slowing to fearful faces. More work is required to determine (1) whether salience processing systems of the brain are hypersensitive in adolescence, and (2) what kind of influence they might have on the day-to-day emotional functioning of adolescents. The relationships among brain function in adolescence, daily moods, and subjective affect are largely unknown, due to an extreme dearth of data that sample subjective affect and brain activity, paired with an inability to leverage animal models.

Finally, one can consider whether a still-maturing prefrontal cortex can accomplish emotion regulation as flexibly and effectively as adults can. Recall that behavioral studies of reappraisal indicated that adolescents were less effective than adults at leveraging reappraisal techniques to reduce negative affect (Garnefski et al., 2002; Silvers et al., 2012). McRae and colleagues (2012) observed that adolescents recruited the lateral prefrontal cortex more than children, but less than adults, while engaging in effortful reappraisal of negative images. This finding is consistent with the interpretation that the continuing maturation of the prefrontal cortex might constrain the effectiveness of reappraisal on decreasing negative affect. More work that incorporates subjective reports of regulatory success is needed to better understand the consequences of brain development on this component of emotional behavior.

Conclusions

The aim of understanding emotional development in adolescence and its neurodevelopmental mechanisms is manifold. Through this research, scientists can simultaneously shed light on the psychological development of emotion subprocesses, the fundamental functional properties of brain circuits and their links with emotional behavior, and the fundamental principles and trajectories of neurodevelopment.

Adolescents' emotional experiences differ from older and younger ages in various ways. Their affective states are frequent and intense. The social context is a primary arena in which adolescents exhibit strong affective reactions. In addition, they are at risk for deleterious outcomes of emotional reactivity, including suboptimal decision making in emotionally heated contexts and vulnerability for impairing clinical and subclinical emotional disturbances. Adolescents' cognition and decision-making behavior is prone to emotional influence, and this influence is particularly robust in emotionally charged and social contexts. These patterns reflect the multitude of changes that take place in adolescence ranging from hormonal to physical to psychosocial, to the changing goals that adolescents must learn to achieve with less "regulatory input" from authority figures.

Trajectories of brain maturation contribute to emotional reactivity in adolescence, although a comprehensive and precise model remains a work in progress. Tuning of brain circuitry underlying emotion reactivity and regulation reflects experience-dependent maturation that results from many causes, including normative hormonal shifts and adolescents interacting with their environments. Thus, developmental differences reported here should not be pathologized or interpreted as adolescent deficiencies. Despite the fundamental importance of this developmental phase, the majority of neurobehavioral findings reported here have emerged within the past decade. With a greater volume of comprehensive and careful empirical research, this area will continue to advance toward the dual objective of advancing theory and empirical understand of emotional processes, and translating these findings in ways that improve adolescent health.

PART IV

Social and Personality Perspectives

CHAPTER 21

Gender and Emotion

Theory, Findings, and Context

Leslie R. Brody, Judith A. Hall, and Lynissa R. Stokes

Gender differences in emotion are widely documented, but are often inconsistent across personality, social, cultural, and situational variables, as well as types of emotional processes, specific quality of emotions, and measurement or task characteristics. This is not surprising, given the multiple processes involved in the umbrella term "emotion," including experiencing, expressing, perceiving, interpreting, and regulating emotions; and the multiple modes of assessing these processes (e.g., physiological arousal, self-report, observational data); as well as the complexity of gender itself. Each type of emotional process is influenced by interpersonal, situational, personality, biological, cognitive, motivational, and cultural factors, as well as interactions among them. The most useful and sophisticated research honors this complexity and attempts to understand the contexts in which gender differences in emotion occur and the moderating and mediating variables that can provide clues as to their nature and etiology.

The Gender Construct

The construct of gender is complex and can be understood through three independent lenses (Greenfield, 2008; Weinrich, 1987). The first lens, core gender identity, includes the conventional categories of men/males/boys and women/females/girls and is usually based on evident anatomy, genetics, assignment at birth, or upbringing. It also includes nonconventional identity as a consequence of ambiguous anatomy or choices made to change the physical or presentational aspects of gender (e.g., intersex, ambigender, transgender, and transsexual persons).

The second lens consists of gender roles (i.e., the behaviors, personality characteristics, occupations, thoughts, and emotions "prescribed" as appropriate for males and females) that are historically and socially constructed. Stereotypic gender roles traditionally associate communion/interdependence/caretaking roles with femininity and agency/independence/instrumental roles with masculinity. Communion and agency are best represented as two independent continua on which an individual can be characterized as having any combination of low or high communal and agentic qualities (Bem, 1981; Spence & Helmreich, 1978).

The third lens, sexual orientation, is also best represented as two independent continua: the degree to which individuals are attracted to women, ranging from not at all to extremely, and on a separate continuum, the degree to which they are attracted to men, also ranging from not at all to extremely (Greenfield, 2008). Terms used to reflect sexual orientation include "asexual," "heterosexual," "homosexual," "bisexual," "gay," and "lesbian," with the umbrella term "queer" used to refer to individuals with nonconventional core gender identity or sexual orientation. In addition to feelings of sexual attraction, sexual orientation can also include behaviors (the degree to which people act on their feelings) and self-concept (the internalization of a particular sexual orientation, e.g., having a sexual relationship with a same-sex partner does not necessarily translate into having an identity as a homosexual).

These lenses (core gender identity, gender roles, and sexual orientation) are conventionally thought of as binary, when in reality they are not, and people can have not only simultaneously existing multifaceted qualities of each aspect, but can also be fluid as to which qualities are expressed in different contexts. Further, these three aspects of gender are often mistakenly conflated—for example, men who have more "feminine" gender roles are stereotyped to be gay, a conflation that can result in confusion for adolescents who are figuring out their sexual orientation and can result in limited behavior choices for people of all sexual orientations.

In research on gender and emotion, only recently have researchers begun to make nuanced comparisons of emotional processes using all three lenses through which gender can be viewed. Furthermore, when more nuanced comparisons are made they are usually between individuals with different sexual orientations (gay, lesbian, and heterosexual people), not between people with nonconventional gender identities. Research on emotional processes in individuals with nonconventional gender identities would be very helpful in understanding the nature and etiology of gender/emotion relationships, but to our knowledge such research does not exist. Thus, this chapter focuses primarily on differences in emotional processes as a function of the binary gender identity categories that are typically studied (female/male, with the unstated presumption of heterosexuality), and includes research on the differences between heterosexual and homosexual individuals when available.

Gender and Context

Women and men have different life experiences that shape their emotions and are shaped by them, with emotion–experience relationships often taking the form of bidirectional feedback loops. Key among these are (1) culturally prescribed gender roles such as the role of child caretaker versus economic provider; (2) socialization experiences, including cultural display rules, norms that dictate and regulate the quality and intensity of emotions each gender can express; (3) social motives, such as needs for intimacy versus control; (4) power and status imbalances between the two sexes—women typically have lower power and status, have less access to economic and material resources, and are more likely to live in poverty than are men (Arulampalam, Booth, & Bryan, 2006; Blau & Kahn, 2006; Chant, 2006); and (5) differences in types of trauma exposure, with higher levels of rape, sexual molestation, and physical abuse experienced by women and higher rates of combat exposure and witnessing violence experienced by men (Kessler, Sonnega, Bromet, Hughes, & Nelson, 1995). Trauma exposure in the general population is not an aberration, but the norm: in a nationally representative sample of almost 6,000 individuals, 60% of men and 51% of women had a lifetime prevalence of at least one traumatic event (Kessler et al., 1995). Nine percent of women and less than 1% of men had a lifetime prevalence rate for rape, and a history of rape was the one trauma most likely to lead to a posttraumatic stress disorder (which is characterized by high levels of anxiety) in both men and women. These differential experiences both elicit and contribute to emotion in the two genders, with emotions serving motivational and communicative functions that are adaptive for particular circumstances and contexts. Individuals' emotions in response to experiences can also become generalized across contexts to form habitual and anticipatory response patterns, some of which may be adaptive and others maladaptive (see Leahy, 2012).

Other Aspects of Identity in Relation to Gender

Emotions differ not only based on experiences that vary as a function of gender but also as a function of multiple other aspects of identity, including age, social class, race, ethnicity, status, religion, interests, values, and professional and interpersonal roles that may be independent of and also interact with gender (Stewart & McDermott, 2004). Some aspects of identity that have been found to be significantly related to gender include interdependent self-construals and interests in working with people (associated with females), and independent self-construals and interests in working with things (associated with males) (Cross & Madson, 1997; Su, Rounds, & Armstrong, 2009). Identities and interests may become more or less salient in a particular context depending on several factors, including the individual's values, the content and goals of the situation (e.g., political vs. personal; Ethier & Deaux, 1994), and the multiple identities of the participants in a social interaction. Each identity may be associated with unique emotional processes that vary as a result of the social expectations, display rules, functions, motives, and goals corresponding to that identity. For example, Palomares (2008) found that women referenced emotions in e-mails significantly more often than men when gender was primed and thus made salient, but when student status was primed, the gender difference in references to emotion was reduced. Because specific aspects of identity are continually shifting in their relative salience depending on the particular situation, gender differences in emotional processes will fail to generalize broadly, instead varying as a function of these same contextual factors.

In this chapter, we highlight contextual, moderating, and mediating variables for gender differences in several different emotional processes, focusing primarily on nonclinical populations. The majority of the research we review is based on European-American adult participants living in the United States. We also present a theoretical model for the etiology of gender differences that addresses the complex transaction between distal and proximal contextual variables, including biological, sociocultural, experiential, developmental, and situational factors.

Stereotypes and Display Rules

The stereotype that women are more emotional than men is pervasive across many different cultures (Timmers, Fischer, & Manstead, 2003). Among North American samples, women are believed to be more emotionally intense (Robinson & Johnson, 1997), as well as more emotionally expressive (e.g., smiling, laughing, crying) and more skilled in the use of nonverbal cues related to emotion (Briton & Hall, 1995). However, stereotypes are also emotion specific: Happiness, embarrassment, surprise, sadness, fear, shame, and guilt are believed to occur more in women, and anger, contempt, and pride more in men (e.g., Hess et al., 2000; Plant, Hyde, Keltner, & Devine, 2000). Although the distinction between expression and experience is not always made, when it is, the results consistently show stereotypes to be stronger for expression than for experience (Plant et al., 2000).

Some of the stereotypes about specific emotions have been found to vary with the ethnicity of the person holding the stereotypes. Participants who were African American, Hispanic American, European American, and Asian American believed that women express and experience more fear, guilt, love, sadness, surprise, shame, and sympathy than men. However, European Americans reported the highest levels of gender-stereotypic beliefs (e.g., anger for men and love for women) when compared with other ethnic groups (Durik et al., 2006).

How well are the stereotypes supported by self-reports and behavioral data? In general, rather well. Stereotypes about gender differences in emotional expression tend to correspond with self-reports of expression (see below), and stereotypes about gender differences in nonverbal behavior correspond well with measured gender differences (Briton & Hall, 1995; Hall & Carter, 1999). Moreover, the belief that gender differences in expression are stronger than gender differences in experience is corroborated when both are measured simultaneously. Kring and Gordon (1998), and Dunsmore, Her, Halberstadt, and Perez-Rivera (2009) found gender differences in facial expressions but not in self-reports of experience, in response to films.

To find that stereotypes are somewhat confirmed in self-reports and in actual behavior should be relatively unsurprising, because our most automatically encoded and retrievable memories are based on frequently occurring behaviors, which may form the basis for many stereotypes (Hasher & Zacks, 1984). On the other hand, gender and emotion stereotypes are imprecise, overly general, and ignore the importance of the modality in which an emotion is expressed, as well as the situational and cultural context within which it occurs. Because stereotypes ignore social context and individual differences, they often lead to the erroneous assumption that gender differences are exclusively biological in origin. This assumption is sometimes reinforced by authors of brain imaging studies who often assume that the brain's functional architecture is the origin of gender differences, rather than vice versa (Fine, 2013).

Despite these cautions, stereotypes warrant a closer analysis, because they powerfully shape the reality of gender differences. In any given interaction, gender stereotypes can generate expectancies about same- and opposite-sex partners that influence and elicit particular behaviors and emotional expressions, becoming self-fulfilling prophecies (Hall & Briton, 1993). Gender stereotypes about the experience and/or expression of emotion are potent enough that they can override the accurate perception of expressions actually conveyed by men and women. Several studies have shown that identical or equivalent facial expressions of men and women produce biases in interpretation (Adams, Nelson, Soto, Hess, & Kleck, 2012; Algoe, Buswell, & DeLamater, 2000; Hess, Adams, & Kleck, 2004; MacGregor & Davidson, 2000; Plant et al., 2000; Plant, Kling, & Smith, 2004). For example, Plant et al. (2004) altered the same faces to appear to be either male or female and gathered perceivers' emotion ratings of them. The "female" faces were judged to be sadder than the "male" faces. Gender-emotion stereotypes are even strong enough to make perceivers erroneously attribute the wrong and more stereotypic emotion to a target male or female face when that emotion is actually being expressed by a *different* face in proximity to the target face; happy male target faces were misperceived as angry when the neighboring face was angry, and angry female faces were misperceived as happy when the neighboring face was happy (Neel, Becker, Neuberg, & Kenrick, 2012). It is not clear in such studies whether the perceived gender of the target face actually influences how the expression is processed (e.g., through selective attention to certain cues) or whether perceivers' judgments follow from their general, base-rate beliefs about men's and women's emotional experience/expression, regardless of what the face is displaying.

The direction of bias does not always match stereotypes in a straightforward way. Hess et al. (2004) found that when the same faces were presented as either male or female, perceivers saw the angry "woman" as especially angry and the happy "man" as especially happy, which suggests that the contrast between stereotypic expectations and actual expressions led to attributions of more extreme emotional experience. But even if the perceiver says, "Women don't usually show anger, so that angry-looking woman must be really angry," it is still the case that stereotypes are guiding interpretation.

Stereotypes also have a strong implicit prescriptive aspect in the form of display rules, which are cultural norms regulating how, when, and where emotions can be expressed by males and females in any particular culture. For example, across 48 countries, adults reported that happiness was more desirable for girls and that fearlessness and anger suppression were more desirable for boys (Diener & Lucas, 2004). A comparison across samples from Canada, the United States, and Japan found that in all three countries men said it was more appropriate for men to display anger, contempt, and disgust than women said of women, while women said it was more appropriate for women to display sadness, fear, and happiness than men said of men (Safdar et al., 2009). However, in a different study, Singaporean males reported it was more appropriate for them to express sadness outside of work than Singaporean females reported for themselves (Moran, Diefendorff, & Greguras, 2013), indicating cultural specificity in display rules.

Violating stereotypic display rules can lead to negative social consequences, such as social rejection and discrimination (Brody, 1999). For example, depressed men were rated as "unmanly" and evaluated more negatively than depressed women (Brody, 1999). Angry women were rated as having lower status and competence and were accorded lower wages than were angry men, sad women, and unemotional women in a laboratory study (Brescoll & Uhlmann, 2008). Among 8- and 10-year-olds, girls who were better at substituting negative displays with positive affective expressions (i.e., emotional substitution) were more accepted by other girls, whereas boys who were better at masking or hiding their negative displays were more accepted overall (Young & Zeman, 2003). For seventh- and eighth-grade boys, peer acceptance was positively related to peer-rated sadness inhibition and inversely related to sadness disinhibition (Perry-Parrish & Zeman, 2011).

Women and men are judged for both under- and overexpressing emotions that are perceived as stereotypic for their sex. For example, women's over- and underreactions to happiness were both evaluated as less socially appropriate than the same reactions displayed by men (Kelly & Hutson-Comeaux, 2000), and men's over- and underreactions to angry events were judged as less socially appropriate than women's comparable reactions. These data are consistent with Shields's (1987) theory that women are placed in a double bind: Because emotionality is expected of women, women who do not express emotions are negatively evaluated, but women's stereotypic emotionality is also negatively evaluated as an "overreaction." Kelly and Hutson-Comeaux's data also extend the idea of a "double bind" about emotional expression to men.

Especially in many professional and business settings, women and men are pressured to conform to display rules for emotions in order to succeed. This is termed "surface acting," hiding one's true feelings about a situation in order to appear professional and competent. Simpson and Stroh (2004) asked human resources professionals to report on the extent to which they were required to cover up and pretend to experience various emotions at work. Women reported having to display positive emotions (e.g., contentment, calmness) and suppress negative emotions (e.g., anger) more than men did, whereas men reported having to display negative and suppress positive emotions more than women did. Although the different job characteristics performed by men and women (e.g., working in administration vs. human resources) were found to account for some of these differences, even after job characteristics were controlled women reported more pressure than men did to display positive emotions they did not feel. Similarly, in a study of over 1,300 career state service workers in the southern United States, Sloan (2012) found that women reported hiding or changing their anger more than men, and men reported hiding or changing their happiness more than women. The gender difference for anger management became nonsignificant when job status was entered into the model; workers who had higher status were disproportionately male and managed anger less.

Conforming to stereotypes has physical and emotional health costs and can result in increased negative affect, especially for women. Although both sexes may be subject to double-bind messages about expressing emotions stereotypically appropriate for their gender, it seems that women are more distressed by the consequences of these messages than are men. The stereotype that women should be "cheerful" and display positive emotions means that underlying negative affective states may persist and fester, producing a cascade of negative effects (Scott & Barnes, 2011). For example, Johnson and Spector (2007) asked customer service employees to report how much they engaged in surface acting and to complete measures of burnout and job-related well-being. Among women, more surface acting predicted more emotional exhaustion and less affective well-being, but this was not the case among men. This result was confirmed in a study of bus drivers using experience sampling methodology over a 2-week period, where surface acting, as in "faking a good mood," was significantly associated with negative affect for women more than for men (Scott & Barnes 2011). Finally, in the study done by Simpson and Stroh (2004) discussed above, among human resources professionals only the women's pattern of feeling pressured to display positive emotions and to suppress negative emotions was significantly associated with feelings of inauthenticity at work. Women who adopted the men's pattern of responding (i.e., displaying negative emotions and suppressing positive emotions) were the least likely to report feelings of inauthenticity.

Surface acting may occur not only in response to display rules but may also occur in response to stereotype threats about gender and emotion. In stereotype threat (Steele & Aronson, 1995), concern about confirming a negative stereotype about one's group (e.g., women are more "emotional" than are men) negatively affects performance on stereotype-related tasks. Impaired performance may be mediated by increased anxiety (Beilock, Rydell, & McConnell, 2007; Osborne, 2001). For example, women exposed to implicit stereotype threat about their leadership abilities (being told that their performance would be diagnostic of their leadership abilities after they had identified their gender) expressed more anxiety in narratives relative to women not exposed to stereotype threat (Brody et al., 2009; Kelso & Brody, 2014). Stereotype threat is also accompanied by negative, self-deprecating thoughts (Cadinu, Maass, Rosabianca, & Kiesner, 2005), such as "People won't respect me if I'm too emotional." It is possible that pervasive stereotype threat about emotionality as well as in other domains (e.g., math or leadership abilities) may contribute to women's heightened tendency to ruminate and engage in repetitive negative thinking, which has been found to mediate higher levels of anxiety and depression (Nolen-Hoeksema, Larson, & Grayson, 1999). Thus, stereotype threat about women's emotionality might ironically increase women's emotionality in the form of anxiety.

Self-Report Measures

Self-report measures, though serving as the basis of much of the available evidence about emotion and expression, are hard to interpret for three reasons. First, gender stereotypes may color participants' self-concepts and therefore their self-descriptions (Robinson & Clore, 2002). Some research supports this idea (Grossman & Wood, 1993). Second, stereotypical responding may be exacerbated by social desirability motives, which in turn may be influenced by display rules. And third, the conceptual distinction between emotional experience and emotional expression is frequently blurred. The items to which participants are asked to respond may not make the distinction; the commonly used term "emotional" implies both experience and expression. Or, participants may have difficulty making this distinction even if asked to do so. With these cautions in mind, we review studies that have used self-report measures.

Self-Reports of General Emotional Experience and Expression

Many studies find that women rate themselves as more emotionally expressive than men rate themselves to be (e.g., Simon & Nath, 2004). Gross and John (1998) factor analyzed six frequently used self-report measures of emotional expression and identified five factors: positive expressivity, negative expressivity, the intensity of emotional expression, expressive confidence (such as enjoying acting), and masking or emotional regulation (such as suppressing anger). Women rated themselves significantly higher on the first three of these factors. Greater intensity is found for women both in their descriptions of specific emotional experiences (Hess et al., 2000; Tobin, Graziano, Vanman, & Tassinary, 2000) and on global self-report measures such as the Affect Intensity Measure (AIM; Diener, Sandvik, & Larsen, 1985). However, intensity must be distinguished from frequency. In the 1996 General Social Survey, involving more than 1,300 respondents, there was no gender difference in reports of overall frequency of emotional experience (Simon & Nath, 2004). Estimates of overall frequency may mask differences for specific emotions.

Consistent with our theoretical framework emphasizing contextualism, even these generally predictable self-report differences do not always appear. In a survey of over a thousand high-level managers (e.g., chief executive officers, executive vice presidents), men reported themselves to be more emotionally expressive in their jobs than women in equivalent leadership positions (Callahan, Hasler, & Tolson, 2005). This result is not surprising because in a male-stereotypic job context women may be aware that "too much" expressiveness will work against them, especially the expression of negative emotion and anger in the workplace, as previously discussed (Simpson & Stroh, 2004). Moreover, global self-reports and cultural stereotypes reflecting the "nonemotionality" of men overlook the fact that men can be and are emotional in many settings, including leadership positions, competitive sports, the entertainment industry, the political arena, and intimate relationships (see Shields, 2013).

Finally, there is emotional contagion: women report a higher likelihood of "catching" the emotions of others than men report (Doherty, 1997). This self-reported difference is corroborated for certain emotions when facial muscle activity is recorded through electromyography. For example, Dimberg and Lundquist (1990) found that women's faces were more responsive to viewed facial expressions than men's. Emotional contagion combined with facial feedback processes (Strack, Martin, & Stepper, 1988) could contribute to women's greater reported intensity of experience in specific contexts.

Self-Reports of Specific Emotions

The specific emotions that women and men report more intensely or more frequently tend to vary depending on ethnicity (more intense gender differences for White and European-American samples than for other ethnic groups) and situational context (Else-Quest, Higgins, Allison, & Morton, 2012; Fischer, Rodriguez Mosquera, van Vianen, & Manstead, 2004). As with self-reports of general emotion, gender differences are larger when measures are more global and nonspecific as opposed to focusing on states and descriptive adjectives at particular moments in time (Else-Quest et al., 2012). This is consistent with the view that gender differences in specific emotions vary depending on the gender role relevance of the target situation (Ferguson, Eyre, & Ashbasker, 2000). The positive emotions sometimes reported more intensely or more frequently by women include joy, love, affection, warmth, and feelings of well-being (see Brody, 1993; Chentsova-Dutton & Tsai, 2007; Fischer & Manstead, 2000). In a meta-analysis, reports of pride showed no gender differences despite the stereotype that favors men (Else-Quest et al., 2012). Women also generally report more empathy and sympathy than do men; these emotions are hard to classify as positive or negative, although they are generally seen as socially valuable (Evers, Fischer, Rodriguez Mosquera, & Manstead, 2005; Lennon & Eisenberg, 1987). However, gender differences in empathy decrease from ages 22 to 92 (Schieman & Van Gundy, 2000), reflecting developmental and/or generational effects.

Higher female reporting of positive emotions is specific to particular measures and situations. For example, when participants are asked about total frequency of affect in the past week, women report significantly less positive affect than men report (Simon & Nath, 2004). Total frequency of emotions over the course of a week may be heavily influenced by the context in which participants are spending their time. When participants recorded their emotions in response to random pager beeps for 1 week, women reported more positive emotions (e.g., happy and friendly, as opposed to unhappy and angry) while at work than they did while at home. The opposite was true of men, who reported more positive emotions while at home (Larson, Richards, & Perry-Jenkins, 1994). Sloan (2012) also found that women reported more happiness at work than men in a sample of over 1,300 people who worked in state service positions, despite the fact that men had higher incomes and more influence in their jobs.

Many negative emotions, including disgust; sadness; feelings of vulnerability, such as fear, anxiety, and hurt; and feelings of dysphoric self-consciousness, such as shame and embarrassment, are reported more by women than by men (e.g., Balzer & Jacobs, 2011; Brody, 1999; Fischer et al., 2004; Hess et al., 2000; Rohrmann, Hopp, & Quirin, 2008; Simon & Nath, 2004). Else-Quest et al. (2012), in a meta-analysis of self-conscious emotions, including guilt, shame, and embarrassment, found that females in adolescence through older adulthood reported more guilt and shame than did males. Embarrassment also tended to be reported more by females than by males; this gender difference, however, was reversed in studies that assessed embarrassment specific to environmental issues such as littering. Extending these findings to earlier ages is work by Lewis and Ramsey (2002), showing higher levels of shame after task failure in 4-year-old girls than boys.

Sadness, depression, and dysphoria are also self-reported to be more intense and of longer duration by women than by men (Scherer, Wallbott, & Summerfield, 1986). In a study of bus drivers using experience sampling methodology over a 2-week period, female bus drivers reported higher levels of negative affect (being irritable, distressed, upset) than male bus drivers (Scott & Barnes, 2011). A study of women and men who had been victims of crime indicated that women endorsed more depression, anxiety, and anger in general than did men (Green & Diaz, 2008). In a study of adolescents, Perry-Parrish and Zeman (2011) found that although boys and girls did not differ in self-reports of the frequency with which they experienced sadness, boys reported inhibiting sadness expression more than girls. This study also underscores our earlier point that experience and expression are not synonymous.

Although men sometimes express more anger through vocal, facial, and behavioral modalities than women, gender differences in anger based on self-reports are inconsistent. When asked general questions about how many days per week they get angry, men and women reported no differences (Simon & Nath, 2004) and there were also no gender differences in reports of anger across 37 different countries (Fischer et al., 2004). However, when asked about the intensity of their anger, sometimes women report getting more intensely angry than men report of themselves, as indicated by a study of European and Hmong Americans asked to remember and relive significant memories (Chentsova-Dutton & Tsai, 2007). Reports of anger are sometimes, but not always, higher in women and girls when a situational context is specified, especially one involving conflict in interpersonal relationships (e.g., Buntaine & Costenbader, 1997; Chaplin, Cole, & Zahn-Waxler, 2005; Fischer & Evers, 2011; Kring, 2000). In a study of married couples who were either middle aged (40–50 years old) or older (60–70 years old), wives in both age groups reported more anger following a conflict discussion than did husbands and also rated their husbands as less friendly (Smith et al., 2009). However, lower reports of anger or unpleasant feelings by men in conflict situations may be a function of lower commitment levels to and salience of the relationship: women in the Netherlands reported less positive affect to treatment they considered to be unfair during relationship conflict than did men, but this gender difference disappeared when relationship commitment and identification were high and when the relationship was made salient by asking participants to name three ways in which they were interconnected with their partners (Kluwer, Tumewu, & van den Bos, 2009).

Gender differences in reports of anger may also be affected by status and power balances in specific relationships. Lower-status males directly express their anger around higher-status work colleagues significantly more often than do lower-status females, with status defined as having supervisory responsibilities (Domagalski & Steelman, 2007). Dutch women in traditional intimate relationships who were employed fewer hours and had less decision-making power than their male partners reported less direct anger and suppressed their anger more than did men, whereas there were no gender differences in egalitarian relationships (Fischer & Evers, 2011).

Compared with men, women also report more enduring experiences of anger (Simon & Nath, 2004), are more likely to report hurt or disappointment in response to anger-inducing situations (Brody, 1993), and are more likely to worry about the social consequences of getting angry than men (Evers et al., 2005), especially when they are in traditional relationships with less decision-making power and financial resources than men (Fischer & Evers, 2011). Women are more likely to express their anger using indirect means, such as crying, disclosing their anger to a third party, or gossiping (Fischer & Evers, 2011). They are more likely to view their anger as appropriate (Simon & Nath, 2004), but are also more likely to report feeling ashamed after expressing it (Kring, 2000). The shame–anger relationship has also been studied in reverse: both boys and girls from the Netherlands with narcissistic tendencies (an inflated sense of their importance) reported more anger after being shamed, but only boys were also nominated by peers as displaying more anger (Thomaes, Stegge, Olthof, Bushman, & Nezlek, 2011).

Emotions that males sometimes report expressing or are reported by others to express more frequently or intensely than females are contempt, loneliness, confidence, and excitement (Brody, 1993, 1999; Simon & Nath, 2004). However, gender differences in contempt and loneliness have been inconsistent across studies, depending on situational circumstances, the characteristics of the particular samples assessed, and methodological variables (including differences between scenario-based methods and trait measures of these emotions; Benetti-McQuoid, & Bursik, 2005; Ferguson et al., 2000).

What Do Self-Reports Measure?

Women's reports of higher affective intensity on global or retrospective self-report measures may not accurately reflect gender differences in emotion at the time feelings are initially expressed or experienced. When daily logs are used to report momentary emotions or mood states, either no gender differences have been found (Barrett, Robin, Pietromonaco, & Eyssell, 1998; Mor et al., 2010), or men have reported positive events in their lives to be more intense than women have reported theirs to be (Seidlitz & Diener, 1998). Moreover, subsequent global self-reports of emotion do not significantly relate to the intensity of emotional reactions reported at the time events occurred (Seidlitz & Diener, 1998). Robinson, Johnson, and Shields (1998) found that men and women retrospectively remembered their emotions as more gender stereotypic than they actually were.

In a theoretical review, Robinson and Clore (2002) argue that global and retrospective self-reports of emotion partially reflect memories for the contextual details of events. Women may have more sophisticated emotion concepts that can serve as retrieval cues, or they may encode emotional experiences in more detail than men do (Seidlitz & Diener, 1998). For example, Wang (2013) used a random sampling method in which participants received a text message three times a day during a 1-week period and were asked to record what was happening during the past 30 minutes. Compared with men, women recorded a greater number of event details at the encoding phase and provided more detailed and accurate memories at a delayed recall 1 week later, even after controlling for the frequency of details at encoding. More detailed encoding at the time of an emotional event may subsequently contribute to women's reports of more intense emotions relative to men's on global measures, even in the absence of gender differences in emotional intensity at the time feelings were initially experienced. These hypotheses are consistent with data that girls and women in the United States and Australia are faster in accessing, and are able to recall more, childhood memories of emotional experiences than their male counterparts (Davis, 1999). Polish women used more positive and negative emotion words when recalling vivid memories than men did (Niedzwienska, 2003). It is also possible that there are gender differences in the mental imagery surrounding emotional events; enhanced mental imagery has been found to be related to heightened affective responding (Miller et al., 1987).

Robinson and Clore (2002) also argue that as the delay lengthens between the occurrence of an emotional event and later recall, detailed memories fade, and self-reports of emotion increasingly rely on belief- and identity-consistent generalizations. Thus, gender-stereotypic beliefs and identity may contribute to gender differences in global self-report measures. This is supported by Wang (2013), who found that after a 1-week delay, women recalled initial experiences (measured with event sampling) by referring more to interpersonal activities than men did, independent of the degree to which they had reported those activities in their initial experiences, which had not differed by gender. Recalling more interpersonal activities is consistent with women's higher levels of motivation to maintain intimacy and affiliation.

Alternative explanations for the discrepancy between global and specific measures are also possible, including the idea that in the time elapsed since an event, women may cumulatively experience more emotion than men—perhaps, for example, ruminating over the event, which retriggers or amplifies emotional experiences. And, as pointed out earlier, global self-report measures often blur the distinction between emotional experience and emotional expressiveness. Finally, people need experiential self-awareness to report that an emotion has occurred and there may be gender differences in this awareness (Else-Quest et al., 2012), as suggested by the literature on emotional competence discussed below.

Verbalization of Emotion

Consistent with self-report data, women have been found to refer to emotions more often in conversations and in writing samples, although this finding holds more consistently for positive emotions than for negative emotions such as anger. For example, in writing a response story to a scenario in which they dealt with an obstructive travel agent, females made more emotional references than did males (Girdler, Turner, Sherwood, & Light, 1990; see also Brody, 1999). In a task involving narrating a wordless picture book, 6- and 7-year-old girls in a British sample used more emotion explanations and more emotion labels than did boys, regardless of the sex of the peer to whom they were "reading" the book (Tenenbaum, Ford, & Alkhedairy, 2011). Similarly, 10- to 13-year-old girls also used more emotion words than did boys when conversing with parents about story vignettes involving conflicts (Aldrich & Tenenbaum, 2006), although when sons conversed with fathers about these vignettes, they expressed more sadness than did daughters. These gender differences in naturalistic conversations may emerge in early school-age children, since emotions in preschoolers' naturalistic conversations were not found to vary by gender (Fabes, Eisenberg, Hanish, & Spinrad, 2001).

In interviews between potential clients and male psychiatrists, controlling for psychopathology, female clients' discourse contained more affect, as seen in the percentage of affect words, and was also more nonverbally expressive than men's (Lecours, Sanlian, & Bouchard, 2007). Further, an analysis of a random sample of 819 public comments to or from U.S. users on a social networking website revealed that females gave and received more positive comments than did males, but there was no gender difference for negative comments and no interaction of sender's gender with that of the receiver (Thelwall, Wilkinson, & Uppal, 2010).

In both self-descriptions and observations of marital interactions, wives are more willing to tell their husbands when they are feeling tense; initiate discussions about areas of disagreement; disclose their feelings, especially distress and anger; and try to explain their feelings than are husbands (Burke, Weir, & Harrison, 1976; Baucom, McFarland, & Christensen, 2010; Smith et al., 2009; Stets, 1997). Men have been found to withdraw from criticism and marital conflict by "stonewalling," which involves inhibiting facial action and minimizing listening and eye contact, more than their wives do (Levenson, Carstensen, & Gottman, 1994; Smith et al., 2009). An observational study of dating couples indicated that in interactions involving high-stress situations, gender differences were maximized, with men being less emotionally expressive and higher in restricted affect and withdrawal than women, as compared with interactions in which low-stress situations were discussed, where no gender differences were observed in these variables (Vogel, Wester, Heesacker, & Madon, 2003).

In lesbian, gay, and heterosexual couples' videotaped interactions in which couples were asked to discuss areas of disagreement (Gottman et al., 2003), across all couples, men expressed more anger than women; women expressed more excitement and joy (as measured by facial expressions, vocal tone, and speech content); and women were sadder when they were the recipient of a conflict-laden message from their partner than men were. When initiating conflict, lesbian women were angrier than gay men, used more humor, and showed more excitement/joy. When listening to an issue, lesbian women showed more humor and interest than did gay men.

Studies also indicate that same- and cross-sex couples engage in demanding and withdrawing behaviors in highly similar ways. Across all couples, women demanded at higher levels than men, including using requests and demands, nagging, blaming, accusing, or criticizing partners, and men withdrew at higher levels than women, including becoming silent, refusing to discuss topics, disengaging from the discussion, hesitating, changing topics, diverting attention, or delaying the discussion (Baucom et al., 2010).

Facial Expressions and Other Nonverbal Behaviors

Women are more accurate facial expressers of most emotions, both when posing in response to experimental instructions and when being observed unobtrusively (Dunsmore et al., 2009; Hall

& Gunnery, 2013). A measure integrating facial, vocal, and postural expressions indicated that girls expressed more sadness and anxiety than boys at ages 4 and 6, and over this 2-year period, boys decreased their expression of these emotions (Chaplin et al., 2005). Similarly, Buck (1977) found that boys between the ages of 4 and 6 showed steadily decreasing facial expressiveness when watching affectively arousing slides, while there was no age effect for girls.

Generally, studies measuring researcher, peer, teacher, and parent observations concur that boys more frequently express negative emotions (e.g., anger, aggression, frustration) with some studies indicating that boys also more frequently express high-intensity positive emotions (e.g., excitement) and girls more frequently express low or moderately intense positive emotions (e.g., happiness) as well as sadness (Else-Quest, Hyde, Goldsmith, & Van Hulle, 2006; Perry-Parrish & Zeman, 2011; Schultz, Izard, & Bear, 2004; Zhou, Eisenberg, Wang, & Reiser, 2004). However, some studies indicate that parents and teachers differ from each other in their ratings of emotional expressivity by child gender, perhaps because display rules in school and home settings differ (Sallquist et al., 2009). It is important to note that peer, parent, and teacher nominations may be confounded by gender stereotypes.

The results for nominations of anger expression being higher for males are borne out by research showing that men convey anger more clearly in their facial expressions than women do. For example, when participants were videotaped as they discussed angry, sad, and happy emotional memories, judges were able to identify men's facial displays of anger (independent of verbal content) more accurately than women's. Although stereotypes, in which observers are more apt to associate anger with men, may spuriously account for these different accuracy rates, this caveat is rendered less likely by the finding that higher sociometric status was associated with anger encoding ability for men and with happiness encoding ability for women (Coats & Feldman, 1996). Men are also more facially reactive in response to angry stimuli than are women, as measured by facial electromyographic activity (Dimberg & Lundquist, 1990).

Quantitative reviews have concluded that women are more generally expressive with their faces and hands, and smile, laugh, and nod more than men do (Hall & Gunnery, 2013; LaFrance, Hecht, & Levy Paluck, 2003). Both European American and Hmong American women showed more smiles than men did when recalling and reliving experiences involving happiness and love (Chentsova-Dutton & Tsai, 2007). Szarota (2010) measured cross-national gender differences in smiling, using adults' pictures that were self-posted on Internet sites as the source of data (100 of each gender in each of 10 countries). Across nine European countries plus the United Kingdom, women smiled significantly more in all but three countries (East and West Germany, Hungary), though even there women smiled more than men.

It is important to note, however, that smiling in particular and other emotion-suggestive nonverbal behaviors do not necessarily reflect actual emotional states (Chovil, 1991–1992; Krauss, Chen, & Chawla, 1996). Smiling is notably ambiguous as to its "real" emotional meaning. Even the supposedly involuntary Duchenne smile has now been shown to be deliberately producible by a substantial number of people (Gunnery, Hall, & Ruben, 2013; Krumhuber & Manstead, 2009). The Duchenne smile engages both the mouth and the cheek-raiser muscle that makes crows' feet and was theorized for many years to reflect spontaneous happy affect without the possibility of willful control.

Some authors have suggested that smiling in women reflects false positivity and thus insincerity—for example, women's smiles were less congruent with the content of verbal statements than was the case for men (Bugental, Love, & Gianetto, 1971). However, women's facial expressions were *less* discrepant from their words than were men's in the better-designed research of Halberstadt, Hayes, and Pike (1988), and women and men displayed Duchenne and non-Duchenne (involving only the mouth) smiles equally in Hecht and LaFrance's (1998) study, which argues against the notion that women's smiles are less "authentic" than men's.

Women are also smiled at more than men (Hinsz & Tomhave 1991; Patterson & Tubbs 2005). The combination of this target effect with the actor main effect described above would lead to frequency of smiling being greatest in same-gender dyads (female–female compared with male–male), which is the case (Hall, 1984). However, a provocative reversal of people's tendency to smile more at women has been documented in studies of group members' unobtrusively observed reactions to female leaders during group interaction. In German and American women and men who were studied during group interactions, female leaders were the recipients of more negative affect by both sexes than were male leaders, even when the leaders' contributions were held constant (Butler & Geis, 1990; Koch, 2005). This suggests that the nonverbal behaviors directed toward women in casual social encounters may be different from those directed toward them in task-oriented or hierarchical situations, especially those stereotyped as inappropriate for women.

Nonverbal Decoding Skill

Across many studies, females score higher than males in identifying the meanings of nonverbal cues of face, body, and voice (Hall, 1984; Hall & Gunnery, 2013; Kirkland, Peterson, Baker, Miller, & Pulos, 2013; McClure, 2000). Most of the studies have tested sensitivity to expressions of affect, which is a female-stereotypic knowledge domain. When the knowledge domain is male stereotypic, such as judging status or dominance (Schmid Mast & Hall, 2004), or nongender stereotypic, such as lie detection (Aamodt & Custer, 2006), the sex differences appear to be much smaller or nonexistent. It has been suggested that the female advantage on nonverbal decoding tasks stems from motivational differences between men and women (Ickes, Gesn, & Graham, 2000), but studies manipulating motivation to influence the accuracy of judging nonverbal cues give very limited support to this hypothesis (Hall et al., 2009).

Emotional Competence

Theories of emotional competence and intelligence define several emotion-related traits and skills to be important for adaptive intrapsychic and interpersonal functioning (Matthews, Zeidner, & Roberts, 2002), including perceiving emotions accurately, using emotion to facilitate thought, and understanding and managing emotion. Women score higher than men on all of these components on the Mayer–Salovey–Caruso Emotional Intelligence Test (MSCEIT; Day & Carroll, 2004; Mayer, Caruso, & Salovey, 2000), including women in a large Greek sample who scored higher than men on empathy, expression, and recognition of emotions, but lower on the use of emotions and no differently on control of emotions (Tsaousis & Kazi, 2013). Consistent with the results favoring women on emotional competence is the large literature showing female advantage in interpreting nonverbally communicated emotions discussed above.

In videotapes of married couples' interactions, Mirgain and Cordova (2007) found that husbands and wives were similar on some dimensions of emotional competence, but when significant differences occurred they showed wives to be more competent (e.g., lack of defensiveness), and trends favored wives for several other coded dimensions (e.g., eliciting positive emotions). In that study, emotional competence predicted own and spouse's marital satisfaction in both husbands and wives. Emotional competence is also relevant in the domain of medical practice, where patient-centered care is now the gold standard for quality medical practice around the world (Mead & Bower, 2000). Female medical students and physicians exceed their male peers on behaviors such as partnership and psychosocial orientation, positivity in verbal and nonverbal communication, accurate interpersonal perception, empathy, focus on feelings, verbal and nonverbal encouragement, and expressions of respect or praise (Roter, Hall, & Aoki, 2002).

Gohm and Clore (2000) found that women reported a greater tendency to pay attention to their emotions. When participants were clustered according to their pattern of scores on attention, clarity, and intensity, women predominated among those who were high on all three but also those high on intensity but low on clarity ("overwhelmed"), while men predominated among those low on all three and those low on intensity and high on clarity ("cerebral").

Women and girls display more complex emotion knowledge than men and boys do when describing the emotions of self and others in hypothetical scenarios. A motivational manipulation brought men's performance up to the level of women's, but only after men spent significantly longer on the task (Ciarrochi, Hynes, & Crittenden, 2005). On tasks where extra effort and thought are beneficial, motivational factors may play an important role, in contrast to the case of accuracy in decoding nonverbal cues (Hall et al., 2009).

Emotional competence is related to a wide variety of adaptive behaviors for both sexes (Nelis et al., 2011), but expressing emotions in words may matter more to women's health than men's. The ability to mindfully describe experiences with words predicted healthier behaviors for females (including physical activity, diet, and self-efficacy), while the ability to step back and observe experience predicted healthier behaviors for males (Gilbert & Waltz, 2010).

Emotion Regulation

Emotion regulation or management consists of behavioral, cognitive, attentional, physiological, or emotional strategies to eliminate, maintain, or change emotional experience and/or expression

(Ochsner & Gross, 2005), in accordance with cultural pressures (display rules, stereotypes, and power/status imbalances), and/or in accordance with personality-related factors (self-construals, motives, conflicts, and goals), with a primary goal being the avoidance of painful affect that might come from negative self- or social judgment and/or relational loss (Cramer, 2002; Matsumoto, Takeuchi, Andayani, Kouznetsova, & Krupp, 1998). Because cultural pressures and personality-related factors differ by gender, it should not be surprising to find gender differences in emotion regulation strategies for specific emotions. For example, females report regulating anger to protect others' feelings and to avoid relational loss, in accordance with interdependence motives, whereas males report regulating anger to avoid nonsupportive interpersonal reactions and to maintain control, in accordance with individualistic motives (Jack & Dill, 1992; Timmers, Fischer, & Manstead, 1998; Zeman & Shipman, 1998).

Several reviews have concluded that girls are more likely than boys to exert voluntary control over emotional reactions (Else-Quest et al., 2006). Similarly, adult women engage in more types of emotion regulation strategies than do men, including rumination, reappraisal, seeking social support that involves emotional disclosure, acceptance, distraction, and problem solving (Cramer, 2002; Nolen-Hoeksema, 2012). Women also report or are observed to use more internalizing strategies such as blaming themselves, and also more emotion-focused strategies such as ruminating, rather than taking active steps (Cramer, 2002; Nolen-Hoeksema & Jackson, 2001; Thayer, Newman, & McClain, 1994). In particular, rumination has been found to significantly mediate gender differences found in depression (Nolen-Hoeksema, 2012) and may partly explain why women have higher rates of depression than do men. The gender difference in rumination has been found to be mediated by trauma and chronic strain histories (Nolen-Hoeksema et al., 1999), as well as by several attributions, including the uncontrollability of negative emotions (Nolen-Hoeksema & Jackson, 2001).

Some research indicates that men use more behavioral and externalizing emotion regulation strategies than do women, including blaming others, taking active steps, seeking social support through shared activities; using humor, withdrawal, disengagement, and distancing in the face of conflict; and engaging in distracting or avoidance activities such as exercise; as well as in impulsive, reward-seeking behaviors such as substance use (Brody, Muderrisoglu, & Nakash-Eisikovits, 2002; Cramer, 2002; Davis et al., 2012; Gross & John, 2003; Lecours et al., 2007; Nolen-Hoeksema, 2012; Zlomke & Hahn, 2010).

Gender differences in emotion regulation strategies need to be qualified by type of emotion. For example, women report that they exert more control over anger, contempt, and disgust than do men, and men report that they exert more control over fear and surprise than do women in the United States, Japan, Russia, and South Korea (Matsumoto et al., 1998). In Kenya, the United States, and Ghana, boys reported more control over sadness than girls, who reported more undercontrol of sadness and more control over anger than boys (Morelen, Zeman, Perry-Parrish, & Anderson, 2012). Women choose rumination strategies when in neutral or depressed moods, but choose distraction when in angry moods (Rusting & Nolen-Hoeksema, 1998).

Although both avoidance and emotion-focused coping strategies tend to be nonadaptive for both sexes (Thayer et al., 1994), evidence indicates that some regulation and defense strategies may be differentially adaptive for each gender, varying in complex ways as a function of type of situation, how gender stereotypic the emotional regulation strategy is, and the quality of the emotion being regulated (Brody et al., 2002; Zlomke & Hahn, 2010).

Relationship Specificity

Gender differences in emotional processes often emerge within the context of interpersonal relationships and are affected by the characteristics of the participants in the interaction (including their identities—e.g., their gender, sexual orientation, and ethnicity) and the nature of their relationship, including their level of familiarity, intimacy, and power and status with respect to each other. For example, women who were treated unfairly by a confederate expressed less anger when they were told they would meet the confederate than when they were not (Evers et al., 2005). Both men and women express more emotions and more intense emotions to people they know intimately and feel closer to (Barrett et al., 1998).

Women from a wide variety of cultures also express emotions to a greater number of people than men, who tend to limit themselves to expressing emotions only to intimate partners (Rimé, Mesquita, Philippot, & Boca, 1991). Women also report controlling their emotions less with family members than males do (Matsumoto et al., 1998). Both genders are more comfortable disclosing feelings (with the possible exception of anger) to women than to men (Timmers et al., 1998). In a meta-analysis of sex differences in self-disclosure, which includes but is not limited to the disclosure of feelings, women self-disclosed more to female partners, but not more to male partners, than males did (Dindia & Allen, 1992). Anger may be the only feeling that is verbally disclosed or directed more toward men than toward women, especially in situations in which no provocation is involved (Bettencourt & Miller, 1996).

Cultural Similarities and Differences

As discussed throughout the chapter, there are cultural differences in the association between gender and emotions (e.g., Fischer & Manstead, 2000; Moran et al., 2013; Novin, Tso, & Konrath, 2013; Szarota, 2010). On the other hand, often similarities are notable. Across 37 countries, women reported more intense emotions that last longer and are expressed more overtly than do men (Fischer & Manstead, 2000), and women in both China and the United States reported a higher intensity of emotion than men after viewing emotionally evocative photographs of negative events, with Chinese men reporting the lowest intensities and American women the highest (Davis et al., 2012). In other cross-cultural studies, females express more nonverbal emotional reactions—including facial reactions, vocal reactions, body movements, laughing, and smiling—when expressing joy, sadness, fear, and anger than males do (Scherer et al., 1986). Moreover, in a six-nation study using U.S. and Japanese college students as posers of facial expressions, the emotions portrayed by females were more accurately judged by every cultural group, even though the photographs were intended to be standardized exemplars (Biehl et al., 1997). However, interactions among gender of judge, gender of poser, and culture have also been found to exist for at least some emotions (Matsumoto, 1992).

Gender differences in emotional expression across cultures are likely to vary as a function of cultural values, especially individualistic versus collectivistic values (giving priority to personal goals vs. loyalty to collective/group goals). Collectivism needs to be distinguished from relational values, which prioritize maintaining intimate relationships and are more characteristic of women than men across cultures (Kashima et al., 1995). In Fischer and Manstead's (2000) data, the extent of gender differences in the intensity and duration of joy, shame, disgust, and guilt, and in the nonverbal behaviors associated with those emotions, were greater in individualistic than in collectivistic countries (see also Novin, Tso, & Konrath, 2013, for similar findings concerning anger). Similarly, gender differences in the reported intensity of emotion in response to scenarios depicting joy, fear, and anger were not significant in a sample of American blacks, who are hypothesized to have more collectivistic values than other American ethnic groups (Vrana & Rollock, 2002). Fischer and Manstead (2000) theorize that males in individualistic cultures are apt to minimize emotional expressions because expressing emotions might threaten the control that is critical to their status.

The expression of specific emotions is also likely to be affected by the gender role norms that characterize each culture. For example, women have been found to express their anger more directly than men in countries with a more egalitarian gender ideology (Fischer et al., 2004). In a recent study, Chinese and American participants were instructed to "just feel" versus "to try not to have an emotional reaction" in response to distressing images (Davis et al., 2012). Chinese women's and American men's responses varied as a function of the two conditions, but Chinese men and American women's responses did not, showing that Chinese men conformed to emotional moderation norms, and American women conformed to emotional expression norms.

Physiological Arousal

Research suggests that gender differences in physiological arousal, including changes in heart rate, blood pressure, skin conductance levels, and levels of catecholamines (epinephrine and norepinephrine), are specific to particular physiological measures and emotions, as well as to particular tasks, sample characteristics, and circumstances (including participants' motives and goals; see Brody, 1999). Studies of neuroendocrine functioning and blood pressure mostly show men to be more aroused than women, while studies of cardiovascular reactivity and skin conductance levels show inconsistent gender difference patterns, most probably because of moderating contextual variables (Chentsova-Dutton & Tsai, 2007; Fernández et al., 2012; Kring & Gordon, 1998; Labouvie-Vief, Lumley, Jain, & Heinze, 2003; Neumann & Waldstein, 2001; Polefrone & Manuck, 1987). Recent research also explores how sex hormones and menstrual cycle phase influence emotion learning processes such as fear conditioning and extinction (Aue & Vuilleumier, 2013).

Internalizers, Externalizers, Generalizers, and Low Responders

Gender differences in the patterns of correspondence between physiological arousal and other modes of emotional expression, such as self-reports and facial expressions, are consistent with gender differences in emotion regulation, and in fact often provide clues as to emotion control strategies. Earlier work (Buck, 1977; Manstead, 1991) suggested that men were more often "internalizers," showing physiological arousal with no overt emotional expressions, whereas women were more often "externalizers," showing overt emotional expressions with no corresponding physiological arousal. More recent studies confirm these patterns (Ordaz & Luna, 2012), but also indicate that women are relatively more likely than men to be "generalizers" (Brody, 1999), showing concordance in their expression of emotion, even at young ages (Quas, Hong, Alkon, & Boyce, 2000), and especially at high levels of physiological reactivity (Avero & Calvo, 1999). In contrast, men are more likely than women to be "low responders" (Kring & Gordon, 1998), showing no or low levels of expression across modalities.

A recent study confirmed these patterns in measuring verbal reports of disgust and skin conductance levels in response to disgusting images, such as vomit, on the part of opponents and supporters of gay marriage. Women's self-reports of disgust and skin conductance levels both predicted gay marriage attitudes; for men, there were physiological, but not self-reported, differences between supporters and opponents of gay marriage (Balzer & Jacobs, 2011). Discordance among males may be related to maintaining control or suppressing the behaviors and self-reports that correspond to arousal (Avero & Calvo, 1999), whereas concordance among females may be related to heightened emotional awareness of self and others and to female-stereotypic gender roles that encourage emotional expression.

Exceptions to these patterns sometimes occur in studies of marital interaction, in which husbands' arousal is more likely to correspond to negative affect than wives' (Levenson et al., 1994; but see Kiecolt-Glaser et al., 1996). Further, men's cardiovascular reactivity is more often related to their expression and suppression of anger than is women's (Burns & Katkin, 1993).

Neural Substrates of Emotion

Using functional magnetic resonance imaging (fMRI) and positron emission tomography (PET), researchers are studying potential sex differences in the brain regions involved in emotional expression, perception, and experience (Proverbio, Adorni, Zani, & Trestianu, 2009), especially in limbic system activation and brain lateralization (Schienle, Schafer, Stark, Watler, & Vaitl, 2005). Although fMRI and PET data are intriguing, they are also plagued with small sample sizes, the lack of a coherent theoretical model incorporating the idea that biological development is both influenced by and influences the social context, and inconsistencies or confusion in interpreting whether and how a gender difference in brain activity might translate to differences in specific mental processes (Fine, 2013). Researchers often fail to consider that gender differences in the activation of a specific brain region in response to emotional stimuli can result from a multitude of processes, including differences in attention, the quality of emotional experience, the imagery associated with the experience, or the expression of emotion in different modalities (Wager & Ochsner, 2005). Activation itself has been interpreted in different and sometimes contradictory ways. Some researchers infer that if a brain area is activated, it means that the area is strong for mediating a particular function, such as language or attention, while in direct contradiction, other researchers infer that activation means the brain area is weak for a particular function, with the area needing to compensate and work harder (see Brody, 1999). Similarly, when sex differences in brain size or activation are observed, results are sometimes interpreted to mean that the biological difference prevents sex differences in behavior, an interpretation made when no behavioral differences are found, and at other times to mean that the biological sex difference creates behavioral sex differences (Cahill, 2006).

Moreover, as pointed out by Fine (2013), false-positive errors are often made because null findings of gender differences (both original studies and attempted replications) are frequently not published. Although biological differences are undoubtedly a contributing factor to gender differences in emotion, and new technologies are an exciting tool to further that understanding, relevant research needs to incorporate a more contextual understanding of gender and a more thoughtful approach to interpreting gender difference results.

Etiology of Gender Differences

Gender-related differences in motives, goals, social circumstances, and life experiences are consistent with many of the data we have reviewed about gender differences in emotion. For instance, the emotions that women tend to express more than men (e.g., warmth, happiness, shame, fear, anxiety, and nervousness), their relatively stronger abilities in emotional decoding, higher levels of emotional awareness and competence, and higher facial and nonverbal expressiveness may be related to motives and interests in affiliation and intimacy; a self-schema based on interdependence; perceived vulnerability in the face of lower resources and power; a history of interpersonal trauma; and traditional gender roles, including child caretaking and social bonding, which necessitate reading others' emotion signals.

Higher levels of shame, guilt, and self-blame have been associated with being a victim of interpersonal trauma (Beck et al., 2011), and women suffer from posttraumatic stress disorder with accompanying heightened anxiety at higher rates than men (Breslau, Davis, Andreski, & Peterson, 1991; Kessler et al., 1995). New research on economic scarcity, suffered by women more than men, indicates that it is associated with impaired problem-solving abilities, perhaps mediated by higher levels of anxiety (Mullainathan & Shafir, 2014). As argued by Chrisler (2008), women's lower power and status affords them fewer opportunities to exercise control over their lives than men have, and leads to feelings of incompetence and self-derogation.

In fact, women rate their emotional intelligence as lower than men rate theirs (in contradiction to their measured emotional intelligence; see earlier section), conforming to a pattern of self-derogation for women and self-enhancement for men even in the emotional realm (Petrides & Furnham, 2000). In German fifth-grade students (Frenzel, Pekrun, & Goetz, 2007), girls' lower competence beliefs about their math abilities compared with boys partly contributed to girls' reports of lower enjoyment and pride, and higher anxiety, hopelessness, and shame in math achievement, even though girls and boys had received similar math grades. Not only do lower status and control lead to more dysphoric emotions but they are also associated with the perception that risks are less manageable, which is in turn associated with the experience of higher fear and anxiety. In fact, women experience stronger negative affect in response to negative outcomes than do men, especially fear and anxiety (Ranehill & Boschini, 2013).

Higher levels of male loneliness and contempt sometimes reported are consistent with male roles of differentiating from and competing with others, with maintaining a relatively high-status position, and with a self-schema based on individualism. Emotional withdrawal and constriction may be adaptive in the face of exposure to combat and violence, experiences more typical of men than women. The types of emotion regulation strategies that differ for women and men, and their differing rationales for using them (maintaining intimacy vs. maintaining control), are consistent with gender role-related motives and undoubtedly contribute to some of the gender differences in patterns of expressiveness, including concordance/externalizing and discordance/internalizing. That gender differences in some aspects of emotion grow weaker as adults age is also consistent with the idea that emotions are adaptive for gender roles, which become less rigid in later life (Gutmann, 1987).

However, sociocultural and gender-related variables (especially in isolation, as main effects) cannot always account for gender differences in emotion. For example, evidence indicates that status differences do not account well for gender differences in nonverbal behavior (Hall, Coats, & Smith LeBeau, 2005). In our view, multiple interrelated factors contribute to the etiology of gender differences that span cultural, biological, societal, interpersonal, and intrapersonal levels of analysis, and that coexist with multiple moderating and mediating factors. We propose two etiological models that encompass proximal and distal factors; interpersonal and intrapersonal feedback processes; and the complex intertwining of situational, sociocultural, biological, personality, and cognitive factors both over time and in specific situations.

A Developmental Perspective

The first model includes distal factors, such as gender differences in temperament, family socialization history, gender-segregated play patterns, and cultural values, all of which contribute to the nature of gender differences. An integration of these factors involves a feedback loop in which differing temperamental characteristics of male and female infants elicit differential responses from caretakers and peers, who are conforming to cultural pressures and display rules for gender socialization.

Differing temperamental characteristics include higher activity and arousal levels in males and faster maturation rates for inhibitory control processes and attention focusing in females (see Brody, 1999; Else-Quest et al., 2006; Goldberg & Lewis, 1969). Females' higher levels of self-control may partly contribute to their higher levels of agreeableness and sociability later in development (Goodwin & Gotlib, 2004), because higher levels of self-control (along with early language development) would make it more likely that girls would attend to socioemotional relationships and rules. In turn, agreeableness significantly predicts other emotional processes that are heightened in women, including emotional intensity and attempts to regulate emotion (Tobin et al., 2000). The finding that 13-month-old boys are less likely to play in close proximity to their mothers as compared with 13-month-old girls (Goldberg & Lewis, 1969) may be partly due to sons' higher activity levels, and this pattern of behavior may result in boys becoming less attuned to the emotional expression of others.

The socialization of emotion is especially influenced by characteristics of the family system, including the parents' own temperaments, their gender role attitudes and behaviors, the quality of their marital relationships, their cultural and socioeconomic backgrounds, and the gender constellation of the children in their families (Brody, 1999). The quality of parent–child narrative discourse and interaction has been found to vary as a function of the gender composition of the parent–child dyad, the type of emotion expressed, and the family's ethnic background, which affects the particular display rules surrounding gender and emotion (Nelson, Leerkes, O'Brien, Calkins, & Marcovitch, 2012). For example, fathers attend more to their preschool daughters' emotions of sadness and anxiety than to their sons', and to their sons' expressions of anger than to their daughters'; parental attention also predicts the later expression of sadness and anxiety 2 years later (Chaplin et al., 2005). In both Chinese and American samples, mothers provide more explanations about the causes of emotion to their 3-year-old daughters than to their sons of the same age (Wang, 2001). American mothers also use more emotion labels in conversations with preschool daughters than with sons, and mothers' use of emotion labels significantly predicts individual differences in children's use of emotion labels (Cervantes & Callanan, 1998; see also Cassano, Perry-Parrish, & Zeman, 2007). These patterns change with age in accordance with display rules (e.g., 11- to 16-year-old boys and their parents reported that boys were punished more for their expression of anger than girls; Klimes-Dougan et al., 2007). Although fathers who were more involved in child care had sons and daughters who expressed less gender role-stereotypic emotions as compared with less involved fathers (Brody, 1997), fathers generally respond more strongly than mothers when their children violate gender stereotypes about emotional expression (Cassano et al., 2007). Parents, especially fathers, were less likely to respond in a supportive manner when they were led to believe that their 8- to 10-year-old children, especially sons, violated gender role expectancies for sadness expression (Cassano & Zeman, 2010). The nature of these gendered parent–child interactions varies by child's age, ethnicity, and culture (Lewis, 1972; Nelson et al., 2012).

Finally, gender-segregated peer groups and differentiated patterns of play and conflict both elicit and reinforce gender role-specific emotional styles (Rose & Rudolph, 2006; Noakes & Rinaldi, 2006). Children report regulating emotions in interactions with peers more than parents for fear of interpersonal consequences (Zeman & Garber, 1996). Teachers also engage in gender-differentiated emotional interactions. More distance and conflict are reported in teacher–male student relationships than teacher–female student relationships in first and second graders (perhaps as a function of boys' higher arousal levels and girls' higher control), which may in turn affect the quality of emotions boys experience and express (Koepke & Harkins, 2008).

Putting Distal and Proximal Causes Together: The Example of Smiling

The second model integrates distal factors—such as gender differences in social roles and cultural values, social knowledge, and developmental history—with proximal factors (including characteristics of the situation, quality of affect, and expectations and treatment by others) to account for gender differences in expressiveness, using smiling as an illustration (Hall, Carter, & Horgan, 2000). Key to the model are feedback processes that intensify women's positive affect during social interactions, thereby increasing their smiling. In turn, smiling enhances positive affect through physiological mechanisms and attributional processes (Strack et al., 1988).

If we take women's greater smiling as a starting point, regardless of its immediate cause, facial feedback would produce more positive affect in women than in men. Positive psychological feedback can also follow from smiling due to gender-related motives and traits. For example, if women smile partly to fulfill their internalized conception of how a woman is expected to behave, this would reinforce feelings of adequacy and generate positive affect, which would produce more smiling. Other gender-related motives are interpersonal trust, liking for others, and capacity for intimacy. Some of these motives intrinsically imply more positive affect and smiling (such as liking others). But, in addition, the knowledge that one has acted on these motives (showing that one is trusting, that one likes others, etc.) produces positive affect, because one is acting in concordance with a gender-relevant value (Wood, Christensen, Hebl, & Rothgerber, 1997). In turn, others respond favorably, contributing to the cycle. Women may also use smiling in the service of social skills to put others at ease, facilitate interaction, and defuse conflict. Again there would be positive feedback, because it is reinforcing to feel socially competent and to know that one has promoted comfort and communication, which in turn promotes more smiling. And others' favorable reactions produce positive affect and more smiling. Finally, smiling itself is highly reciprocal: The more one is smiled at, the more one will smile back (Hinsz & Tomhave, 1991). Because women are smiled at more than men, this could contribute to women's smiling and produce a self-fulfillment of others' expectations. And reciprocity (or mimicry as behavioral matching is often called) is itself rewarding, contributing yet more to the intensity of women's positive affect and smiling.

Thus, women experience numerous positive feedback cycles involving their own behavior, their cognitions, their physiological processes, and others' expectations and behaviors. These combine to create enhanced positive affect in their immediate social interactions compared with men's, which ultimately influences how much they smile relative to men. No research has connected all of the elements in this model so it remains hypothetical at present (see also Hankin & Abramson, 2001, for a similar model explaining women's depression).

Concluding Thoughts

In this chapter, we have emphasized that gender itself is multifaceted and that participants categorized as "women" or "men" based on an assumption of shared biology do not necessarily share a common identity or identical biological and social experiences. Further, the pattern and complexity of gender differences in emotional processes (with "gender" needing specific definition and deconstruction) can only be understood as a function of the motivational, situational, social, and cultural contexts in which they occur, as well as with reference to the characteristics of the specific participants, emotional tasks, and processes being investigated (see also Shields, 2013). Understanding the etiology of gender differences involves integrating multiple interacting variables, including those that are distal (e.g., temperament) and proximal (e.g., situational context). The most productive strategy for future research involves incorporating a diverse set of variables as both mediators and moderators, seeking to understand the types of contexts in which gender, as one aspect of identity among many, becomes salient; studying samples that vary in ethnicity, country of origin, sexual orientation, gender roles, and gender identities; recognizing the complex reciprocal interactions among biological and social processes; and understanding the role that different socialization experiences and life circumstances, including exposure to poverty and different types of trauma, play in gender differences in emotional processes.

CHAPTER 22

The Cultural Psychology of Emotions

Batja Mesquita, Jozefien De Leersnyder, and Michael Boiger

Cultural differences in emotions inform us about the ways in which socio-cultural environments influence emotions. Cultural differences make us aware of our own culture: They challenge what we assume to be "natural," and they show the boundary conditions of the emotional processes as we know them. Most of all, cultural differences in emotions show the plasticity of emotions, and their adaptation to the specific socio-cultural environment in which they occur. In this chapter we discuss the many ways in which emotions differ across cultures.

Evidence for cultural differences in emotions is not sufficient in and of itself to prove the accuracy of particular theories of emotion. Yet, it does render certain theoretical claims about emotions more plausible and more useful than others. This chapter not only reviews cultural differences in emotions but also speaks to the power of various theoretical perspectives to account for the established differences.

In order to understand why there may be cultural differences in emotions at all, it is important to see that emotions imply the positioning of individuals in their context. "The point is that an emotion is not merely a 'feeling,' as, say, pain is a feeling. It is . . . a reaching out to the world" (Solomon, 2003, p. 49). Emotions are not just subjective experiences, but rather, they claim a particular representation of the world and they represent the individual's (intended) dealings with this relationship (Frijda, 1986, 2007; Mesquita, 2010; Parkinson, Fischer, & Manstead, 2005). For instance, anger is a claim that the individual is entitled to more than he or she receives, and it represents a stance of nonacceptance. Emotions (aim to) change relationships in a given direction, or alternatively, maintain their current state. They are thus consequential to the individual's social environment.

Because emotions stand for certain interpretations of reality, they are culturally "moralized" (Shweder, Haidt, Horton, & Joseph, 2008). Emotions that fit the cultural ideals are valued or condoned, whereas emotions that violate the cultural ideals are condemned. In the previous edition of this volume, Shweder and his colleagues illustrated this principle by comparing American *anger* with its Tibetan counterpart, *lung lang.* Whereas the dictionary translation of *lung lang* is "being angry," *lung lang* and anger have divergent moral connotations. Anger fits the central American value of autonomy and assertiveness, and is regarded as a natural response that should be accepted by an individual. In contrast, *lung lang* is considered a morally bad feeling because it is at odds with the Buddhist emphasis on compassion and the ethical code of speaking, acting, and living in nonharmful ways. The Buddhist Tibetans regard *lung lang* as "a fundamentally destructive sentiment, equally harmful to self and others . . . as arising from an intrinsically flawed motivational state (a desire to harm another sentient being) and generative of ultimately bad results" (p. 416). Shweder and colleagues showed how these different moral connotations translate into differences in the quality, prevalence, intensity, and duration of the respective emotions themselves. In many cases, cultural differences in emotions can be understood from differences in the moral meaning of the interpretations they represent. Cultural differences in morality of particular emotions make the landscape of cultural differences in emotions meaningful and coherent.

In this chapter, we review evidence for cultural differences in the experience, expression, and regulation of emotion. In doing so, we discuss how cultural variations in emotions may be adaptive in the respective cultural contexts.

Cultural Differences in Emotional Experience

Cultural differences in emotional experience have been established in different ways. A first line of research has established cultural differences in the prevalence and intensity of particular emotional experiences, such as anger and shame. The guiding assumption in this type of research is that there is overlap in the experiences cross-culturally associated with the emotion concepts included in the study. For example, anger and shame are, at some level, comparable across cultures; starting from this assumption, the research then compares the prevalence and intensity of these experiences. A second line of research starts from one or more particular emotion concepts that have comparable equivalents across cultures, and investigates the degree to which these emotion concepts in fact reflect similar (or different) experiences. Here the assumption is that, while different concepts for anger can be meaningfully compared, they diverge in equally meaningful ways. A third line of research takes a slightly different approach, and studies cultural differences in the kinds of phenomena that are recognized as emotional. It assumes that an emotion like shame does not just exist but rather is constructed from available information, and it studies cross-culturally which types of information are required in order to have an emotional experience of shame. We discuss these different types of evidence.

Cultural Differences in the Most Prevalent and Intense Emotions

The most prevalent and intense emotions differ across cultures in ways that can be understood from differences in their moral connotations (Mesquita, 2003; Mesquita & Leu, 2007). Emotions that are conducive to important cultural ideals tend to be more prevalent and intense, and emotions that violate cultural ideals tend to be rare and suppressed (see Mesquita, 2003; Mesquita & Leu, 2007, for overviews). Many ethnographies evolve around the conspicuous presence of emotions that are conducive to cultural ideals, or the conspicuous absence of emotions that violate them. For instance, the anthropologist Lila Abu-Lughod (Abu-Lughod, 1986) describes the ubiquity of shame (*haslam*) in the Awlad 'Ali, a Beduin tribe in Egypt. Shame occurs whenever one's honor is threatened or violated, but every event that reveals a person's lack of autonomy or dependence is interpreted as such, including every encounter with people higher in the hierarchy (for women: men). In contrast, in *Never in Anger* the anthropologist Jean Briggs (Briggs, 1970) takes the near absence of anger as the starting point of her ethnography on the Utku Inuits in Northern Canada. Because the Utku Inuits depend on one another for survival during the long, severe winter, maintaining harmony is a central goal that is cultivated in many ways. Avoidance of anger, and the confrontations that ensue, is one of them.

Cross-culturally comparative research has similarly yielded cultural differences in the most prevalent and intense emotions that can be understood from important cultural ideals (Kitayama, Markus, & Kurokawa, 2000; Kitayama, Mesquita, & Karasawa, 2006). Shinobu Kitayama and his colleagues compared the prevalence and intensity of emotions in North American and Japanese college students. The emotions included in this research were sampled from the four quadrants of a two-dimensional space defined by valence (positive, negative) and social engagement (socially engaged, socially disengaged). Previous research had yielded the same two dimensions in the United States and Japan (Kitayama et al., 2000). In this space, the social engagement dimension describes the extent to which emotions reflect the relatedness, or conversely, the separation between people. For example, friendliness (positive) and shame (negative) are engaging emotions that underscore the relatedness and interdependence with other people. That friendliness emphasizes relatedness is obvious; for shame it may be less obvious. However, shame reflects concern with (the opinion of) others and promotes alignment with the social rules; in this sense, it is focused on restoring the relationship as well. In contrast, pride (positive) and anger (negative) underline the separation between people, and thus serve independence and autonomy.

Cross-cultural comparison of the frequency and intensity of emotions yielded a clear pattern (Kitayama et al., 2006). In each culture, emotions that promoted culturally central goals and values were more frequent and more intense. In (middle-class) European American contexts, where individuals strive to be both independent and autonomous, socially disengaging emotions were found to be more intense and more frequent; in contrast, in Japanese cultural contexts, where the main goals are interdependence, relatedness, and harmony, socially engaging emotions were found to be more intense and more frequent (Kitayama et al., 2000; Kitayama et al., 2006). The cultural differences were replicated across different methods: They were found for frequency ratings in a retrospective self-report study (Kitayama et al., 2000), for intensity ratings with regard to the most important emotional event in a daily diary study (Kitayama et al., 2006, Study 1), and for intensity ratings with respect to recently experienced instances of a standard list of about 20 situation types (Kitayama et al., 2006, Study 2). The latter study suggests that cultural differences in intensity were not merely due to differences in the types of situations that people from different cultures typically encounter (but see the section "Cultural Promotion of Situations"). The findings are corroborated by observations from other research, and thus inspire confidence. For instance, other researchers have also described shame as a focal and valued emotion in Japanese cultural contexts (e.g., Benedict, 1946; Heine, Lehman, Markus, & Kitayama, 1999; Lebra, 1983).

Other evidence for nonrandom culturally different patterns of emotions comes from research comparing the intensity profiles on a variety of emotional experiences across different cultural groups. In this research, participants described their experience in response to a number of well-chosen, standardized situational prompts. The prompts were representative of the domain of emotional experience, and varied with respect to valence (positive, negative), social engagement (engaged, disengaged), and context (work/school, home). For each prompt, we compared individuals' patterns of emotion ratings (on 20–30 different emotions) to a cultural average pattern for the same prompt (De Leersnyder, Mesquita, & Kim, 2011). In two studies, we respectively compared the emotional patterns of European Americans against those of Koreans, and of Belgians against those of Turks (De Leersnyder, Kim, & Mesquita, 2015). All participants resided in their native countries, and in both studies, cultures were chosen to differ in important ways. Same-culture fit was consistently higher in all cultures, meaning that there are cultural differences in the typical patterns of emotions.

In the same studies, we also included immigrant groups: first and later generations of Korean Americans and Turkish Belgians, respectively. We found that immigrants' fit with the new culture's average emotional pattern held the middle between that of individuals from the new and from the heritage culture (De Leersnyder et al., 2011, 2015). For instance, Turkish Belgians fit the average Belgian emotional patterns significantly better than did Turks in Turkey, but worse than the Belgian majority. This suggests the possibility that exposure to a new culture changes the most prevalent/intense emotions. Consistently, immigrants' emotional fit with the new culture's emotions could be predicted from the number of years spent in the new culture and number of contacts with majority members of the new culture; this was true for Turkish immigrants in Belgium and Korean immigrants in the United States. Other studies replicated these findings: Contacts with majority members predicted fit with the new culture's emotions in a nationally representative sample of minority youth in Belgium (Jasini, De Leersnyder, & Mesquita, 2015) as well as with four different groups of immigrant minority women in the United States (Consedine, Chentsova-Dutton, & Krivoshekova, 2014), rendering more confidence in the results. We have not yet examined the nature of the changes in detail, but would predict that emotional patterns change to better fit the ideals and values of the new culture. The data with immigrants suggest that engagement in the culture contributes to the cultural shaping of emotions. Moreover, cultural shaping may happen throughout life and is not restricted to early socialization.

Cultural Varieties of Emotional Experience

The research reviewed so far suggests that there are differences in the frequency and intensity of emotions, but is not conclusive with respect to the quality or nature of emotions. There is increasing evidence that the quality of emotions varies across cultures as well (see Mesquita, 2003; Mesquita & Frijda, 1992; Mesquita, Frijda, & Scherer, 1997; Mesquita & Leu, 2007; Shweder et al., 2008). We distinguish two approaches to research on the varieties of emotion. In a first approach, researchers cross-culturally compare the characteristic components of a given emotion. This approach has essentialist overtones, in that it assumes the correspondence of an emotion concept to one particular experience (see the section "Characteristic Components of Emotions"). The question addressed by this research is to what extent the experience is similar or different in different cultures. In a second approach, researchers are interested in the different varieties of experience subsumed under one emotion concept. This approach starts from the assumption that, in each culture, people use a given emotion concept to refer to a variety of experiences (see the section "Varieties of Emotional Experience"). The question addressed by research following this second approach is to what extent certain varieties of an emotion cross-culturally occur at different rates.

Characteristic Components of Emotions

One strand of research starts from the idea that there may be cross-cultural differences in the components characterizing certain emotions. Much of the cross-cultural research has used a single format: Across various cultures, participants describe a situation in which they experienced a given emotion, and rate the presence of different aspects of that emotion—most notably appraisals, action tendencies, and somatic changes. Given that this type of research starts from the lexical equivalents in different languages, it should not be surprising that most of this research yields a cross-culturally similar core of meaning for each emotion. In one of the key studies, students from 37 different countries across the world (Scherer, 1997a, 1997b; Scherer & Wallbott, 1994) reported instances of joy, fear, anger, sadness, disgust, shame, and guilt. Each of these emotions was characterized by a similar core of appraisal and action readiness. For instance, joy was characterized as very pleasant, expected, requiring no action, and enhancing self-esteem, and was associated with "moving toward."

Against the backdrop of these similarities, many studies have found meaningful cultural differences in appraisal as well. For instance, individual agency and control (self-responsibility vs. other responsibility) were more strongly associated with negative emotions in Western than in non-Western cultures (Mauro, Strefeler, Weeden, & Reisch, 1992; Scherer, 1997b, as cited in Mesquita & Ellsworth, 2001). In one of the early studies comparing emotions in Japanese and U.S. contexts (Matsumoto, Kudoh, Scherer, & Wallbott, 1988), agency was found to be a central aspect of negative emotional experience for U.S. students, but considered "not applicable" by many Japanese students. Differences in appraisal can often be related to the dominant cultural views on reality: In cultures that value the independence of individuals, personal agency and control are "chronically accessible," and, therefore, become readily part of the meaning of emotional events.

Differences in control appraisals were also central in a study that compared the experience of *amae* for North American and Japanese participants (Niiya, Ellsworth, & Yamaguchi, 2006). *Amae* is a Japanese emotion that does not have an equivalent in English. It has been described as the feeling you have when another person depends on your love, makes inappropriate requests, and expects you to indulge or help him or her. Despite the absence of an English equivalent, North American and Japanese participants in this particular study appraised situations in which Japanese participants had previously reported to feel *amae* (i.e., others making inappropriate requests) in similar ways—for example, both North American and Japanese participants perceived the relationship with the other as closer during *amae* situations than during similar situations that did not involve *amae*. However, against the background of this cross-culturally similar experience, there were differences in control appraisals, with North American participants experiencing higher levels of control than Japanese in situations of *amae*. These differences in control can be understood from differences in the meaning of *amae*: For Japanese, "Amae implies closeness, trust, and security in relationships," whereas for Americans, "issues of patronage and pity may lurk in the background, creating heightened sensitivity to issues of control and the balance of power" (p. 292). Amae is a good experience in Japan where it stands for the right kind of interdependence, but is ambivalent in the United States where it signals intimacy, but potentially a threat of independence as well. The different connotations of amae have consequences for the frequency of the emotion in the respective cultures as well: "in a culture that emphasizes interdependence, people may be more tolerant of inappropriate requests, may interpret them more as a sign of intimacy, and may consequently experience positive Amae more frequently. On the other hand, in a culture that emphasizes self-sufficiency, people may experience positive Amae in fewer situations, with a more limited number of close others, and hence less frequently" (p. 292). Differences in the experience of emotions may thus have consequences for the frequency and intensity of the emotion as well.

This is also clear in the example provided by Shweder and his colleagues (2008) in the previous edition of this volume. Shweder compared the North American emotion of anger with its Tibetan equivalent *lung lang*, with respect to different components. The affective phenomenology, appraisals, self-management, communication, symbolization, and social management of anger and *lung lang* were all different in ways that could be understood from the respective connotations of anger and *lung lang*. For instance, anger lingered longer than *lung lang*, which can be understood from its positive connotation. In contrast, *lung lang* felt "as though drunk or crazy," and it co-occurred with a host of other dysphoric emotions, such as regret, shame, and unhappiness (affective phenomenology), because *lung lang* is a morally bad emotion. Consistently, anger was expressed, channeled, cultivated, and sometimes controlled, but *lung lang* was transformed, calmed, prevented, and extinguished by the respective cultural practices.

Cultural Differences in Appraisals

Some cross-cultural research has moved away from comparing emotions and toward comparing the particular ways in which people in different cultures make meaning of similar situations; this is what cognitive theories of emotion have called "appraisal." The findings from this type of cross-cultural research suggest, once again, that cultural differences in appraisal can be reduced to, and understood from, the prevalent cultural meanings and practices.

For example, claiming responsibility and having a sense of personal control is particularly important to independent cultural contexts, especially the European American; success thus stems from personal accomplishment (Markus & Kitayama, 1991b). In contrast, East Asian models of self stress fate and the interdependence of an individual and his or her social context; outcomes thus stem from a combination of circumstances (Fiske, Kitayama, Markus, & Nisbett, 1998; Heine et al., 1999; Nisbett, Peng, Choi, & Norenzayan, 2001). Indeed, it has been widely documented that European Americans have a pervasive tendency to attribute success to themselves, and failure to others or the situation, whereas the opposite is true for East Asians (e.g., Heine et al., 1999). A recent study tested what consequences these cultural differences in the appraisal of causal agency would have for emotional experience (Imada & Ellsworth, 2011). In this study, Japanese and European American college students were asked to remember success and failure situations; indicate if these situations had been caused by themselves, others, or circumstances; and rate the intensity of their feelings. The pattern of success and failure attributions was consistent with the observed self-enhancing tendency that is characteristic of European American contexts (attributing success to the self and failure to the context) and the tendency to focus on self-improvement that is characteristic of interdependent Japanese contexts (attributing success to circumstances and failure to the self). Furthermore, this cultural difference in appraisal was reflected in cultural differences in experience: European Americans reported to feel pride in success, and anger or bad luck when they failed; Japanese reported to feel lucky in success, and shame when they failed. Thus, people's habitual appraisals may differ across cultures in ways that make culturally valued emotional experiences more likely.

Similarly, some studies have further documented how cultural differences in the appraisals of agency and control may be linked to differences in the experience of frustration and anger. In fact, to experience frustration or anger is to appraise the situation in terms of its inconsistency with personal goals, the responsibility of other people, and the possibility of gaining control over the situation by forcing others to accommodate to your wishes (Frijda, 1986). Because in independent cultural contexts there is an emphasis on pursuing personal goals, protecting high self-esteem, being in control, and on influencing others, people in these contexts may more readily make use of the appraisals that are central to anger and frustration, rendering these experiences more likely in independent than in interdependent cultural contexts (Boiger, Mesquita, Tsai, & Markus, 2012; Morling, Kitayama, & Miyamoto, 2002; Savani, Markus, Naidu, Kumar, & Berlia, 2010; Weisz, Rothbaum, & Blackburn, 1984). A study by Roseman and colleagues nicely illustrated this idea (Roseman, Dhawan, Rettek, Naidu, & Thapa, 1995). In this study, Indian and American college students reported instances of anger, sadness, and fear, and rated their experiences on several appraisal dimensions. Consistent with the reasoning outlined above, Roseman and colleagues (1995) found that Indian college students not only reported lower overall intensities of both sadness and anger but also rated their self-reported emotional events to be less "incongruent with their motives" than did their American counterparts; in fact, the cultural differences in emotion intensity were fully mediated by the perception of motive incongruency.

Another domain of appraisal on which cultures tend to differ is the domain of morality (Shweder et al., 2008; Shweder, Much, Mahapatra, & Park, 1997). In fact, three forms of ethics have been proposed: (1) the ethics of autonomy, which have to do with individual rights, freedom, and justice; (2) the ethics of community, which center around social hierarchy, duty, and loyalty; and (3) the ethics of divinity, which are about sanctity, purity, and "the natural order of things." There is some evidence that another person's violation of each of these ethics is paired to a rather specific negative emotional experience toward that person. Several vignette studies (Laham, Chopra, Lalljee, & Parkinson, 2010; Rozin, Lowery, Imada, & Haidt, 1999) have found that violations of the ethics of autonomy were more readily associated with anger, violations of community with contempt, and violations of divinity with disgust.

What most of these cross-cultural studies have in common is that they compare the average, modal, or typical emotional experiences in different cultures. This assumes that, within each culture, a given emotion concept corresponds to *one* characteristic experience. The next section describes a different approach to cultural differences in emotional experience.

Varieties of Emotional Experience

It may be more accurate to assume that there is more than one type of emotional experience associated with a given emotion concept, say anger (Kuppens, Van Mechelen, Smits, De Boeck, & Ceulemans, 2007). If this were the case, averaging responses by culture is not the best way of describing emotional experiences associated with an emotion concept: Averaging the ratings across different instances of an emotion has the disadvantage that cultural differences in the varieties of emotions can be over- or underestimated. For instance, anger may in most cases be felt in the same way as *lung lang*, with some notable differences that skew the average; or alternatively, anger may in most cases be a distinct experience from *lung lang*, but different varieties of, respectively, anger and *lung lang* average each other out, and conceal the differences.

In a recent study, we examined cross-cultural differences in the types of experiences most typically associated with anger and shame in three different cultures: the United States, Belgium, and Japan (Boiger, De Leersnyder, et al., 2013). We looked at respondents' intensity ratings of either anger or shame as well as their appraisals and action readiness in particular situations. We started from a representative sample of situations, which ensured that the varieties of anger and shame that emerged from the data reflect the range of experiences as they occur in the three cultures. To infer the varieties of anger and shame, we used a bottom-up classification program (CLASSI; Ceulemans & Van Mechelen, 2008) that infers different "types of people" from the data, using the associations between appraisal and action readiness patterns and emotions across many different data points—the different situations.

In this study, we found three different varieties of anger—actually three types of people who have unique patterns of appraisals and action tendencies associated with anger across the different situations included. All three varieties occurred in every culture, but not to the same extent. The most typical experiences of anger could be understood from the respective cultural models. There was a clear Japanese type of anger, in the sense that 55% of the Japanese respondents were classified under this "person type." Scrutinizing the specific appraisals and action tendencies revealed that this type of person experiences anger in ways that hurts the relationships with others least: nodding and smiling is a prominent response, and so is rumination. The American person type for anger (i.e., the type that described the largest proportion of Americans; 43%) emphasized the boundaries between the person and other people the clearest: It was strongly associated with both blaming the other person and giving him or her a piece of your mind. Finally, there was a third type of anger that can be referred to as the "Belgian type" (37%) in the sense that it was not taken by the other two cultural groups. Although the different person types did not fully coincide with the different cultural groups—all three types occurred in all three cultures—we were still able to correctly predict the culture of a particular respondent from the type of anger he or she experienced with 43% accuracy (which is significantly higher than chance level).

For shame we found two varieties: one "American" (85% of the American respondents belonged to this person type for shame) and one "Japanese" (92% of the Japanese belonged to this person type). Still, both varieties occurred in all three cultures. The specific appraisal and action readiness pattern associated with American shame involved a focus on what others were thinking and on your own responsibility for what happened. This is an understandable variety, given the American concern with self-esteem. In contrast, Japanese shame was characterized by an attempt to regain composure, which fits the Japanese emphasis on relational smoothness. Interestingly, the Belgian respondents were almost equally divided between these two varieties of shame. Based on these two varieties, we were able to correctly predict whether the respondent was Japanese or Western with more than 70% accuracy.

From this research, we conclude that there are multiple varieties of emotions, in terms of the appraisals and action tendencies associated with emotional experience. Even if the same varieties of experience can be found in different cultures, there appear to be cultural differences in the prevalence of each variety. The most typical variety appeared to be the one that best fit the cultural meanings and ideals. This new approach to study cultural differences in emotional experience—in terms of the frequency distributions of certain varieties of emotions—leads away from an essentialist notion of emotions: An emotion is a concept referring to a cluster of experiences, rather than a "thing." It is a first step to the question of how people "do emotions," and away from the question of which emotions people "have" (Mesquita, 2010). We return to this issue later.

Cultural Differences in the Experiences Recognized as Emotions

A final way to approach differences in emotional experience is to focus on differences in the types of phenomena recognized to constitute an emotion. This is what the anthropologist Paul Heelas (1986) refers to when he puts forward the hypothesis that

> Emotion talk functions as a kind of spotlight. Depending on culture, it dwells on whatever is taken to be associated with those raw experiences necessary for emotions . . . . How raw experiences are constituted as emotions depends on how they are illuminated. . . . Emotional elements which have no light thrown on them remain in the dark. And emotions which are focused on become enriched and highlighted in experience. (p. 257)

This perspective approximates a constructivist model of emotions (Barrett, 2012; Barrett & Russell, 2015), as it assumes that emotional experience emerges from the selective perception of a large variety of phenomena (subjective, physiological, situational, behavioral). There is anthropological evidence consistent with this hypothesis, but psychologists have started to test it as well.

Differences in the cultural "spotlight" on emotional phenomena reflect the differences in cultural models of behavior generally. In independent cultures, such as the United States, feelings, thoughts, and actions are understood to arise from the individual and his or her internal states. In contrast, in interdependent cultures, such as Japan, feelings, thoughts, and actions are understood to arise from the relationships between individuals; emotions here are an interdependent project, necessarily involving the psychological states and actions of others (Markus & Kitayama, 2004). Emotions are defined accordingly: either as phenomena within a person (in independent cultures) or as phenomena between people (in interdependent cultures).

In a series of studies, Uchida and colleagues found that emotions are differently defined in Japanese and American contexts (Uchida, Townsend, Markus, & Bergsieker, 2009). In Japanese contexts, emotions were understood as "between people," whereas in American contexts, emotions are understood as primarily "within people." The research provided four types of evidence for this idea by analyzing the emotions of Olympic athletes (2004 Olympic games in Athens). First, in television interviews, Japanese athletes used more emotion words than American athletes when talking about their relationships. Second, when Japanese and American students had to write about the typical reactions of an athlete who had just won, Japanese students wrote more about athletes' relationships than American students. Third, Japanese participants inferred more emotions when an athlete mentioned relationships, whereas American participants inferred more emotions when the athlete focused only on him- or herself. And finally, when viewing images of athletes, Japanese participants inferred more emotions for athletes pictured with teammates, whereas American participants inferred more emotions for athletes pictured alone. In sum, Americans saw emotions essentially as inner experiences, but Japanese focused on the interaction side of emotions. This finding is consistent with many early observations by anthropologists (e.g., Heelas, 1986; Heider, 1984; Lutz, 1982, 1983; Shweder & Bourne, 1982). As Catherine Lutz (1983) put it: "What we term emotion is seen by [other cultures] as relational, and as a product of social interaction, rather than as a purely mental [. . .] process occurring within the individual" (p. 251).

In a study with West Sumatran participants, Levenson, Ekman, Heider, and Friesen (1992) happened upon these different ways of defining and recognizing emotions. The participants were asked to pose certain facial expressions (using a directed facial action task), with the expectation that these expressions would elicit similar automatic nervous system (ANS) responses and similar emotional experiences in the West Sumatran participants as they had done in American college students. The West Sumatran participants showed many of the same ANS responses in response to posing the facial expressions, yet none of the West Sumatran participants reported *experiencing* "emotion": For them, emotions necessarily involved other people, and they did not recognize emotion when they were by themselves.

Conversely, in several facial recognition studies in which participants judged a target person's emotions (Masuda et al., 2008; Masuda, Wang, Ishii, & Ito, 2012), Westerners' ratings of the target's facial expressions were not at all influenced by the facial expressions of the people surrounding the target: The emotions of the surrounding people were deemed irrelevant to the target's emotions (which were read from his or her face). However, Japanese participants clearly used the surrounding people's facial expressions when judging the target person's emotions (e.g., the smiling target person was judged less happy if the surrounding people portrayed angry or sad expressions). For Japanese, emotions are "between people," whereas for Americans emotions are "within people."

Perhaps related is the finding by Chentsova-Dutton and Tsai (2010) that a focus on the individual self produced more intense positive emotions in European Americans, whereas a focus on a family member increased, in two out of three studies, the intensity of positive emotions in Asian Americans. Specifically, participants were asked to write about themselves in one condition, and to write about a family member in the other condition, after which they watched an amusement-inducing film, or listened to upbeat music. Participants' emotions during the viewing or listening part were more intense in the culture-relevant condition, as measured by self-report, facial behavior, and heart rate. One way of explaining this finding is that activation of the culture-relevant self (as either individual or as related) focused attention as well as thoughts on aspects of the situation that are consequently defined as "more emotional."

Some differences in emotion construction can be plotted along the dimension of "mentalistic" versus "somatic" interpretations. A well-known example comes from Robert Levy's (1973) ethnography about the Tahitians and concerns the emotion of sadness. The Tahitians have

> no unambiguous terms which represent the concepts of sadness, longing, or loneliness [. . .] People would name their condition, where I supposed the context called for "sadness" or "depression" as "feeling troubled" (the generic term for disturbances, either internal or external). (p. 305).

One way of understanding the absence of a word for "sadness" in Tahitian, and one that Levy himself favors (p. 224), is that Tahitians "somatize" an experience that is essentially mental (see Mesquita & Frijda, 1992, for a similar view). However, it is also possible to understand the Tahitians' "troubled feelings" as simply a different "spotlight" on the complex set of phenomena that we associate with "sadness." It is very possible that Tahitians focus on somatic impact, where many Westerners would focus on the meaning of the situations, and thus "mentalize" (the word is borrowed from Ryder & Chetsova-Dutton, 2012, who make a similar argument for cultural differences in the experience of depression).

That differences in the defining features of emotions go beyond semantics is suggested in a recent study by Immordino-Yang, Yang, and Damasio (2014). In this functional magnetic resonance imaging (fMRI) study, Chinese, Asian American, and European American participants viewed 40 video clips of admiration, compassion, or empathy-inducing narratives that had been introduced to them more extensively in a preparatory stage of the research. Half of the clips had been derived from Chinese true-life narratives, the other half from sources from the United States. During each clip, participants underwent blood-oxygenation-level-dependent (BOLD) fMRI with simultaneous electrocardiogram (ECG) recording, and reported the strength of their emotion by pressing a button. The researchers focused on the association between feeling strength and the activation of the anterior insula (AI), which has been found to be one of the sites of (emotional) experience. The ventral AI has been associated with autonomic processes, and the dorsal AI with somatosensory and cognitive processes. There were no cultural differences in the mean intensity of reported emotions, cardiac arousal, and magnitude of BOLD signals. However, there were cultural differences in the relative association of ventral and dorsal activity of the AI with feeling strength. In Chinese, feeling strength was associated with activation of the ventral AI, and thus relied on autonomic changes; in contrast, in European Americans, feeling strength was associated with activation of the dorsal AI, and thus relied more on expression and/or cognitive processes. The bicultural East Asian American group showed patterns of brain activity that were "in between" those of both monocultural groups. The study is consistent with the idea that cultural learning influences the types of information selected or highlighted when "constructing" emotional feeling (Barrett, 2012; Immordino-Yang, 2010).

Cultural differences in emotional experience may thus be seen as resulting from differences in the phenomena defined to be emotional—"the spotlight." This process is very close to what Barrett (2012) calls "collective intentionality":

> To create emotions, there must be a group of people who agree that certain instances (e.g., body states or physical actions) serve particular functions (to make sense of the world, to direct subsequent action, to communicate intentions, to control the actions of others). [. . .] One implication from this perspective is that the reality of emotion is always embedded in a certain situation or context, even though typically the context is not made explicit. (p. 420)

By ascribing differences in emotional experience to cultural differences in collective intentionality, we once again answer the question of how people "do emotions," rather than what emotions they "have."

How Do Cultures "Do" Emotions?

Describing these nonrandom cultural differences in emotions is only a first step toward understanding the relationship between culture and emotion. It does not reveal the processes by which cultures promote functional and suppress dysfunctional emotions (Mesquita, De Leersnyder, & Albert, 2014). Evidence on how cultures "do" emotions is scattered, and a full picture emerges only when combining the insights from different strands of the literature. We subsequently discuss several aspects of "doing emotions": (1) the cultural differences with respect to the norms and ideals of emotions; (2) the ways in which cultures promote situations that elicit norm-consistent emotions, and avoid or discourage situations that elicit norm-inconsistent emotions; and (3) how emotions unfold in culture-specific types of interactions and relationships.

Ideal Emotions, Emotion Norms

Cultures differ with respect to their emotion norms and ideal emotions and, while far from perfect, there is overlap between actual emotions and the respective norms for what emotions people should experience, as well as the ideals of what emotions people would like to experience (Eid & Diener, 2001; Tsai, Knutson, & Fung, 2006). A culture's emotion norms and ideals will motivate people to actually experience these emotions, even if the emotional outcomes are not perfectly matched.

Emotion norms and ideals tend to be meaningful in the light of the cultural models. For instance, Eid and Diener (2001) conducted a large cross-cultural study in which participants from both independent (European American and Australian) and interdependent (China and Taiwan) cultural contexts rated the desirability of several emotions, both positive and negative. The largest cultural differences in desirability were found for "pride" and "guilt." Feelings of pride were more positively valued in independent than interdependent cultures, whereas the opposite was true for feelings of guilt. This may be the case because pride signals a person's autonomy and uniqueness, which is valued in independent cultures, but at the same time, is considered "dangerous" in interdependent cultures that recognize the potential of pride to disrupt social harmony. Conversely, guilt may be desirable from the point of view of East Asian cultural models, because it signals an individual's concern for relational harmony (and the readiness to take full responsibility for a violation of this harmony), but not in Western cultures because it hints to a less-than-positive performance of the individual.

Systematic cultural differences in the emotions people "ideally would like to feel" (Tsai et al.,

2006) can equally be understood from the central cultural models. Tsai and her colleagues asked people from different cultures to rate their "ideal feelings" on emotion scales that represented the four quadrants of the affective circumplex; the affective circumplex is defined by the dimensions of pleasantness (unpleasant–pleasant) and activation (low–high). Tsai found consistent differences between European Americans, who "ideally" wanted to feel more high-activation positive states, such as excitement and elation, and East Asians, who preferred low-activation positive states, such as peaceful and serene feelings (e.g., Tsai et al., 2006). Further research showed that ideal emotions prepare individuals best for the tasks that are culturally central (Tsai, Miao, Seppala, Fung, & Yeung, 2007): High-activation positive emotions that are promoted in North American contexts prepare individuals for influencing others. In contrast, low-activation positive emotions that are promoted in East Asian contexts facilitate social adjustment.

Similarly, in a comparison between European American and German students, Koopmann-Holm and Tsai (2014) found that European Americans want to avoid negative emotions more than Germans. The differences in avoided negative affect were larger than the differences in actual negative affect, although they did seem to impact actual affect as well: Germans felt more sad, unhappy, and lonely than European Americans. The authors explain the difference in avoided negative affect from a difference in values: Whereas European Americans focus on achievement and mastery values, Germans prioritize harmony values. Achievement and mastery values are associated with "achieving one's goals, influencing others, and overcoming nature" (p. 19). Indeed, cultural differences in the avoidance of negative emotions was mediated by the achievement and mastery values.

Cultural differences in emotion norms and ideals are not only visible in terms of differences in attitudes but also in the different cultural worlds in which people engage. Several studies have compared popular children's books from different cultural contexts, because these books are important tools for socialization (at least in literate cultures). Tsai found that best-selling children's storybooks in the United States and Taiwan portrayed the culturally ideal emotions: Storybooks in North America typically portray their main characters with excited rather than calm smiles, whereas storybooks in Taiwan portray more calm smiles (Tsai, Louie, Chen, & Uchida, 2007, Study 2).

Boiger and colleagues compared the prevalence of shame and anger in popular children's books from the United States and Belgium (Boiger, De Deyne, & Mesquita, 2013, Study 2). Belgium, like the German culture described earlier, is less achievement and mastery oriented than the United States, and more focused on universalism (respect for everybody and everything), harmony, and equality. In line with these cultural differences, anger—as an emotion that facilitates achievement and mastery—was more frequently depicted by U.S. than Belgian children's books. In contrast, shame—as an emotion that points to failure and contrasts with mastery—was nonexistent in the U.S. books, whereas it was portrayed in 26% of the Belgian children's books, which is again in line with the relatively stronger Belgian concern for harmony and equality. Finally, Vander Wege and colleagues (2014), found a similar pattern of highlighting valued or normative emotions when comparing popular U.S. children's books against children's books from Romania and Turkey. Again, the American books emphasized negative powerful emotions (such as anger) in comparison to Romania and Turkey, both in terms of frequency and intensity of the emotions that characters displayed.

Cultural products are not limited to children's books. Tsai and colleagues found representations of ideal affect in advertisements in American and Chinese women's magazines (Chim, Moon, & Tsai, 2009) and in religious texts (Tsai, Miao, & Seppala, 2007). American advertisements had more excited (vs. calm) smiles than did Chinese advertisements (Chim et al., 2009). Consistently, contemporary Christian self-help books (the dominant religion in North America) endorsed more high-arousal positive states than Buddhist contemporary texts, which endorsed more low-arousal positive states (Tsai, Miao, & Seppala, 2007). In a related vein, Koopmann-Holm and Tsai (2014) found that German sympathy cards contained more negative and less positive content than American sympathy cards. A typical German card would encourage and acknowledge grief (e.g., "In deep sadness" or "Sharing your sadness"), whereas a typical American card would encourage and wish something positive (e.g., "The memories are yours" or "Hold on to hope"). Moreover, the degree to which individuals wanted to avoid negative emotions predicted which kind of sympathy card they selected. Therefore, the sympathy cards may in fact be seen as a means to regulate emotions in line with the cultural ideals. Together, the evidence suggests that ideal affect is not only in the head of people, it is also in their cultural worlds.

Emotion norms guide cultural *practices* as well. European Americans chose more profile photos with excited smiles for their Facebook pages than did Hong Kong Chinese, with Asian Americans falling in between the two groups (Moon, Chim, Tsai, Ho, & Fung, 2011). Similarly, North Americans and (Dutch-speaking) Belgians associated different words with the emotions of anger and shame, and the respective associations resonated with the cultural emotion norms. In a large-scale word association task, anger in the United States was associated with words that indicated yielding to the emotion (e.g., through hitting or shouting), whereas anger in Belgium was associated with words indicating containment of the emotion (e.g., through withdrawing or ignoring) (Boiger, De Deyne, et al., 2013, Study 3). Connotations for shame were the opposite of anger: Americans associated words of containment with shame, whereas Belgians associated words of yielding with shame. Thus, Americans and Belgians associate anger and shame with different connotations, and the respective connotations reflect the extent to which these emotions are valued in the two cultures.

Cultural Promotion of Situations

One reason for cultural differences in emotional experience may be that, across cultures, people seek out and encounter different types of situations. For example, it is possible that people in some cultures simply receive more compliments than in other cultures. To the extent the compliments elicit feelings of pride in all cultures, this means that there would be cross-cultural variation in the frequency and/or intensity of pride.

Several studies have suggested that situations that help to accomplish central cultural goals or tasks are relatively frequent. An example is the relatively high rate of compliments (or stickers, smiley faces, and awards in schools) in Northern American contexts (D'Andrade, 1987). Compliments fit—and help to achieve—the culturally central goals of enhancing a person's self-esteem and making him or her feel unique. In contrast, compliments are rare in cultures with less emphasis on self-esteem, such as Japan, where the focus is rather on fitting in. In Japanese schools, children are encouraged to be self-critical and reflect on ways to overcome their shortcomings in order to meet the group's standards (Lewis, 1995).

In a series of comparative survey studies from our own lab, we predicted the frequency of a set of emotion-eliciting situations from (1) their potential to elicit a given emotion, and (2) the value of that emotion within the particular culture (Boiger, De Deyne, et al., 2013, Study 1; Boiger, Güngör, Karasawa, & Mesquita, 2014; Boiger, Mesquita, Uchida, & Barrett, 2013). The research focused on shame and anger. In a first comparison between the United States and Japan, we expected that anger situations are afforded in the United States and avoided in Japan. In the United States, anger is a hallmark of autonomy and independence (Markus & Kitayama, 1994), but in Japan it violates the interdependent model of relatedness and harmony. Conversely, we predicted that shame situations are avoided in the United States but afforded in Japan. Shame violates the U.S. cultural model, because it undermines positive self-regard, but it is consistent with the Japanese ideal of self-reflection and self-improvement, as it increases an individual's awareness of his or her own shortcomings (Heine et al., 1999; Lebra, 1992; Oishi & Diener, 2003). Consistent with these expectations, we found that the higher the potency of a situation to elicit (high-intensity) anger, the higher its (perceived) frequency in the United States and the lower in Japan; conversely, the higher the potency of a situation to elicit (high-intensity) shame, the lower its rated frequency in the United States and the higher in Japan. In sum, situations that elicit culturally condoned emotions seem to be afforded, whereas situations that elicit culturally condemned emotions seem to be avoided.

When repeating this study with Turkish and Japanese situations and respondents, Boiger and colleagues (2014) replicated the pattern of results in Japan, but found that both anger and shame situations were perceived to occur frequently in Turkey. This concurrent "up-regulation" of anger and shame situations may be typical of an honor-based interdependent cultural context, such as Turkey. In honor cultures, "honor must be claimed, and honor must be paid by others" (Leung & Cohen, 2011, p. 509). The need to take a stand and uphold a reputation of toughness, while at the same time having to rely on others to confirm one's reputation may explain the concurrent promotion of anger (as an emotion that helps in claiming honor) and shame (as an emotion that protects honor by preventing others from losing respect) in Turkey. In comparison, in face cultures, such as Japan, face cannot be claimed but is obtained by social conferral only; this explains why only shame-promoting situations were perceived as frequent in Japan. Thus, cultural differences in the affordance of anger- and shame-eliciting situations may contribute to our understanding of the previously reported differences in emotional experience.

Consistently, research by Tsai, Knutson, and Rothman (2007) has found that people individually and culturally select situations that will lead to ideal emotions. When given a choice in an experimental setting, European Americans selected artifacts (e.g., CDs) that elicited high-arousal over those eliciting low-arousal activities, whereas the reverse was true for East Asians. Societal statistics corroborate these experimental results: North Americans prefer re-creative drugs, leisure activities, and music that elicit high-arousal positive emotions over their counterparts that elicit low-arousal positive emotions, whereas East Asian societies prefer low-arousal positive activities. Moreover, within a North American sample, individual differences in the preferential activities (leisure time, drugs, types of vacations) were predicted by ideal affect in ways that mirrored cultural differences between North Americans and East Asians (Tsai, Knutson, & Rothman, 2007). The more people valued excitement states, the more they preferred partying versus reading, running versus walking and stimulating versus calming drugs. Moreover, these differences in ideal affect accounted for cultural differences in these mood-producing behaviors, even after controlling for actual affect.

Culture-Specific Types of Interpersonal Emotion Regulation

Finally, emotional experience may come to differ across cultures because people help one another deal with emotional experience differently or because they structure one another's social contexts in different ways. For example, people may actively support and positively reward certain emotions in others, while ignoring or even punishing other kinds of emotions. The combined evidence suggests that interpersonal regulation is often geared to aligning emotions with the respective cultural models. Relatedly, emotions are often used to align people, children and adults alike, to the social order.

Emotions as Socialization Practices

Parents' socialization practices are examples of interpersonal emotion regulation that are conducive to the culturally valued emotions. For example, Cole and colleagues investigated how parents respond to their children's emotions in a series of studies with the Tamang and Brahman—two Nepali ethnic groups (Cole & Tamang, 1998; Cole, Tamang, & Shresta, 2006). On the one hand, the Tamang value harmony and self-effacement, and therefore, discourage anger but encourage shame. On the other hand, the Brahman associated their high-caste status with social dominance and self-control, encouraging anger but discouraging shame. In the case of anger, both Tamang and Brahman mothers were equally likely to ignore their children's anger (25%), yet the mother's active responses to anger (the other 75% of the cases) differed: Whereas Tamang mothers actively discouraged anger by rebuking, scolding, or teasing their angry children, Brahman mothers actively supported their children's anger in the form of teaching (i.e., calmly reasoning with the child), and to a lesser degree in the form of nurturance (i.e., hugged, kissed, spoke endearingly, or gave a treat that was not requested by the child), thereby communicating that anger is a justified experience of an individual with high status, such as they were. Tamang mothers were equally likely to respond by ignoring, teaching, and nurturing (each about 30%) when their child displayed shame, whereas Brahman mothers largely ignored their child's shame (about 75% of all responses), thereby communicating that shame is not a justified experienced for a high-status individual.

Similar cultural differences have been observed with Japanese and German mother–child dyads. Friedlmeier and Trommsdorff (1999) studied how mothers and their 2-year-old daughters work together in regulating the daughters' distress after being confronted with a playmate who felt sad about a broken toy. German mothers communicated that while it is important to know what other people feel, this should not affect your own feelings. They did so by emphasizing the distress of the playmate, while simultaneously ignoring that their daughters themselves were distressed. In contrast, Japanese mothers communicated that the emotions of ingroup members are ultimately to some extent your own emotions as well. They emphasized and acknowledged their daughters' empathy and feeling of what the playmate was feeling. The differential emotion regulation left the Japanese children more tense than the German children; however, each child was also socialized to be culturally attuned in this way.

Parents also strategically deploy emotions in interactions with their children to socialize cultural norms. The strongest evidence probably comes from developmental psychology and anthropology, where a number of studies have shown that parents use emotions strategically to modulate their children's behavior, and ultimately their acquisition of cultural norms. Trommsdorff and Kornadt (2003) have shown that German and Japanese mothers engage in particular emotion strategies in order to socialize the receptive cultural norms for autonomy (in Germany) and relatedness (in Japan). During conflicts with their children, German mothers tend to engage in escalating interactions of reciprocal anger and frustration, during which both the mother and the child communicate and enforce their own, autonomous perspective. In comparison, Japanese mothers tend show disappointment, yet make concessions by comforting their child and appeal to their empathy in order to maintain harmony and the desired feeling of "oneness" (*ittaikan*). These different strategies of German and Japanese mothers had long-term effects on children's emotional development: Escalation of interactions in early childhood predicted the level of empathy-based altruism and aggression 9 years later (Kornadt & Tachibana, 1999, as cited in Trommsdorff & Kornadt, 2003). Importantly, the emphasis on self-assertive or domineering emotions (e.g., anger) in the German dyads can be seen as a means of fostering the German cultural norm for autonomy, while the focus on submissive emotions (e.g., sadness, shame) in the Japanese dyads appears to foster the Japanese cultural norm for relatedness.

Parents use emotions as socialization tools not only during conflict, but also in the way they highlight certain emotional events over others. By highlighting those emotional experiences that match their cultural goals, parents pull attention to emotional states that support their socialization goals. For example, Taiwanese parents frequently instill shame in their children to mark transgressions of social rules (Wang, 1992; Fung, 1999; Fung & Chen, 2002). Fung (1999) reports how Taiwanese mothers frequently shamed their youngsters of 2½–3 years. Remarkably, most of the shaming was conducted in a rather playful format, teaching the children to distinguish right from wrong as the transgressions were unfolding. Shaming was not intended to harm or ostracize the child, but rather to "transmit the cultural values of discretion shame [. . .] teaching children how to be part of society, to include them rather than to set them apart" (pp. 202–203). The emotions that Taiwanese parents instilled in their children stand in stark contrast to the behavior of American, lower-class parents of Baltimore (Miller, Fung, & Mintz, 1996; Miller, Wiley, Fung, & Liang, 1997). In the Baltimore context, parents actively avoided turning their children's norm transgressions into shameful experiences by paying little attention to norm-inconsistent behavior. In the rare cases that parents did bring up their children's transgressions, they framed them as nonserious wrongdoings in order to "toughen" their children for their daily realities.

One of the most vivid examples of how parents strategically use specific emotions to socialize culturally desirable behavior comes from anthropological research with the Bara in Madagascar and the Minangkabau in Indonesia. Röttger-Rössler, Scheidecker, Jung, and Holodynski (2013) argue for the role of different, so-called socializing emotions in these two cultural contexts. Based on evidence that parenting practices need to be emotionally arousing to be memorable and effective across cultures (Quinn, 2005), Röttger-Rössler and colleagues propose that socializing emotions are those emotions that parents instill in their children in response to norm-inconsistent behavior in order to "support and mediate the transmission and education of social norms in a culturally adaptive way" (p. 263). Socializing emotions, in part, are assumed to work through the associated action tendencies that are used to override other, less desirable, emotions and behaviors. As children repeatedly experience these emotions in situations in which they do not comply with the social norms, they eventually become internalized responses. The Bara use beating to instill strong experiences of fear (*tahotsy*) and a strong aggressive action tendency; the Mingangkabau use social exclusion strategies to instill shame-like emotions (*malu*). While both fear of pain/aggression and shame provide the function of warning children about norm violations, they aim to socialize different cultural norms and support local social structures. Fearful emotions (felt toward the sanctioning authorities such as elders) as well as the aggressive action tendencies (which are channeled at outgroup members and younger members) are functional for the Bara context, where society is segmented, competition between patrilineages is high, and hierarchies within patrilineages are clear-cut. In contrast, shameful emotions are more suitable for maintaining smooth relations in the more stratified Mingangkabau society, where social harmony rather than conflict is the goal.

Interestingly, the predominant Taiwanese, Bara, and Mingangkabau socializing emotions stand in stark contrast to Western ideas about socialization, according to which shaming or physical punishment/fear induction are seen as extremely harmful for norm internalization (e.g., Dix & Grusec, 1983; Tangney, Stuewig, & Mashek, 2007). We discussed the tendency to ignore shameful emotions among Baltimore parents; this leaves open the question of what emotions U.S. parents use to instill cultural norms in their children. Pride is a likely candidate (see also Quinn, 2005; Holodynski & Friedlmeier, 2006): By emphasizing personal achievements rather than failures, pride instills the much-valued feelings of self-esteem and uniqueness that are at the core of American culture. This is also in line with the observation that U.S. socialization contexts instill pride and other positive emotions by frequent mutual praise (Kitayama & Markus, 2000) and with awards and medals (D'Andrade, 1987).

Co-Regulation in Adults

Co-regulation of emotion is not restricted to mother–child dyads. There are many examples of adults co-regulating each other's emotions in ways that align them with the cultural models. For example, the Toraja (Indonesia) have elaborate interpersonal scripts for controlling anger and aggression in order to maintain the culturally central values of social harmony and cohesion (Hollan, 1988). Anger is socially controlled in two different ways: On the one hand, the Toraja cultivate a social etiquette that is geared toward maximizing predictability of social behavior and thus limiting frustration—for example, through "mandatory offerings of food, drink, and shelter; deferential, sometimes obsequious, behavior toward social betters; and dissimulation, including the use of indirect, allusive speech to "disguise" remarks that could be interpreted as critical or negative" (p. 56). On the other hand, the Toraja help each other stay "cool" when a person is perceived as potentially being angry. The typical strategy is to avoid direct contact with presumably angry persons in order not to further enrage them and thus to allow their anger to cool down; if contact is unavoidable, one is not to make direct eye contact with the angry person. A more radical way of dealing with emotions that may potentially disrupt group cohesion has been reported for the Ilongot (Rosaldo, 1980). In this small Philippine community, ingroup cohesion is central for the survival of the group. *Liget*, a powerful emotion that among others denotes energy, passion, and anger, holds the potential to threaten ingroup harmony. When an Ilongot experienced *liget*, a headhunting raid on an enemy tribe was initiated. Having beheaded a member of the enemy tribe, the beheader cast the head on the ground, thereby ridding himself of all powerful emotions such as *liget*.

The specific relationship arrangements in which people engage in a culture also affect how they disclose and retell their experiences or, in other words, share their emotions with others. Sharing emotions plays an important role in how diffuse emotional episodes are turned into accessible and coherent narratives and helps people take a more distanced view on the event (yet not necessarily providing relief; Rimé, 2009). One would expect that in cultures that emphasize social group cohesion, emotional experiences of any one group member are relevant to the others of the group. This appears to be the case. Mesquita (1993) found that in the interdependent cultures of Turkey and Surinam, participants report more active sharing of their emotional experiences with others while at the same time experiencing more active support from others than in the independent Dutch context. It appears that in these interdependent cultures, emotions take on a more "collective" narrative and are consequently dealt with as a common responsibility.

That emotions are socially regulated in ways that are adaptive to the specific cultural context also becomes visible during ritualistic events, which temporarily set established cultural models out of action and thus function in what has been coined a "liminal" space (Turner, 1969). Burning Man, a yearly temporary community festival in the Black Rock desert of Nevada that celebrates art and radical self-expression, is an interesting case in point. Burning Man provides its 70,000 participants with a space that is set outside the boundaries of U.S. mainstream culture, both spatially and in terms of its cultural practices. Among the shared practices, which are held up as the "10 principles," are radical reliance on one's own inner resources, radical expression of personality, and immediacy of (social) interactions, but also radical inclusion of every participant and a gifting rather than exchange economy. Structuring community and social interactions in this way appears to have a marked impact on how individuals regulate their emotions and, consequently, how they feel. Research by McRae and colleagues found that participants at Burning Man use less emotion suppression and more reappraisal during the festival than at home (McRae, Heller, John, &

Gross, 2011). The decrease in emotion suppression was surprising, seen that this regulatory strategy is usually associated with negative outcomes. In a set of follow-up studies, Snyder and colleagues found that the tendency to suppress emotions less was mainly driven by decreased suppression of positive emotions (Snyder, Heller, Lumian, & McRae, 2013). Suppressing positive emotions to a lesser extent may be functional in a

> cultural environment that supports joyful experimentation among adults. . . . The increased expression of positive emotion might encourage adults to play, by experimenting with new identities, emotional repertoires, senses of self, and cultural tools more than they would in other situations. (p. 9)

Conclusion

Emotional experience differs across cultural contexts. Cultural differences, for the most part, can be understood from culture-specific moralities (see Shweder et al., 2008): What constitutes a good person, good relationships, or moral behavior? Emotions that foster or highlight cultural norms and ideals are prevalent and intense, whereas emotions that violate or undermine these norms and ideals are rare. Anger experiences are frequent and intense in cultures that value independence and assertiveness, but not in cultures that center on interpersonal harmony. Similarly, certain aspects of emotional experience fit the cultural morality and they occur frequently, but aspects that are considered immoral or irrelevant are rare; personal agency resonates with cultural ideals of independence, but not with those of relatedness. The most typical emotional experiences thus differ across cultures.

We have gone beyond descriptive data of frequency and intensity, suggesting different approaches to describing emotional differences. These approaches have in common that they abandon essentialist ways of describing "emotions" (the word has one referent) in favor of process approaches. A first approach that we have described compares the relative frequency of different varieties of emotions in different cultures. In this case, it is assumed that across cultures, people use a particular emotion word for a variety of experiences or meanings (in terms of appraisal and action readiness), and the experiences most typically referred to may differ across cultures. This type of research preselects the types of experiences compared. For example, one study found that "shame" cross-culturally comprises two varieties (defined by particular sets of appraisals and action tendencies), but that cultures differ with respect to the variety of shame that most frequently occurs. The most prevalent variety of experience appears to follow naturally from the cultural norms and ideals. Shame always describes a larger collection of experiences, but which subset is salient depends on the culture.

A second approach challenges the essentialist notion of emotions even more: It suggests that cultures differ in the very phenomena they define as emotional, with some cultures focusing on subjective contents, and others on aspects of the emotional interaction; with some cultures focusing on "mentalistic," and others on "somatic" phenomena. These differences in "spotlight" or "collective intentionality" can be understood from morality issues as well. In cultures that focus on relatedness, interactive aspects of emotions come to the foreground, but in cultures emphasizing individuality, the subjective feeling is what counts.

The reviewed literature challenges the notion that emotional experiences are fixed—if cross-culturally different—patterns of responses, and calls instead for a view of emotions as action. The combined research on cultural differences suggests that the question should be *how people do emotions* across cultures, rather than *what emotions people have* (Mesquita, 2010). Adopting a perspective of action means that the research naturally shifts to the different factors that influence how people do emotions. Culture, then, becomes a framework within which people jointly and collectively do emotions, rather than a one-time determinant of emotion.

Our review of the literature suggests several ways in which people jointly or collectively do emotions. Cultural products, practices, rituals, socialization strategies, and interpersonal regulation behaviors all help to do emotions in ways consistent with cultural morality. These joint and collective processes are geared toward the cultural alignment of individuals' emotional experiences. In all these different ways, cultures afford and promote ideal and normative emotions, while simultaneously steering individuals away from condemned emotions; cultures help define if emotions are within or between people, primarily physical or cognitive, desirable or dangerous, and healthy or unhealthy.

This view on emotions as joint and collective actions has implications for our study designs. The focus should be on the cultural differences and similarities in the way people make emotions interactively and in context (Boiger & Mesquita, 2012; Mesquita & Boiger, 2014; Saarni, 2008), and away from cross-cultural comparisons of the emotions people have. Currently, very few cross-cultural studies take this perspective: The bulk of cross-cultural studies compare the modal or average individual responses to decontextualized stimuli. A more ecologically valid approach would consist of studying the interactions and cultural practices in which emotions are made. It is in these contexts that we will be able to see what the processes are that lead to cultural alignment of emotional experience.

It is worth mentioning that this approach challenges the traditional approach to the study of emotions that "control" for context effects. Given the intricate relationships between emotions and the specific socio-cultural contexts in which they occur, it is time to start considering contexts as part of the phenomenon to be understood. As Richard Shweder (1991) eloquently put it: "the so-called 'noise' is not really noise at all; it is the message" (p. 99).

CHAPTER 23

Intergroup Emotions

Eliot R. Smith and Diane M. Mackie

Current emotion research and theory generally assume that emotions are adaptive and functional, with a strong focus on their functionality at the biological or individual level. This focus has often involved the use of nonsocial "prototype" emotion situations (such as encountering a bear while walking in the woods) as conceptual touchstones. However, social aspects of emotions are increasingly being investigated, following from the recognition that (in humans) emotions involve socially constructed meanings and most often occur in a social context.

In this chapter, we describe a specific class of social emotions, which we have called "intergroup emotions"—emotions that arise when people identify with a social group and respond emotionally to events or objects that impinge on the group. After introducing the concept of intergroup emotions, we describe its relationship to theoretical models of emotions that usually are applied to individuals. We review evidence (from our own work and that of others) regarding the key properties of intergroup emotions, and conclude by summarizing the implications of this conceptualization, both for emotion theory in general and for intergroup relations. As we show, this model shares the assumption that emotions are generally functional, but at the level of social groups and not solely at the level of the individual.

What Are Intergroup Emotions?

Group Identification and Depersonalization

The fundamental insight underlying the concept of intergroup emotions derives from a major line of social-psychological theory and research inspired by social identity theory (Tajfel, 1978) and self-categorization theory (Turner, Hogg, Oakes, Reicher, & Wetherell, 1987). This is the idea that important group memberships (those with which people psychologically identify) become a part of a person's identity, along with the person's unique, personal, individuating attributes. The "group" in this conceptualization can be a relatively small number of people who interact face to face (such as a committee or a sports team), or a larger social category of people who do not interact face to face (such as a national, ethnic, gender, or religious identity). Either type of group can serve as a vehicle for social identification and can constitute an important and meaningful aspect of someone's identity.

Under circumstances that make a particular group membership or social identity salient, people do not think of themselves as unique individuals, but rather as relatively interchangeable members of the group (a process known as "depersonalization"). This occurs primarily in what is termed an "intergroup situation," one in which social comparisons, competition, or conflict between groups are salient—hence the name of our theoretical model, "intergroup emotions theory" (IET). The consequences of depersonalization are many (see Oakes, Haslam, & Turner, 1994, for a review). People conform to the norms of the activated group in their beliefs, attitudes, and behaviors. They become motivationally aligned with the group, so they see actions that advance the group's interests as desirable and beneficial. They perceive other members of the same group (the "ingroup") as similar to themselves and as likable, and tend to treat them with justice and fairness, while withholding these benefits from members of outgroups.

Tajfel's (1978) original formulation of social identity theory included the idea that when group identification turns a group into an important social identity for an individual, the group takes on emotional significance. However, compared with the cognitive, motivational, and behavioral consequences of group identification, until recently, emotional consequences received little theoretical or empirical attention in the large literature inspired by social identity theory. This seems odd in view of the obvious fact that intergroup conflicts (whether labor–management disputes, ethnic or religious conflicts, clashes between street gangs and police, or international wars) are regularly characterized by extreme levels of emotion. Both direct participants and bystanders who identify with one of the groups involved but are not directly affected tend to experience strong negative feelings, including anger, fear, resentment, contempt, and so on.

Group Identification as a Basis for Intergroup Emotions

The core concepts underlying IET, introduced by Smith (1993), flow from this theoretical background. The fundamental idea is that when someone in an intergroup situation is thinking of him- or herself in terms of a social identity, objects or events that affect the ingroup will elicit emotional responses, because the group becomes in a real sense an aspect of the person's psychological self (Smith & Henry, 1996). Simply put, under these conditions depersonalization causes the person to react to the world as a group member rather than a unique individual, and thus objects and events have emotional consequences based on the way the objects or events relate to the group, not the individual. These group-based emotions can be understood and analyzed in the same way as any others—by using theories of emotions in general, such as appraisal theories. At the heart of IET, therefore, is the distinction between intergroup emotions and the more commonly studied individual-level emotions.

Let us clarify two important points. First, in our conceptualization, intergroup emotions are experienced by individuals (when they identify as members of a group), not by some kind of group mind. Whether intergroup emotions are actually shared across many members of a group is not definitional but is an empirical question, and we present relevant evidence later. This point is in line with Niedenthal and Brauer's (2012) useful distinction:

> Group emotions are the emotions that arise as a function of being in a collective such as a work team or a crowd; they occur in groups. Group-based emotions are emotions that are elicited in an individual because of his or her identification with a group and knowledge that the group has caused or been the target of an emotion-inducing event. (p. 269)

Group-based emotions by this second definition are our topic here. Second, we assume that intergroup emotions are generally similar to individual-level emotions in the ways they are experienced; the effects they have on cognitive, perceptual, and motor processes; and so forth (see Rydell et al., 2008). They differ in the ways they are elicited (i.e., by group-relevant rather than personally relevant events) and in their functions (i.e., in regulating group-related or collective behavior rather than purely individual behavior).

As background for IET, the broader idea that intergroup relations and especially intergroup conflict might trigger emotional responses has been investigated since the 1980s, with seminal work by Dijker (1987), Gaertner and Dovidio (1986), and Stephan and Stephan (1985). Their research examined the usually negative emotions that people can experience when encountering individual members of outgroups, triggered by cultural differences (e.g., the outgroup member may violate ingroup norms) or by an anxiety-toned desire to make the interaction go smoothly and not to give offense. Research has amply demonstrated that these emotional reactions can occur and can motivate avoidance of outgroup members—demonstrating that avoidance need not necessarily be attributed to sheer antipathy for the outgroup.

From the standpoint of IET, an important question is whether these negative emotions experienced during intergroup contact are individual-level or intergroup emotions. They may often remain at the individual level, if the emotions are generated by perceptions of an outgroup member's *individual* annoying or offensive characteristics, or by one's perceived *personal* lack of knowledge about the outgroup and uncertainty about how to interact appropriately. Still, the definition of a situation as interpersonal or intergroup depends on the way the perceiver thinks about it. So a white person's concern about personally appearing prejudiced in an interracial interaction would be an individual emotion, but if he or she feels like a representative of the entire white group and is concerned about confirming the stereotype that whites are generally racist, this would be a group-level emotion. A woman's anger at being made to look stupid by a man's cutting comment might be individual, but if she feels that she was made to look stupid *because* she was a woman, the emotion might be group-based.

One test of whether an emotion is individual or group based is to ask this question: Would the emotional response be similar if the same event happened to some *other* ingroup member? For a group-based emotion, the answer is probably yes. For example, someone might be angered by perceiving that another ingroup member was "victimized" by an unfair affirmative action program, even if the perceiver was personally unaffected. In fact, the late U.S. senator Jesse Helms ran a TV ad in his 1990 campaign, showing a pair of white hands crumpling a letter (presumably a rejection letter) while a voice-over stated, "You needed that job, but they had to give it to a minority" (the ad can be viewed at *www.pbs.org/30secondcandidate/timeline/years/1990.html*). Evidently, the goal was to anger white viewers at the thought that other members of their ingroup were being treated unfairly.

Whether an emotion is individual or group based, if repeated encounters with members of a particular group consistently give rise to feelings of annoyance, anxiety, and the like, the emotion may become associated with the mental representation of the group in general (just as for some individuals feelings of anxiety may become associated with dentists in general). As a result, the perceiver might start to experience anxiety, irritation, and so forth, on any thought about or encounter with that particular outgroup.

Intergroup Emotions and the Regulation of Behavior

Just as any emotion motivates people to take specific sorts of action (Frijda, Kuipers, & ter Schure, 1989), intergroup emotions should do the same. Generally, intergroup emotions should lead to actions specifically related to the intergroup situation. Examples include desires to confront or attack an outgroup, to avoid an outgroup, to affiliate with ingroup members, or to support or oppose government policies that have an impact on entire social groups. In this way, intergroup emotions involve appraisals, feelings, and action tendencies that are all at the group level: The individual who identifies with an ingroup may feel that *they* are threatening *us*; *we* feel angry at *them*; *we* support policies designed to keep *them* from immigrating to our country, cut off *their* government benefits, and so on. The distinction between individual and intergroup emotions is parallel to that between individual and fraternal (i.e., group-based) relative deprivation (Runciman, 1966). The former is the perception that one is not doing as well as other individuals, and the latter is the perception that one's group is not doing as well as other groups; fraternal deprivation has more potent effects on political and social attitudes. Similarly, intergroup emotions are important causes of behavioral outcomes such as support or participation in collective action intended to improve a group's situation in society (van Zomeren, Leach, & Spears, 2012).

Two Foci of Intergroup Emotions

Individual-level emotions can be specifically targeted, or can be more general moods or feeling states. Individuals at times experience emotions targeted at specific other individuals or objects (e.g., anger at a threatening rival, sympathy for a person in distress), and also possess relatively stable profiles of emotional feelings (e.g., general tendencies to feel angry, anxious, or happy) that relate to their personality characteristics (Watson & Clark, 1992).

The same distinction applies to group-level emotional responses. First, emotions such as anger, fear, disgust, or envy targeted *specifically at an outgroup* may relate to perceptions, prejudiced attitudes, or discriminatory behaviors directed at the outgroup. This line of thinking leads to the important hypothesis that all negatively evaluated outgroups are not treated the same way. For example, outgroups that are targets of anger may be actively attacked or confronted, while outgroups that are targets of disgust may be avoided. Several studies have confirmed such hypotheses (Ray, Mackie, & Smith, 2012; Cottrell, Richards, & Nichols, 2010). Outgroup-directed emotions need not always be negative, for in some circumstances people who identify with one group may feel sympathy or pity toward an outgroup, leading to desires to offer help.

Second, people may experience more general emotional feelings when they are thinking of themselves in terms of a particular social identity. These may include not only emotions directed at outgroups, but also positive or negative ingroup-directed emotions (such as group-based pride or collective guilt) and general affective feelings (such as happiness, anxiety, or irritation) that are based on group membership. Thus each group may have a typical "profile" of emotional tendencies, such that when thinking of themselves in terms of that group membership, people often feel proud, irritated, anxious, and so on, in a pattern that systematically differs from what they would report when thinking of themselves as individuals (Smith, Seger, & Mackie, 2007; Seger, Smith, & Mackie, 2009).

Relation of IET to Emotion Theory in General

Appraisal Theories of Emotion

Our original outline of IET (Smith, 1993) and subsequent work (Mackie, Devos, & Smith, 2000; Mackie, Silver, & Smith, 2004; Smith, 1999) adopted the assumptions of appraisal theories of emotions, because they seemed to us to fit well with our general theoretical structure. Our sole modification to appraisal theory was the assumption that in an intergroup situation, events, objects, and groups are appraised in terms of their implications for the ingroup (not just the individual self). Intergroup emotions are generated by this appraisal process, just as individual-level emotions are generated by appraisals of objects or events that impinge on the individual self (Scherer, 1999). For example, a person who identifies with a group and sees the ingroup as threatened by a powerful outgroup's actions may experience intergroup anxiety or fear. One consequence may be a desire or impulse to avoid or escape from the outgroup. As we have discussed earlier, intergroup emotions may be directed at the ingroup as well. For example, in an intergroup situation that makes social comparisons between groups salient, people may feel collective pride if they believe that their group has succeeded in an important task. Or feelings of collective guilt may result if people appraise their group as having violated important moral principles (Doosje, Branscombe, Spears, & Manstead, 1998). Appraisals of the same situation may even differ depending on the specific group membership that is salient. In one study, participants who categorized themselves as students appraised a proposal to raise nonresident tuition at the University of Colorado as more unjust, compared with when they were categorized as Colorado residents (Gordijn, Yzerbyt, Wigboldus, & Dumont, 2006).

Although many appraisal theories (e.g., Roseman, 1984) suggest that appraisals cause emotional states, the causal direction is not one-way. Tiedens and Linton (2001) have demonstrated that emotional states influence people's judgments on appraisal-related dimensions—for example, because anxiety is related to the appraisal of uncertainty, people in an anxious state judge events as highly uncertain. This process operates in the same way with regard to intergroup emotions as it does with individual-level emotions (Rydell et al., 2008).

Finally, appraisal theories suggest that emotions lead to specific behavioral action tendencies (Frijda, 1986). Intergroup anger may lead to a desire to attack or confront the outgroup, disgust to a desire to avoid, or guilt to a desire to make reparations for the ingroup's actions. By adopting the assumptions of appraisal theories in this way, IET makes predictions about linkages of appraisals of the intergroup situation, specific emotional experiences that people report when they are thinking of themselves as group members, and motives or tendencies to engage in collective (group-level) actions. These predictions have been tested (e.g., Mackie et al., 2000).

Core Affect Model of Emotion

However, IET does not necessarily rest solely on appraisal theories. Its fundamental insight is the idea that group identification makes the ingroup part of the psychological self and hence makes group-relevant events or objects able to trigger emotions (as self-relevant events or objects always do). The process of "triggering" could be described by using the concepts of appraisal theories, as in our earlier presentations of the IET model, or can be described in alternative ways. As an illustration, we consider the "core affect" model (Russell & Barrett, 1999; Russell, 2003; Barrett, 2006). In this model, states of core affect, which are described in a two-dimensional space whose axes are pleasantness and arousal, are fundamental components of all experienced emotions (as well as moods). Core affect can change for many reasons: in response to external stimuli such as pleasant or unpleasant environmental states or positive or negative events, or in response to internal physiological processes such as diurnal rhythms. Core affect is assumed to be subjectively perceptible (as the sense of feeling good, bad, energized, tired, etc.).

An experienced episode of emotion begins with a change of core affect that is consciously noted and attributed to some cause. This attribution makes the difference between just feeling negatively aroused and feeling negatively aroused *because* of a specific event. Attributing affective states to external objects or events is often unproblematic, because of the frequent close co-occurrence in time of external events and the affective reactions that they cause. And these attributions are adaptive, for they allow the perceiver to direct attention and behavior appropriately with regard to the object that is responsible for the feeling. However, the true causes of affective states are not always obvious, so people may make misattributions. A feeling of negative arousal that is actually due to irrelevant reasons (such as unpleasantly hot temperatures) may be misattributed to another person's annoying behavior, leading to the experience of anger, and potentially to aggression (Berkowitz, 1998).

How is an emotional experience labeled as an instance of a specific emotion such as anger, fear, sadness, or guilt? The core affect model holds that various factors—including the core affect and its perceived cause, as well as the situational context, one's overt behaviors, and bodily experiences (such as physiological changes)—become input to a perceptual categorization process in which the experience is categorized as a discrete emotion. Russell (2003) holds that the episode is categorized on the basis of the resemblance between these factors and the person's mental representation of a given emotion's prototype. Barrett's (2006) model differs in postulating not a fixed prototype representation, but a situated reconstruction—an emotion representation that is created online and flexibly tuned to the constraints and goals of the situation. In either case, these mental representations (prototype or situated reconstruction) can and will vary between people because of individual experiences and cultural differences. As a result of the categorization, a person could say that he or she feels *afraid* of the specific object. This labeling process produces the conscious awareness of having an emotional episode.

The core affect model incorporates many substantive predictions of appraisal theories, by postulating that appraisals (the person's interpretations of various aspects of the situation) relate to the process of categorization and self-perception of a specific emotion, rather than seeing appraisals as initiating the emotional state with all its concomitants (subjective feelings, autonomic changes, instrumental actions, etc.). See Russell (2003) for further discussion of relations between the core affect model and appraisal theories.

IET is broadly consistent with the core affect model as well as with appraisal theories. How might the process differ if a group (rather than an individual) identity is at stake? First, assume that an event occurs with implications for a person's important group membership, such as a reminder of a nation's colonial past for a person who identifies strongly with the national group. The event may lead to changes in core affect—in this example, negative arousal. Next, the person may search for a cause of that change, perhaps making a misattribution or perhaps correctly attributing it to the event in question. The individual will then draw on his or her affective feelings and attributions, as well as other aspects of the situation, to label the emotion as an instance of guilt—in this case, collective guilt. Desires to take collective actions, such as to make reparations or to offer aid to the victims of the ingroup's actions, may ultimately result. The overall process is not greatly different from that postulated by the core affect model in general; the key differences are that the self-relevance that triggers affective changes in the first place is relevance to a collective (rather than an individual) self, and that the interpretive and categorization processes that follow identify the emotion as an intergroup rather than individual-level emotion. In our example, the perceiver will be readily able to categorize the experience as one of collective guilt, because he or she will have no reason to feel *individually* guilty about ingroup actions that occurred perhaps hundreds of years ago.

Another example illustrates how the process of making an attribution can switch a perceiver between an individual or intergroup emotion. Someone who learns that he or she was not chosen for a much-wanted promotion (and hence feels strong negative arousal) may decide that the reason was his or her boss's ignorance and failure to recognize talent—and may thus experience anger or disappointment at the individual level. Alternatively, the same event may be attributed to the boss's prejudice against a group to which the employee belongs—in which case the individual's anger may be at the intergroup level. The action tendencies will be quite different in this case than in the case of individual anger.

As this discussion indicates, each of the three main elements of the core affect model can be influenced by a person's group identifications. Core affect changes can arise from events that have an impact on the ingroup and not just the person as an individual (a common example is the way we feel great when our team wins). Attributions concerning the cause of a change in core affect may implicate social groups—for example, when we decide that an outgroup member is treating us unfairly because he or she is prejudiced against our group, not just for idiosyncratic personal reasons. And categorization processes may tell us that we are feeling an emotion as an individual (e.g., individual guilt for some personal action) or as a group member (e.g., collective guilt for an ingroup's historical acts).

Evidence Regarding Intergroup Emotions

In this section, we review evidence regarding the properties of intergroup emotions, especially those that distinguish them from individual emotions. We describe evidence on four fundamental questions: (1) Are intergroup emotions distinct from the same person's individual emotions?; (2) Are they related to group identification?; (3) Are they shared among members of the same group?; and (4) Do they functionally regulate intragroup and intergroup attitudes and behaviors? Our discussion also emphasizes studies that demonstrate roles for intergroup emotions in several specific phenomena relevant to prejudice and intergroup relations.

Differences from Individual-Level Emotions

One important distinction between intergroup and individual emotions is that a group-relevant event can cause people to experience emotions on behalf of a group or fellow group members even when the perceivers are not personally affected (e.g., Mackie et al., 2004). For example, in one study, people learned of an event that harmed students at a different university, but that had no conceivable implications for the perceivers as individuals (Yzerbyt, Dumont, Wigboldus, & Gordijn, 2003). They reported feeling more unhappy and angry when they self-categorized as students (making the victims fellow ingroup members), compared with when they self-categorized as members of their own university. Such results indicate that the self-categorization has emotional consequences above and beyond empathy or other individual-level types of emotion contagion.

In a more direct examination of relations between group- and individual-level emotions, Smith et al. (2007) had students report the extent to which they generally felt 12 specific emotions, as individuals and as members of several different ingroups (university, national, and political party groups). As might be expected, reports of emotions at the individual and group level were correlated at about the .3 level (e.g., people who reported feeling more angry as individuals also tended to report feeling more angry as group members). Despite this correlation, analyses showed that profiles of group emotions and individual emotions were meaningfully distinct—qualitatively different, not merely differing in the overall level or intensity of individual versus group emotions. For example, participants reported experiencing lower levels of irritation and guilt, but higher levels of pride and disgust as Americans, compared with their reports of individual-level emotions.

Relationship to Group Identification

For all groups, Smith et al. (2007) found a strong relation between positive group emotions and ingroup identification. This relation occurs for a wide range of groups and is present even when group identification is subtly induced by incidental exposure to ingroup symbols (Seger, Smith, Kinias, & Mackie, 2009; Seger, Smith, & Mackie, 2009). This pattern makes sense both because group identification is a condition that enables the experience of intergroup emotions, and because positive intergroup emotions such as pride and satisfaction are likely to reward and encourage strong identification with a particular group. The relation of anger at the outgroup to group identification was also positive, consistent with some other research (Kessler & Hollbach, 2005). Pennekamp, Doosje, Zebel, and Fischer (2007) found that among Surinamese immigrants in the Netherlands, Surinamese identification related positively, while Dutch identification related negatively, to group-based anger about past slavery.

In contrast, negative group emotions other than outgroup anger (such as guilt, anxiety, and irritation) relate more weakly and generally negatively to identification (Smith et al., 2007). The data patterns suggest that the negative correlation is largely due to a type of motivated cognition: Strong group identification leads people to reinterpret and reappraise group-related events to avoid negative feelings (Doosje et al., 1998). An additional process that may contribute to the negative correlation is that over time, negative emotions may motivate decreased identification with the particular group.

Social Sharing within an Ingroup

Our results (Smith et al., 2007) also demonstrate that people's group-level emotions are socially shared, and shared more strongly by people who identify more with the group—that is, each social group (Americans, Democrats, university students, etc.) has a specific profile of group-level emotions (e.g., high happiness, low anger, moderate guilt). When reporting their emotions for that particular group, members tend to converge toward the group profile, and those who identify more strongly with the group converge to a greater extent. Other studies similarly show that people's perceptions of typical emotions in their group as a whole (whether measured or experimentally manipulated) influence their self-reported emotions, appraisals, and collective action tendencies (Leonard, Moons, Mackie, & Smith, 2011).

Three distinct processes may contribute to this convergence. First, the convergence may be due to "emotional contagion" (Neumann & Strack, 2000), meaning that people tend to take on the emotions displayed by fellow ingroup members with whom they interact. However, the contagion mechanism may be more relevant to face-to-face interacting groups than to the social category groups used in this study. Still, members of larger groups may be affected by emotional contagion when leaders or prototypical members are portrayed in the media and other group members model their emotions (Pescosolido, 2002). Second, people could be regarded as conforming to ingroup norms with regard to their group-level emotions. It has long been known that when people strongly identify with a group, and their membership is made salient in a specific situation, their behaviors and attitudes tend to conform to group norms or move closer to the group prototype (Hogg & Turner, 1987; Simon & Hamilton, 1994). Recent research confirms that emotions are affected in the same way by group norms (Moons, Leonard, Mackie, & Smith, 2009; Leonard, Moons, et al., 2011). Finally, a third possibility is that group emotion convergence occurs because thinking about a group membership makes the same key group-relevant events and appraisals salient to different perceivers, so that emotional responses to such events are generally shared among group members. For example, when many individual Americans think of themselves as Americans, the same limited number of events and situations may be salient, such as attacks by militant anti-Americans. So these individuals may all report feeling angry as Americans because they are all responding to more or less the same salient events in more or less the same way. In general, all three of these processes (emotional contagion, conformity to emotion profiles that function as group norms, and shared reactions to salient group-relevant objects or events) may be important causes of group emotion convergence.

Regulation of Intergroup and Intragroup Attitudes and Behaviors

Smith et al. (2007) found that group emotions predicted both ingroup- and outgroup-directed action tendencies, above and beyond the relatively weak predictive power of individual-level emotions. These studies investigated a wide range of specific action tendencies involving ingroup support and solidarity, outgroup confrontation, and outgroup avoidance. The results suggested that anger at the outgroup (and, to a lesser extent, anger at the ingroup) was the most powerful predictor across all categories of action tendencies. The fact that anger at the outgroup predicts the desire to engage in confrontational behavior would be expected from standard theories relating emotion to action tendencies (Frijda et al., 1989; Mackie et al., 2000). The relation of anger at the outgroup to tendencies to support and affiliate with the ingroup is also consistent with previous research (Kessler & Hollbach, 2005) showing that this group emotion tends to increase ingroup identification.

The regulation of intergroup behavior by intergroup emotions has also been demonstrated in research examining the antecedents of collective action. A meta-analysis (van Zomeren, Postmes, & Spears, 2008) and proposed theoretical model (van Zomeren et al., 2012) both give group-based anger a central role in motivating people to support or participate in collective action on behalf of their group. Consistent with this idea, Leonard, Moons, et al. (2011) found that manipulations that increased women's group-based anger also led to increased support for collective action against a sexist act. Collective guilt as well as anger lead members of advantaged groups to support demands for justice made by disadvantaged groups (e.g., Iyer, Schmader, & Lickel, 2007).

Yet another aspect of behavioral regulation by intergroup emotions is that if intergroup emotions are functional, successfully implementing an emotion-linked behavioral tendency should allow the emotional feelings to dissipate, whereas impeding the behavioral tendency should intensify the emotion. Maitner, Mackie, and Smith (2006) investigated the emotional consequences of satisfying or thwarting behavioral intentions related to intergroup emotions. Study 1 showed that if an attack on the ingroup produced anger, retaliation increased satisfaction, but if an attack produced fear, retaliation increased fear and guilt. Study 2 showed that outgroup-directed anger instigated via group insult dissipated when the ingroup successfully responded, but was exacerbated by an unsuccessful response. Responding in an emotionally appropriate way was satisfying, but ingroup failure to respond elicited anger directed at the ingroup. Study 3 showed that intergroup guilt following aggression was diminished when the ingroup made reparations, but was exacerbated when the ingroup aggressed again. These findings demonstrate that satisfying behavioral intentions associated with intergroup emotions fulfills a regulatory function.

Many other studies show that intergroup emotions are related to desires to take actions relevant to group memberships. For example, the specific group-based emotions that Americans experienced in response to the attacks of September 11, 2001, predicted respondents' support for restrictions on civil liberties measured several months later, with fear increasing such support and anger decreasing it (Skitka, Bauman, & Mullen, 2004). A number of researchers have demonstrated potent effects of group-level guilt and ingroup-directed anger on action tendencies related to apologizing and making reparations for past group-based offenses (Branscombe & Doosje, 2004; Leach & Iyer, 2006; Iyer & Leach, 2010). And when intergroup apologies are made, their effects on forgiveness and desires for retribution are mediated by outgroup-directed emotions (Leonard, Mackie, & Smith, 2011). Finally, recent work shows that teaching emotion regulation strategies to people involved in an intractable conflict situation (the Israeli–Palestinian conflict) successfully reduces their support for policies aimed at harming those on the other side (Gross, Halperin, & Porat, 2013). These studies not only provide additional experimental support for the role of intergroup emotions in regulating intergroup behavior but also open up new possibilities for handling and perhaps defusing intractable conflicts.

Relations of Intergroup Emotions to Prejudice

The theme that intergroup emotions regulate and direct people's attitudes and behaviors toward an outgroup has specific implications for understanding prejudice—a topic that has been the focus of much of our research. Miller, Smith, and Mackie (2004) examined the role of intergroup emotions directed at a specific outgroup (African Americans) in predicting European Americans' prejudice against that group. The studies replicated large bodies of research showing that past intergroup contact reduces prejudice, and that "social dominance orientation" (SDO), a personality-like individual difference reflecting desires to maintain hierarchies of group inequality, is associated with increased prejudice. The studies also demonstrated that intergroup emotions (self-reports of different emotions experienced by European Americans when encountering or thinking about African Americans) played a major role in mediating both of those effects. We also examined stereotypes of the outgroup as an alternative potential mediator. Stereotypes had no significant role in mediating the effects of past intergroup contact, and mediated part of the effect of SDO in one of the two studies. These results fit with the existing empirical and conceptual evidence for the priority of affective (emotional) over cognitive (stereotype beliefs) mediators of effects on prejudice (e.g., Pettigrew, 1998). Other work shows that in a cross-categorization situation, different discrete emotions underlie prejudice toward others who may share one ingroup membership but differ on a second dimension (Ray et al., 2012). Such findings underline the importance of understanding group-level emotions as part of the entire picture of prejudice, as well as their important role in strategies (such as intergroup contact or cross-categorizations) for prejudice reduction.

Conceptualizing prejudice as often including an emotional component also helps understand why people's perceptions and desired actions toward different outgroups may differ. Cottrell et al. (2010) demonstrate that general prejudice (defined as a negative attitude toward an outgroup) failed to predict such distinctions, while the particular emotions (such as disgust, anger, or guilt) felt toward specific groups were much more powerful predictors of preferences regarding group-relevant policies, in ways that could be understood in terms of the specific emotions' action tendencies.

Summary and Implications

The perspective described in this chapter rests on the simple yet powerful idea that a social identity based on group identification—not just a biological/individual self—can have emotional implications. Many concrete research hypotheses can be generated by combining this fundamental idea with assumptions based on emotion theory in general, yielding the insight that appraisals of social situations, experienced emotions, and emotion-driven desires for action can all occur at the level of the social group as well as the individual.

Implications for the Study of Intergroup Relations

This set of ideas has several implications for our understanding of prejudice and intergroup relations. First, consider the relations of group-based emotions directed at a particular outgroup and the more traditional concept of stereotypes of the outgroup. IET holds that stereotypes are far from irrelevant, for they may feed into appraisals. For example, an outgroup may be seen as hardworking and achievement oriented, which could lead to its being appraised as a potent threat to the ingroup's economic status in society. Note that, as this example implies, there is no necessary direct relationship between the valence of stereotypes and the valence of people's emotional responses to groups. Positive traits ascribed to the outgroup can lead to negative responses, because emotional responses rest on relational appraisals (What does the outgroup mean for us?) rather than on the valence of the outgroup's characteristics in isolation.
