Second, thinking about intergroup perceptions and behavior as being at least in part based on emotions leads to a whole new portfolio of approaches to reducing prejudice and discrimination. Group stereotypes are often deep-seated and resistant to change, as people employ various attributional and subtyping processes in their defense. Hence, changing stereotypes may not be broadly effective in reducing prejudice. However, emotion regulation approaches may have much promise. As mentioned earlier, Gross et al. (2013) found that teaching reappraisal techniques to members of a group enmeshed in an intractable conflict successfully improved their attitudes on policies related to the conflict. As the authors conclude,

> These results suggest that emotion regulation can affect not only emotional reactions but also political ones. Moreover, they indicate that reappraisal may be an efficient tool for regulating emotions even in the context of one of the most ideologically driven, intense, and highly emotional settings and in the face of an ongoing stream of negative information and events. (p. 427)

Finally, thinking about emotions as an important component of people's reactions to outgroups also leads to new conceptions regarding time. In traditional views, stereotypes and prejudiced attitudes toward an outgroup are typically regarded as highly stable (in fact, their resistance to change has been a core issue motivating much research). In contrast, emotions are labile, varying over seconds and minutes. This raises new research questions, such as whether someone's thoughts, evaluations, and behaviors toward an outgroup may differ specifically when the individual is in an emotional state from when he or she is not. At least one study suggests that the answer to this question may be yes (DeSteno, Dasgupta, Bartlett, & Cajdric, 2004).

Implications for Emotion Theory and Research

Just as IET encourages a rethinking of some issues related to prejudice and intergroup behavior, it also has implications for theory and research regarding emotion more generally. Perhaps the most fundamental implication is the idea that emotions pertain to an *identity* and not to a biological individual. An individual typically has multiple identities (including a personal self, many group memberships that may become salient in different circumstances, and possibly several important relational identities as well; Sedikides & Brewer, 2001). Each of these identities is an aspect of the self, so it remains true that, as emotion researchers assume, emotions always implicate the self. In addition, there will generally be a degree of continuity between emotions experienced in different identities (illustrated by the .3 correlations between group- and individual-level emotions; Smith et al., 2007), perhaps partly due to biologically based differences in emotional reactivity. Still, each identity may have a distinctive emotion profile, both short term and chronically. This idea has many as-yet-unexplored implications—for example, in regard to emotional vulnerability.

The idea that emotions are rooted in identities also has implications for emotion regulation: Because people can shift rapidly between identities (e.g., between one group membership and another, or between a group- and an individual-level identity), such shifts can be part of an emotion regulation process (Smith & Mackie, 2006). People may be expected to adopt identities associated with positive group emotions or disidentify from groups associated with negative group emotions, and there is evidence consistent with this idea (Kessler & Hollbach, 2005). Research might productively examine more details of this identity-based emotion regulation strategy, and compare its effectiveness against other strategies on which the literature has focused (Gross, 1998).

IET encourages theorists and researchers to look into social influences (especially influences of the intergroup context) on all aspects of emotional responding. Whereas a number of theorists (e.g., Smith & Lazarus, 1991; Mesquita, 2003) have argued that emotions are inherently relational or interpersonal in nature, our argument is slightly different: that emotions arise from group memberships or collective (not only relational) aspects of the self (Sedikides & Brewer, 2001). Group memberships may influence all aspects of emotional responding: changes in core affect, the causal attributions people make for such changes, the way they categorize their emotional experiences, and the types of actions that they may seek to perform when in emotional states. Investigations of these issues may clarify the ways emotions are functional at the level of groups and not solely individuals. Indeed, such group-level functionality is to be expected, for group living is evolutionarily ancient in humans as well as related primate species, and it would be surprising indeed if emotions did not play a role in shaping our feelings about and reactions to other ingroup members as well as outgroup members (Cottrell & Neuberg, 2005; Caporael, 1997).

We close with one obvious point. For emotion researchers, intergroup relations offer a powerful venue in which to investigate emotions and their effects. This is a domain of social life in which emotions are often intense, compelling—and highly consequential (with effects including persecutions, pogroms, and genocides). It is also a domain in which, as we argue, emotions are often driven by people's self-identification with important social groups, rather than by their individual selves. Increases in our understanding of emotions themselves, as well as understanding of the social phenomena to which they contribute, may result from an increased focus on social group memberships as bases for emotions.

Acknowledgments

Preparation of this chapter was supported by Grant No. R01 MH-63762 from the National Institute of Mental Health. We are grateful to Lisa Feldman Barrett, Angie Maitner, and Charlie Seger for helpful comments and assistance.

CHAPTER 24

SOCIAL FUNCTIONS OF EMOTION AND EMOTION REGULATION

Agneta H. Fischer and Antony S. R. Manstead

The classic perspective on the functionality of emotions is that they increase the probability of an individual's survival and/or reproductive success. The general argument is that emotions are functional in the sense that they help the individual to address or overcome problems (e.g., Frijda, 1986; Lazarus, 1991; Levenson, 1999; Cosmides & Tooby, 2000). Fear of predators or enemies, for example, is adaptive in the sense that individuals who have the capacity to experience such fear are more likely to be vigilant and avoidant, and thereby to escape the threat of predation or attack (Cosmides & Tooby, 2000; Öhman, 2000).

In this chapter, we shift the attentional focus to functional analyses of emotion that emphasize "social survival"—that is, our human capacity to build social bonds and address and overcome social problems such as social exclusion or loss of power (see, e.g., Barrett, 1995; Fridlund, 1994; Griffiths & Scarantino, 2009; Keltner & Haidt, 1999). The central argument we advance is that emotions are important to social well-being because the emotions we experience and express help us to (1) form and maintain positive social relationships (affiliation function); and (2) establish or maintain a social position relative to others, and to preserve our self-esteem, identity, or power, sometimes at the expense of others (distancing function). Both functions point to the importance of a precarious balance between maintaining close and harmonious relations without sacrificing a secure and healthy sense of self. We summarize evidence for the affiliation and distancing functions of positive and negative emotions first at the interpersonal level and then at the group level. Because these functions cannot be served without social regulation, we also discuss the social function of emotion regulation, and the issue of how other people play a role in regulating our emotions.

The Nature of Social Functions

Some social functions of emotions may have an evolutionary origin, because humans compete and cooperate in order to meet survival and reproduction goals. Cultural and social norms, however, have become increasingly important in our complex, industrialized societies, where social well-being is based on how well we adjust to the challenges of different social goals. Living a socially successful life has become a complex endeavor that requires knowledge of norms, sensitivity to one's own and others' needs, and the ability to regulate one's emotions in a socially appropriate way. This entails striking a balance between competing social goals, which can be described as social connectedness and cooperation, on the one hand, and autonomy and competition, on the other. Humans are social creatures who need social bonds in order to thrive (Baumeister & Leary, 1995): We affiliate with others, work together with others, and seek harmony, closeness, and love. The importance of social bonds is illustrated by research on social isolation, showing that this leads not only to poorer health and well-being, but also to inhibited development of various social, emotional, and cognitive skills (Williams, 2001). On the other hand, we also have goals that set us apart from others: We are keen to avoid others who might pose a threat to us, excel above others and win when competing with others, exert control over others, or enhance our social power or social standing. These latter social goals cannot simply be achieved through cooperation and affiliation; they typically require distancing ourselves from others, or even being ready to compete with other persons or groups.

Emotions play an important role in realizing these two types of goals, and we therefore draw a broad distinction between two general social functions of emotion. The "affiliation function" of emotion refers to the idea that emotions help an individual or group to establish or maintain cooperative and harmonious relations with other individuals or other social groups. The "distancing" function of emotion serves to differentiate or distance the self or group from others (see also Brewer, 1991) and even to compete with these others for social status or power. Each of these general social functions of emotion operates at both the interpersonal and group level.

Any analysis of the social functions of emotion is likely to encounter the same conceptual and empirical issues as those encountered by analyses of its nonsocial functions (Gross & John, 2002; Oatley & Jenkins, 1992; Parrott, 2001, 2002). Emotion expressions typically have social effects (e.g., Algoe, Fredrickson, & Gable, 2013; Fischer & Roseman, 2007; Giner-Sorolla, 2012; Hess & Fischer, 2013; Hutcherson & Gross, 2011; Tiedens & Leach, 2004; Van Kleef, De Dreu & Manstead, 2010; Van Kleef, van Doorn, Heerdink, & Koning, 2011), whether or not these effects are intended. However, social effects are not the same as social functions.

Social effects of emotions depend on the way in which the emotion is expressed, and also on the specific features of the social and cultural context (e.g., Fischer, Manstead, & Zaalberg, 2003; Mesquita, 2003; Parkinson, 2005; Parkinson, Fischer, & Manstead, 2005; Van Kleef et al., 2011). For example, anger can be expressed by ignoring, criticizing, or shouting at someone. These behaviors are likely to have different effects, and these effects are also likely to vary as a function of the identity of the target and the appropriateness of the expression. Scolding a friend because he or she forgot an appointment might elicit an apology on the part of the friend, but the same expression of anger toward a superior who forgot an appointment might evoke a contemptuous response (e.g., Van Kleef & Côté, 2007). In the same vein, the effects of emotion are likely to vary across cultural contexts, depending on what is considered a typical or desirable expression in a specific situation (see also Kitayama, Mesquita, & Karasawa, 2006; Tsai, Knutson, & Fung, 2006). Thus, the social effects of emotion expressions are quite concrete and also context specific (see also Philippot, Feldman, & Coats, 1999).

Social functions are defined at a more abstract level and are inferred from the social-relational goals inherent in the appraisals and action tendencies that are typical of a given emotion (e.g., Roseman, Wiest, & Swartz, 1994; see Table 24.1). The social distancing function is typical of contempt (wanting to exclude another person), anger (wanting to confront, attack, or criticize), disgust (wanting to move away, isolate oneself from), social fear (wanting to flee from someone), or *schadenfreude* (being pleased about or amused by another's misfortune). The affiliation function, on the other hand, is typical of happiness and other positive emotions, such as gratitude, love, or admiration (sharing positive experiences with or communicating positive experiences to others), but is also characteristic of certain negative emotions, such as guilt (acknowledging that you have harmed someone), shame (acknowledging one's faults), or sadness (seeking help and support from others).

We therefore propose that each emotion has a prevalent social function, based on the individual's

TABLE 24.1. Illustrative Social Functions of Some Emotions

Affiliation function	Distancing function
Happiness	Anger
Love	Hate
Gratitude	Contempt
Admiration	Disgust
Sadness	Social fear
Guilt	Schadenfreude
Shame	Pride about self
Regret	Disappointment in others

goals in a social situation (affiliating with another or distancing from another). It is possible, however, that a single emotion can serve both social functions, depending on the context and taking the time frame into account. This is a point we return to below.

The idea that emotions have social functions does not imply that emotions are always socially functional—that is, that they always have the social effects that would be predicted on the basis of their relational goals. Anger, contempt, and even hate can be socially functional if they help to protect the self from destructive relations with others. However, these emotions can be and frequently are socially dysfunctional when expressions of anger or contempt are targeted either at others who pose no threat to the self or at others who have the power to inflict even greater damage. In the case of others who pose no threat to the self, expression of these emotions may irreparably damage relationships with them, without achieving anything in terms of social control or social standing. In the case of others who have the power to inflict greater damage, expression of these emotions clearly runs the risk of eliciting such damage.

The same applies to positive emotions such as pride, happiness, or love: Rather than strengthening social bonds, they may cause others to take exception to what they regard as inappropriate in the circumstances. Social dysfunctionality is especially likely to occur if the social impact of one's emotions is not taken into account or if inappropriate appraisals of the social context are made (e.g., Evers, Fischer, Rodriguez Mosquera, & Manstead, 2004; Manstead & Fischer, 2001; Parrott, 2001). According to Giner-Sorolla's (2012) functional conflict theory, dysfunctionality may also be a consequence of emotions having different functions at different levels, at least some of which can be contradictory. Thus, the social functionality of emotion in a particular set of circumstances is not a given, but rather depends on the way in which the person assesses his or her concerns or goals in relation to others' concerns or goals, and regulates his or her emotions accordingly. Becoming "too" jealous, getting angry "too often," or feeling contempt for many people is unlikely to be socially functional, although it can sometimes be functional at an individual level (e.g., by allowing the individual to vent negative feelings). Below we further explore the social functions of emotion, starting with emotions in interpersonal relationships.

The Affiliation Function of Emotions at the Interpersonal Level

Social relations between individuals vary in emotional tone from love affairs to work relations, but any relationship between two persons involves some degree of emotion. The amount of emotion that is experienced and expressed, however, is closely related to the nature of the relationship, reflecting an important function of emotions at the interpersonal level: Emotions enable us to form and maintain long-term and intimate relationships by promoting closeness and harmony, by providing comfort and avoiding social isolation. This function can be inferred from research on the social effects of emotions on others or on the relationships with others.

There is evidence that the frequency and intensity of emotion experience and expression increase with the intimacy of the relationship. For example, research by Clark, Fitness, and Brissette (2004) has shown that emotions are more often experienced and expressed in communal or intimate relations than in other types of relationships. Barrett, Robin, Pietromonaco, and Eyssell (1998) also found that the degree of expression of specific emotions, as reported in diary entries, was highly correlated with the closeness of the interaction partner. Research on social sharing has also repeatedly shown that people share their emotions mainly with family and friends (Rimé, Philippot, Boca, & Mesquita, 1992). A related point is that an absence of emotions in relationships casts doubt on the strength of the social bond between the relationship partners (Laurenceau, Barrett, & Pietromonaco, 1998). In their analysis of marital conflicts, Gottman and Levenson (2002) found that an absence of affect during such conflicts was a predictor of subsequent divorce. Studies of anger and aggression have shown that people, especially women, are most often angry with intimates (Fischer, Rodriguez Mosquera, van Vianen, & Manstead, 2004; Kring, 2000), and that physical aggression, especially on the part of women, also occurs more often within intimate relationships (Archer, 2000).

These various lines of research provide support for the idea that intimate and communal relationships are characterized by strong mutual concerns and therefore give rise to emotions (e.g., Frijda, 1986), whether positive or negative. In addition, intimate relations also allow the expression of emotions, especially emotions that may expose weak or vulnerable facets of the self (such as jealousy, powerlessness), which may then further strengthen the emotional involvement. Indeed, suppression of emotional expressions in such relationships may be dysfunctional, because it may reflect a lack of trust or support. The suppression of emotional expressions in relations between strangers may also be dysfunctional, however. Research on the social effects of emotion suppression (Butler et al., 2003), for example, has shown that if one individual is instructed to suppress his or her emotions, the other person feels less emotional rapport, and exhibits heightened cardiovascular responding. Van Kleef, Oveis, Van Der Löwe, LuoKogan, Goetz, and Keltner (2008) further showed that a higher sense of power leads to being less emotionally responsive to a conversation partner's distress, which then resulted in partners' feeling less understood and less keen on befriending the other. In addition, a study of the long-term social relationship effects of emotion suppression showed that suppression as measured in freshmen prior to entering college led to poorer social relations 4 years later (English, John, Srivastava, & Gross, 2012). In other words, suppressing emotions may not only be detrimental in intimate relationships but also limit the formation of new relationships.

Previous research also shows that the expression of virtually all positive emotions promotes the development of stable and close relationships. This applies not only to romantic relationships but also to relations between strangers. Smiling people, for example, are more likely to be ascribed positive traits, such as kindness, humor, intelligence, or honesty, than are their nonsmiling counterparts (Hess, Beaupré, & Cheung, 2002; Reis et al., 1990). Krumhuber and colleagues (Krumhuber & Kappas, 2005; Krumhuber, Manstead, & Kappas, 2007) showed that these positive effects of smiling are moderated by the perceived genuineness of the smile. The more we believe that a stranger's smile reflects sincere positive feelings, the more cooperative we are likely to be toward that person (Krumhuber, Manstead, Cosker, et al., 2007).

The reciprocal expression of gratitude has also been shown to be very functional in close relationships. Showing that one is grateful for what one's partner has done leads not only to positive and appreciative feelings in the partner, but also to the recognition that one's relationship is valuable and that one feels secure and appreciated by the other (Algoe, Gable, & Maisel, 2010; Gordon, Impett, Kogan, Oveis, & Keltner, 2012). Expressions of gratitude also benefit relations between strangers and result in prosocial behavior, even if such behavior is effortful and unpleasant to carry out (Bartlett & DeSteno, 2006). One of the few positive emotions that does not necessarily result in closeness and affiliation is pride because (along with positive affect) this emotion signals high relative social status (Shariff & Tracy, 2009), and this is more likely to serve the social distancing function than the affiliation function. However, this only applies when the pride is expressed in relation to one's own attributes or achievements; in cases where one expresses pride in relation to the attributes or achievements of others, as is quite common in collectivistic cultures (Fischer, Manstead, & Rodriguez, 1999), such expressions can clearly serve the affiliation function.

Negative emotions play a different role in the development and maintenance of interpersonal relationships. The evidence suggests that negative emotions serve three specific social functions that all promote the more general affiliation function, namely *signaling*, *support*, and *social change*. These functions are not mutually exhaustive but refer to different processes. Signaling refers only to providing information about the state of the expresser, which can then result in different behaviors from the recipient. Support refers to a specific type of behavior that is elicited in the recipient, namely psychological (consoling, offering solutions) or material (e.g., financial) support. Social change also refers to the elicitation of a specific range of behaviors, namely those that evoke a change in the other person's behavior that may in turn improve the relationship with another person.

A classic example of the signaling function (also referred to as the alerting function; see Parkinson, 2011; Parkinson & Simons, 2012) is provided by research on social referencing (e.g., Sorce, Emde, Campos, & Klinnert, 1985), showing that 12-month-olds are less likely to proceed in an uncertain and possibly unsafe situation when their mothers display a negative expression. Thus, negative emotions potentially have informational value for others because they communicate concerns and appraisals of the current situation. The use of others' nonverbal expressions as a signal has been referred to as social appraisal and has been seen as one of the mechanisms in how others' emotions affect one's own (Manstead & Fischer, 2001). Mumenthaler and Sander (2012) demonstrated this idea at a very basic level by showing that the recognition of a facial expression on a computer screen is facilitated by another facial expression that gazes at the target face, but not by a facial expression that gazes away. More specifically, when a target face shows anger, the presence of a fear face gazing at the target face leads to a stronger rating of the anger face. This phenomenon also occurs in daily life, as illustrated in a diary study by Parkinson and Simons (2009). They found that anxiety and excitement about decisions involving another person are predicted by the (perceived) anxiety and excitement of the other person, even after controlling for one's own appraisals. Although the nature of the relationship was not examined in these studies, we know from other lines of research that the extent to which emotion signals are sent and the extent to which they are acted upon by receivers is also a function of relational closeness (e.g., Bruder, Fischer, & Manstead, 2013; Erber, Wegner, & Therriault, 1996; Hess & Fischer, 2013). The fact that a key outcome of emotional signaling is the strengthening of trust and social connection between signaler and receiver (Campellone & Kring, 2013) suggests that this process is bidirectional.

Second, expressing negative emotions may not only signal that a person is in danger or helpless, but may also evoke help or support. Studies on social sharing of emotions (see Rimé, 2009) have shown that we are inclined to share nearly all of our negative emotions, with the possible exception of shame, after an emotional event. Research on crying also provides evidence of this support function, because individuals are more likely to cry in the company of partners or intimates than in the company of strangers (Vingerhoets & Becht, 1997). Independently of the motive of seeking support, perceivers also actually tend to provide help when someone cries or shows signs of distress (e.g., Coke, Batson, & McDavis, 1978).

A third way in which the expression of negative emotions can directly serve an affiliative function is because it acknowledges one's own wrongdoing and is thereby intended to rescue or reaffirm the relationship with the other person. This is clearly the case in episodes of regret, guilt, or shame. Research on regret, for example, shows that it motivates efforts to undo the harm done in relationship contexts (Zeelenberg, Van der Pligt, & Manstead, 1998). Studies of guilt (Baumeister, Stillwell, & Heatherton, 1994; Tangney, Miller, Flicker, & Barlow, 1996) have shown that this emotion is typically expressed in the context of valued relationships and where people have high respect for the other. Embarrassment displays have also shown to be beneficial for one's relations with others, because they evoke sympathy, positive evaluations, or helpful behavior in others (Feinberg, Willer, & Keltner, 2012; Keltner & Buswell, 1976, 1997; Ketelaar & Au, 2002; Miller, 2004), as well as increased perceptions of trustworthiness and conscientiousness—as, for example, in studies on blushing, a typical signal of embarrassment (de Jong, 1999; Dijk, Koenig, Ketelaar, & de Jong, 2011). Interestingly, embarrassment displays tend to elicit more positive evaluations on a "warmth" dimension, but not on a "competence" dimension (Semin & Manstead, 1981), consistent with the notion that this emotion serves an affiliation function. The expression of these emotions thus promotes harmonious relationships.

Although there is abundant evidence of the affiliation function served by both positive and negative emotions, we argued above that social functionality does not necessarily mean that these emotions serve this social function regardless of context. An important boundary condition for social functionality is that the emotion display should be perceived as appropriate by targets or observers of the display. For example, individuals who are regarded as *too* happy, or who display smiles for self-interested reasons (see Maringer, Krumhuber, Fischer, & Niedenthal, 2011), are likely to be regarded as inauthentic. Clearly, smiles can be interpreted in different ways, depending on culture and context (Hess et al., 2002). The expression of negative emotions, such as shame or guilt, may also fail to serve an affiliation function if they are seen as ambiguous or unjustified. For example, individuals who blush when there is no reason to blush may be regarded as being guilty of something they have not done. In such situations, blushing may backfire and have negative effects on the blusher (de Jong & Dijk, 2013). In other words, social functions of emotions are at least partly related to the perceived appropriateness of the emotion expression in the situation (see also Parrott, 2001; van Kleef et al., 2011), and whether the expresser is regarded as sincere and as willing and able to change his or her behavior.

The Social Distancing Function of Emotion at the Interpersonal Level

Emotional expressions in interpersonal contexts do not always serve to increase relational closeness. Indeed, emotions such as anger, contempt, disgust, or fear of another person do the reverse, increasing the social distance between self and other (e.g., Fridlund, 1994; Oatley & Jenkins, 1992). Markus and Kitayama (1991) alluded to a similar notion when they distinguished between "socially engaging" and "socially disengaging" emotions. The latter are more socially acceptable or even desirable in cultures in which an independent rather than an interdependent self is promoted. The emotions of anger, contempt, socio-moral disgust, *schadenfreude*, and pride are assumed to serve this function. We now consider examples of these emotions, and the ways in which they increase social distance.

Although anger is generally categorized as belonging to the "approach" family of emotions, the nature of the approach is confrontational, which is likely, at least in the short term, to increase the distance between self and other. If directly expressed to the object of the anger, this emotion confronts the other person with the fact that the angry person wants to change the target's behavior and exert some control over the target (e.g., Fischer & Roseman, 2007; Fischer & Evers, 2011; van Dijk, van Kleef, Steinel, & Van Beest, 2008). This implies that the target of the anger should apologize, yield, show submissiveness, or simply stop doing whatever he or she was doing. Studies by Van Kleef and colleagues have shown that the verbal expression of anger in a negotiation context does indeed result in greater concessions by the other party (e.g., Van Kleef, De Dreu, & Manstead, 2004). Indeed, even when others do not visibly and immediately react to the expresser's anger, they may covertly retaliate against the angry person (e.g., Wang, Northcraft, & Van Kleef, 2012).

In keeping with the idea that direct anger expression is an attempt to regain or maintain status or power, or simply to control the other, research by Tiedens (2001) confirms that high-status persons are expected to respond to negative outcomes with anger (rather than sadness or guilt), and to positive outcomes with pride (rather than appreciation; see also Kuppens, Van Mechelen, & Meulders, 2004). Moreover, when people express anger or pride they are regarded as high in status, but when they express sadness, guilt, or appreciation they are regarded as low in status. The underlying explanation for these differences, according to Tiedens (2001), lies in the appraisals of agency that are inferred from the expression of each of these emotions (see also Hareli & Hess, 2009). An expression of anger is seen as reflecting an appraisal of other-blame, implying not only greater social distance but also self-elevation; by contrast, an expression of guilt or sadness reflects an appraisal of self-blame. On the other hand, actual social status, power, or dominance increases the likelihood that one expresses one's anger (Fischer & Evers, 2011; Van Kleef & Côté, 2007).

Schadenfreude is another example of an emotion that serves a social distancing function, as is clear from evidence that one feels greater *schadenfreude* following others' misfortune if these others pose a threat to one's self-esteem (Van Dijk, Ouwerkerk, Wesseling, & van Koningsbruggen, 2011). A more extreme example is provided by contempt. The expression of this emotion, typically in the form of derogation and rejection, often results in social exclusion of the object of the contempt (Fischer & Roseman, 2007; Fischer & Giner-Sorolla, 2014; Gottman, 1994). The aim is to make it clear that the other person is inferior or even worthless, which is a way of boosting one's own social position or status, either as an individual or as a group member. Contempt as well as anger may be elicited if alternative ways of changing others' behavior are expected to fail. Disappointment *in* another person is less extreme than contempt but nevertheless serves a similar function, because it implies that the target of these emotions has not met one's expectations, and one therefore feels distance from or even abandonment of the person who is the object of the emotion (van Dijk & Zeelenberg, 2002).

Thus anger, disappointment, hate, and contempt all serve a social distancing function because they imply that the target is responsible for a negative outcome. The social distance results from the negative appraisals of the actions or character of the other person and can be further reinforced by tendencies to attack the other (in the case of anger and hate) or to treat the other as an inferior being (in the case of contempt). Although these emotions all serve a social distancing function, they differ in the extent to which they are also able to serve an affiliation function: Whereas contempt is highly unlikely to give rise to any improvement in a social relationship (see Fischer & Giner-Sorolla, 2015), anger can do so, especially in the longer term (Fischer & Roseman, 2007). This suggests that whereas the primary social function of anger is to criticize the other person, and thereby to increase distance, it can also serve an affiliation function, but at a later point in time.

To summarize, we have considered evidence that certain emotions have the effect of creating social distance between self and others in a way that may enhance one's social standing or self-evaluation. Expression of these emotions implies movement away from, and sometimes above, the other person(s). Confronting and constraining the antisocial or dysfunctional behaviors of others by expressing anger and contempt toward them thus serves the function of protecting the individual or group from the harmful or disruptive behavior of others. Likewise, it is sometimes functional for individuals and groups to set themselves apart from or to cut themselves off from other individuals or groups. For example, anger felt toward an ex-partner can be helpful not only in detaching oneself from that relationship but also in creating the possibility for a new one. Likewise, contempt expressed toward others who fail to endorse or live up to key norms and values can be beneficial in protecting those norms and values.

Affiliation Functions of Emotions at the Group Level

Affiliation and social distancing functions can also be identified at the group level. In line with social identity theory (Tajfel & Turner, 1979), which argues that self-esteem derives in part from the status and achievements of the groups with which we identify, we can safely assume that emotions serve the function of strengthening ingroup bonds as well as creating distance from outgroups. The strength of these group-based emotions is related to one's categorization as a group member (e.g., Smith, 1993). For example, Dumont, Yzerbyt, Wigboldus, and Gordjin (2003) showed that mere social categorization could increase or decrease the intensity of group-based emotions. When Dutch or Belgian participants categorized themselves as Westerners, a social identity that includes Americans, they reported experiencing more fear after being reminded of the terrorist attacks on the World Trade Center in 2001 than when they categorized themselves as Europeans, an identity that excludes Americans.

Typically, the more one identifies with a group, the stronger the positive group-based emotions one experiences (Smith, Seger, & Mackie, 2007). However, strong identification with a group can also lead to weaker group emotions if such emotions could be harmful to one's social identity and/or beneficial for an outgroup. This is the case with group-based guilt (Branscombe, Doosje, & McGarty, 2002; Doosje, Branscombe, Spears, & Manstead, 1998). Doosje et al. (1998) found that strength of identification with Dutch identity among Dutch participants was inversely related to guilt about the way that Indonesians were treated during the colonial era. High identifiers appeared to engage in defensive denial that wrongdoing had been perpetrated. In a study on European Americans' "White guilt" with respect to African Americans, Iyer, Leach, and Crosby (2003) further suggested that group-based guilt may involve a focus on the ingroup with a view to alleviating ingroup distress, rather than a more outgroup-focused desire to help members of the disadvantaged group. The aversive nature of group-based emotions such as guilt and—especially—shame is also functional in preventing group members from engaging in actions that might give rise to these emotions. Shepherd, Spears, and Manstead (2013a, 2013b, 2013c) have shown that *anticipated* group-based shame results in less ingroup favoritism and motivates group members to engage in collective action to stop the shame-evoking behavior.

The affiliative, group-bonding function of positive group emotions is shown more directly in a study where group-based emotions resulted in stronger identification with a group (Kessler & Hollbach, 2005). Shared positive emotion is likely to play a role in the "basking in reflected glory" phenomenon (Cialdini et al., 1976). The shared positive affect that supporters experience as a result of their team's success on the football field presumably serves to strengthen their ingroup identification. Likewise, it seems plausible that shared negative emotions provide an emotion-based account for the related phenomenon of "cutting off reflected failure" (Snyder, Lassegard, & Ford, 1986), in which group failure leads individuals to distance themselves from the ingroup in question. Livingstone, Spears, Manstead, Bruder, and Shepherd (2011) have gone a step further by showing that similarity between own and others' emotional reactions to an event led participants to be more inclined to see themselves as having a shared identity. Just as shared identity strengthens group-based emotions, shared emotions in a group strengthen social identity.

One way in which emotions serve an affiliative, group-bonding function is because the communication of emotion within a group provides group members with rapid information about group structure and the environment (Spoor & Kelly, 2004). Furthermore, if others share one's emotional reactions to an event, one is more likely to regard oneself as sharing group membership with them (Livingstone et al., 2011) and to feel emotions on behalf of that group (Kuppens, Yzerbyt, Dandache, Fischer & van der Schalk, 2013). Moreover, emotions within one's group also seem useful when distinctions from other groups are relevant. This is nicely illustrated by research on sports teams, where individual team members' moods are correlated with their own team's aggregate mood, and not with that of a competing team (Totterdell, 2000). Work teams also experience "group moods," and the extent to which group members have similar moods has an influence on levels of cooperation and conflict in the group (Barsade, 2002; Bartel & Saavedra, 2000). In particular, the collective display of positive emotion leads to greater cooperation and reduces conflict in the group, whereas the display of negative emotion is associated with the opposite outcomes. George and her colleagues have also shown that group affective tone is related to prosocial behavior (see George, 1990).

Group emotions may also serve an affiliation function in cases where groups are less cohesive and when group members do not agree or have different opinions. For example, Heerdink, Van Kleef, Homan, and Fischer (2013) examined expressions of anger or happiness toward a group member's deviant opinion and found that happy expressions by other group members led to stronger feelings of being accepted, whereas angry expressions led to stronger feelings of being rejected. In other words, as well as strengthening group bonds, emotions can also maintain cohesiveness in less cohesive groups by excluding deviant members. This has also been illustrated in research by Sani and colleagues (e.g., Sani, 2005; Sani & Reicher, 1999), who showed that schisms develop from perceptions that positions taken by other ingroup members threaten the shared identity of the group. Shared identity is a core attribute of the group, so any threat to it is likely to evoke negative emotions such as dejection and agitation, resulting in decreased identification with the group and lower perceived cohesiveness. In a field study of the secession of a subgroup from the Church of England, Sani (2005) showed that strong negative emotion aroused by a perceived threat to group identity was a positive predictor of intentions to secede from the group.

A third way in which group emotions may have an affiliative function is at the level of intergroup relations: By eliciting and expressing (social distancing) emotions toward outgroups, one can strengthen relations within one's own group. The stereotype content model (Cuddy, Fiske, & Glick, 2008) proposes that group-based emotions are a key feature of stereotypes and prejudice, reinforcing not only differences between groups but also a social hierarchy. Fiske, Cuddy, Glick, and Xu (2002) argued that stereotypes are based on two dimensions, warmth and competence, and depend on social structural features of intergroup relations in a society. A group's status predicts the degree to which a group is seen as competent, whereas its cooperativeness predicts the degree to which it is seen as warm or cold. These dimensions also predict how people emotionally react to members of specific outgroups. Envy is felt toward groups seen as cold but competent; in the North American context such groups include Asians, Jews, and rich people. Contempt or disgust are felt toward social groups that are seen as both cold and incompetent, such as welfare recipients, homeless people, or drug addicts. Pity and sympathy are felt toward those seen as warm but incompetent, such as the elderly. By contrast, groups seen as warm and competent elicit admiration (Sweetman, Spears, Livingstone, & Manstead, 2013).

Although much research has been conducted on anger, other emotions also help to sharpen group boundaries by stressing dissimilarities with the outgroup, or by promoting prejudice. For example, studies on intergroup *schadenfreude* (Leach, Spears, Branscombe, & Doosje, 2003; Spears & Leach, 2004) have shown that its intensity is, among other things, associated with feelings of inferiority with respect to the outgroup, suggesting that intergroup *schadenfreude* can be seen as a way of coping with the lower social status of one's own group.

Distancing Functions of Emotions at the Group Level

Clearly, group-level emotions can also serve a social distancing function when they are targeted at outgroups. In particular, anger challenges existing social hierarchies. Indeed, anger has been considered to be the basis of intractable intergroup conflicts, such as the one between Israelis and Palestinians (Bar-Tal, Halperin, & Rivera, 2007). These group-based distancing emotions are also strengthened by identification with one's group. The more strongly people identify with a group or take the perspective of a group, the more group-based anger they feel toward an outgroup that threatens the well-being of the group—even if they are not personally affected by any injustice (Mackie, Devos, & Smith, 2000; van Zomeren, Spears, Fischer, & Leach, 2004). Gordijn, Yzerbyt, Wigboldus, and Dumont (2006) found that a perceiver's degree of identification with the victims of an injustice affected not only the perceiver's level of group-based anger, but also his or her willingness to engage in collective action or protest to redress the wrong. Van Zomeren and colleagues (2004) sought to understand why collective disadvantage sometimes does and sometimes does not lead to collective action, and hypothesized that this was due to different expectations about the type of support that members would receive from their group. These researchers drew a distinction between "instrumental support" (support for action) and "emotional support" (sharing opinions). They found that the anticipation of instrumental support was sufficient to predict collective action in the absence of anger; however, if group members anticipated emotional support, this led to more group-based anger and thereby to collective action. In the latter case, anger served the function of motivating group members to engage in collective action.

Group-based anger therefore has the effect of mobilizing people who are not themselves directly affected by the perceived injustice. Research by DeSteno, Dasgupta, Bartlett, and Cajdric (2004) has shown that even the memory of a personal anger incident can automatically evoke negative evaluations of outgroups in an intergroup context, supposedly because of its functional relevance to intergroup conflict and competition.

It should be noted that whereas anger has often been thought of as providing the basis for strong intergroup conflict, there is recent evidence suggesting that its social function is more complex, in keeping with our reasoning about the possibly beneficial effects of anger in interpersonal relations in the longer term. Anger appears to have a distancing and even destructive effect if it is accompanied by hatred or contempt, associated with appraisals of the other group as evil, or expresses a long-term negative sentiment (Fischer & Roseman, 2007; Halperin & Gross, 2011). If, however, anger is simply based on appraisals of a group's negative behavior, and is expressed to communicate an injustice and to change the outgroup's attitude, it may ultimately decrease the social distance between groups. For example, the communication of pure group-based anger (without contempt) toward an outgroup can evoke empathy in the outgroup and decrease the intention to engage in a conflict (De Vos, van Zomeren, Gordijn, & Postmes, 2013).

Consistent with this reasoning, Halperin, Russell, Dweck, and Gross (2011) showed that it was the level of hatred that determined whether anger toward an outgroup was destructive or constructive. Inducing anger toward Palestinians in Israeli respondents who had low levels of hate toward Palestinians resulted in stronger support for compromise in an upcoming peace negotiation, whereas it decreased support for compromise among Israelis who had high levels of hatred. Another way in which group-based anger can bring groups closer together is when group members express moral outrage at the actions of other ingroup members who have adversely affected members of a disadvantaged outgroup (Leach, Iyer, & Pedersen, 2006). Such outrage motivates political action aimed at reducing the outgroup's disadvantage. In sum, anger serves a distancing function in intergroup relations when it is based in long-term negative sentiments, such as hatred and contempt, but it can serve a constructive role when it signals unjust treatment that may be acknowledged by the perpetrating group.

In summary, there are different ways in which group emotions help to promote emotional bonding within groups (affiliative function) and to delineate the boundaries between groups (social distancing function; see also Keltner & Haidt, 1999). First, positive group-based emotions, such as happiness or admiration, promote group cohesiveness, ingroup identification, and ingroup cooperation. Second, ingroup bonds can also be strengthened by emotions that serve a distancing function when these are expressed toward deviant group members, thereby promoting cohesion within the group. Third, certain negative group-based affiliative emotions, such as guilt and shame, may strengthen bonds within groups because they are collectively experienced as aversive and/or threatening to the group's social identity; group members may then become motivated to defend their group identity by engaging in reparation or collective action. Fourth, group bonds can also be strengthened by differentiating one's group from other groups and/or challenging the social hierarchy by expressing anger, hate, or contempt toward outgroups that are seen as threatening the ingroup's interests or values. At the same time, positive emotions, such as admiration for another group, may also help to maintain social hierarchies. Finally, positive intergroup relations can be promoted by group-based anger, but only if the anger is focused on the outgroup's behavior, rather than being based on appraisals of the outgroup's negative nature.

Interpersonal Regulation of Emotions

If emotions serve social functions, a natural place to look for the origin of these functions is the reactions of others to expressions of emotion. The fact that others respond to our emotions—and because we often care about the way in which they respond—means that emotions are subject to regulation, both by the person experiencing the emotion and by others. Interpersonal emotion regulation is defined as the explicit or implicit attempt to change someone else's emotions. The related concept of co-regulation refers to a process of reciprocal regulation of each other's emotions. Both types of emotion regulation are often preceded by the perception and appraisal of anticipated, imagined, or actual emotional reactions by others (i.e., social appraisal; Manstead & Fischer, 2001). The functions that emotions serve in interactions and relationships with others are therefore intertwined with the interpersonal regulation of emotion (e.g., Lopes, Salovey, Côté, & Beers, 2005; Niven, Macdonald, & Holman, 2012; see Emotion Regulation, Chapter 26, this volume).

It has been argued that the concept of emotion regulation is difficult to define, because it is unclear where emotion ends, where emotion regulation begins, and who is regulating what (Kappas, 2013). We might shout a little harder at a friend than at a superior, or we might cry more overtly in the company of a friend than in the company of strangers, without even noticing that we are regulating our emotion. Thus it can be argued that emotion regulation, like emotions themselves, serves the same two social functions that we have described in this chapter (see also Keltner & Haidt, 1999). Emotions are typically regulated in such a way that they are socially functional, helping us to establish or maintain closeness and cooperation with some but separation and distance from others (see also Emotion Regulation, Chapter 26, this volume).

Interpersonal regulation starts already early in life (Trevarthen, 1984): Parents adjust their own facial and vocal expressions of emotion in order to soothe, interest, or bring pleasure to a baby. When children are older, caregivers try to calm agitated or angry children by encouraging them to reappraise the situation, count to 10, or go to their room. Children who are unhappy are stimulated to smile; children who appear to be ungrateful are encouraged to express their gratitude (Eisenberg, Cumberland, & Spinrad, 1998). Parents' regulation of their children's emotions is later supplemented or superseded by peers (Helsen, Vollebergh, & Meeus, 2000) and still later by partners, who tell one to calm down, give disapproving looks, offer verbal comfort or criticism, or laugh with someone or at someone when expressing or sharing an emotion (Rimé, 2009). In communal relationships, partners are both targets of emotional expression and regulators of such expression (see also Clark et al., 2004). Interpersonal regulation thereby serves an affiliative function, because it is essentially cooperative.

Co-regulation involves not only telling others how to modify unwanted feelings, but also expressing one's own emotions in a way that regulates others' emotions. By expressing anger when one's partner is jealous, displaying shame when one's child has a temper tantrum in public, or expressing empathy when one's friend is in distress, we also attempt to help others to regulate their emotions. In the context of cooperative relationships, co-regulation is likely to involve encouraging affiliative emotions, and discouraging social distancing emotions.

Sharing the experience of affiliative emotions in interpersonal relations or groups is likely to enhance the closeness (see also Laurenceau, Barrett, & Pietromonaco, 1998), intimacy, or positivity of a relationship, and may result in emotional transference, convergence, or contagion (Hatfield, Cacioppo, & Rapson, 1992; Parkinson & Simons, 2012). Indirect evidence for such co-regulation of affiliative emotions can be found in a study by Anderson, Keltner, and John (2003), who found that dating partners and college roommates became emotionally more similar over the course of a year. This emotional convergence effect applied to both positive and negative emotional reactions to events and could not be explained by increased similarity in personality variables. More direct evidence for co-regulation comes from research by Bruder, Dosmukhambetova, Nerb, and Manstead (2012), who found that dyads jointly exposed to emotional films converged in their appraisals, emotions, and nonverbal behavior.

Regulating others' emotions can also operate via emotional mimicry (e.g., Dimberg, 1982; Dimberg & Lundquist, 1990). Research has shown that we mimic intimates more than strangers (Fischer, Becker, & Veenstra, 2012), ingroup members more than outgroup members (Bourgeois & Hess, 2008, Study 2; Van der Schalk et al., 2011), and people whom we like more than people whom we do not like (Likowski, Mühlberger, Seibt, Pauli, & Weyers, 2008). Instructions to mimic another person also lead to more affective bonding with this person, in comparison with conditions in which people are instructed not to mimic (Stel & Vonk, 2010). In short, interacting with others involves regulating our tendencies to mimic the other's emotional expressions, which is likely to serve an affiliative function.

The social consequences of interpersonal emotion regulation are also apparent when emotions are socially shared (Rimé, 2009). Sharing any emotion is likely to involve some degree of co-regulation, and to the extent that the emotion is not only communicated but also shared, the effect is likely to be one of strengthening social bonds. Indeed, a study by Kuppens and colleagues (2013) showed that talking about an emotionally relevant topic in a group resulted in stronger indignation than did discussing an emotional topic that was irrelevant to the group, suggesting that sharing emotions within a group can lead to the up-regulation of group-based emotions and thereby serve an affiliative function. In general, we assume that the expression of anger, rage, antipathy, and other negative emotions may serve a social distancing function with respect to the outgroup (moving away from the threatening group), whereas sharing these emotions with ingroup members serves an affiliation function (see also Hess & Fischer, 2013).

Conclusion

Emotions are experienced and expressed in social contexts, and they help us to deal with the challenges posed by the social environment. We have distinguished two general social functions of emotion: affiliation and social distancing. Emotions can reduce or increase the social and psychological distance between self and others, or between one group and another. However, it should be evident from our review of the literature that the social functions of emotion cannot be equated with the social effects of expressing that emotion in any given setting. The social functions of emotion are relatively independent of specific context, but rather are intrinsic to the social-relational goals and prototypical features of the emotional reaction, whereas the social effects of an emotion are contingent on both the way in which the emotion is expressed and the specifics of the social context. Social functionality thus depends on the typical social action tendencies intrinsic to an emotion, such as wanting to hide, avoid, run away, promote the self, attack, stay as close as possible to another, or make up with another. These goals are met only when an appropriate balance is struck between affiliation and cooperation, on the one hand, and social distancing and competition, on the other (see also Salovey & Mayer, 1990). Social survival and social well-being involve a compromise between these fundamental social goals.

We have argued that each emotion can be seen as having a primary social function, either affiliation or social distancing. Most positive emotions—but also some negative emotions like regret, embarrassment, sadness, shame, or guilt—serve an affiliation function. By contrast, anger, contempt, and (social) disgust serve an individual's or group's need for social distance and increased social standing. However, when we take into account the way in which an emotion is expressed, or the target of the emotion, or the time frame of the emotion, other effects may become apparent. For example, anger generally increases social distance in the short term, but may ultimately be constructive in a relationship. Whether or not this latter effect takes place depends primarily on the perceived appropriateness of the anger.

A final point that bears repetition is that although we firmly believe that emotions serve social functions, this does not mean that emotions are always socially functional. The potential social functionality of emotions can be inferred from their social-relational goals and typical features. In practice, this functionality depends on how the individuals or social groups involved appraise the social context, and the extent to which they regulate their emotions and expressions in ways that are consistent with those appraisals. Perhaps the ultimate social function of emotions is to persuade others to acknowledge the validity of one's own or one's group's appraisals (see Parkinson, 1995).

Acknowledgments

We thank Lisa Feldman Barrett, Keith Oatley, Brian Parkinson, Jerry Parrott, and Gerben van Kleef for their helpful comments on previous versions of this chapter.

CHAPTER 25

Social Pain and Social Pleasure

Two Overlooked but Fundamental Mammalian Emotions?

Naomi I. Eisenberger

> A sense of separation is a condition that makes being a mammal so painful.
>
> —Paul MacLean (1993)

> There is something in staying close to men and women and looking on them, and in the contact and odor of them, that pleases the soul well. . . .
>
> —Walt Whitman (1855)

Paul MacLean, a 20th-century neuroscientist, and Walt Whitman, a 19th-century poet, each highlighted one of the fundamental truths about human nature: that our social relationships can have profound effects on our emotional experience. Indeed, it is hard to imagine an experience more pleasurable than the formation of a loving relationship or one more painful than the loss of those closest to us. In fact, when asked to list the single most positive and the single most negative emotional event of their lives, approximately three out of four individuals listed events that involved close social relationships (Jaremka, Gabriel, & Carvallo, 2011). The creation and dissolution of social bonds has a significant impact on our emotional lives. Yet, even though these intense feelings of pleasure and pain that stem from social relationships are one of the most basic building blocks of human emotional experience, these experiences have typically not been included, by scientists, as fundamental emotional states. Why is this? Why have these experiences been largely overlooked in the study of emotion?

In this chapter, I argue that experiences of "social pain" (the painful feelings following social rejection, exclusion, or loss) and "social pleasure" (the pleasurable feelings associated with feeling connected to others) should be considered fundamental emotional states. These emotional states (like others) stem from an inherent mammalian survival need (LeDoux, 2012)—the need for social connection. Given that most mammalian infants are born relatively immature and completely dependent on a caregiver for nourishment and protection, there may be multiple systems in place that promote social connection by eliciting painful, distressing feelings in response to social separation and pleasurable, warm feelings in response to social connection (Eisenberger, 2012; Inagaki & Eisenberger, 2013; MacDonald & Leary, 2005; Panksepp, 1998).

Indeed, the need to stay connected may be so essential that these experiences of social pain and pleasure may have co-opted other basic regulatory systems to ensure social connection. Specifically, experiences of social pain may have co-opted the physical pain system, that is, borrowing the pain signal to highlight and prevent experiences of social separation (Eisenberger, 2012; MacDonald & Leary, 2005; Panksepp, 1998). Likewise, one type of socially pleasurable experience, "social warmth"—the warm feelings associated with feeling connected to and loved by others—may have borrowed the temperature regulation mechanisms involved in detecting and approaching physical warmth in order to promote and maintain the warm experience associated with feeling loved and connected (Inagaki & Eisenberger, 2013; Panksepp, 1998).

In this chapter, I first review evidence supporting the idea that these emotional experiences of social pain and social warmth are so critical to mammalian survival that they rely on the more basic systems involved in physical pain and temperature regulation mechanisms. I then review several possible reasons for why these emotional states may have been overlooked in the study of emotion. These include the possibility that (1) early emotion research categorized emotions based on external (rather than internal) manifestations of emotional states (expressions, behaviors) and social pain/warmth may not have uniform expressions or behavioral outputs; (2) pain and temperature, the hypothesized substrate of social pain and social warmth, have typically been classified as sensory processes rather than emotional states; and (3) pain and temperature are different from emotions in that pain and temperature convey information about how the environment affects the body, whereas emotions convey information about how the environment affects the self.

Social Pain and Physical Pain

If we examine the way that individuals describe experiences in which they have been rejected, excluded, or have lost a loved one, we notice an interesting pattern. People use physical pain words to describe these negative social events—complaining of "*hurt* feelings" and "*broken* hearts." In fact, these physical pain words are often considered better and more accurate descriptors of the feelings that follow these negative social events than more standard emotion words, such as "angry," "sad," or "upset." Moreover, this pattern of using physical pain words to describe socially painful experiences is observed across many different languages and is not exclusive to the English language (MacDonald & Leary, 2005). Yet, does this observation provide meaningful insight into the way people process these negative social events or is the pain associated with social rejection or loss more metaphorical than real?

Over the past several decades, accumulating research has started to indicate that the painful feelings associated with social rejection or loss may be more than just metaphorical. Research across multiple species has shown that experiences of social pain rely on some of the same neural and neurochemical substrates that are involved in the distressing experience of physical pain (Eisenberger, Lieberman, & Williams, 2003; Eisenberger & Lieberman, 2004; Eisenberger, 2012; MacDonald & Leary, 2005; Panksepp, 1998). Indeed, such a physical–social pain overlap makes sense from an evolutionary perspective. Compared with other species, mammals are unique in that they are born relatively immature without the capacity to feed or fend for themselves. Given this innate dependency, it is critical for mammalian infants to stay close to a caregiver in order to obtain the appropriate nourishment and protection. To the extent that being separated from a caregiver is such a threat to the survival of young mammals, feeling hurt by separation may be an adaptive way to prevent it. In fact, it has been hypothesized that, over the course of our evolutionary history, the social attachment system may have piggybacked onto the physical pain system, borrowing the pain signal to prevent social separation (Eisenberger et al., 2003; Eisenberger & Lieberman, 2004; Eisenberger, 2012; MacDonald & Leary, 2005; Panksepp, 1998).

Shared Neurochemical Substrates

Evidence for a physical–social pain overlap comes from several different lines of research. The earliest research in this area focused on the shared neurochemical substrates underlying physical and social pain in animals and demonstrated that mu-opioids, known for their powerful pain-relieving effects, also reduced separation distress behaviors, such as distress vocalizations—characteristic calls made by infant mammals following mother–infant separation. For example, low, nonsedating doses of morphine, a mu-opioid agonist, can decrease distress vocalizations when pups are separated from their mothers, whereas naloxone, a mu-opioid antagonist, can increase distress vocalizations (Herman & Panksepp, 1978; Kalin, Shelton, & Barksdale, 1988; Panksepp, Herman, Conner, Bichop, & Scott, 1978). Interestingly, blocking opioids in humans has also been shown to reduce feelings of social connection (Inagaki, Ray, Irwin, Way, & Eisenberger, in press).

Similarly, genes that regulate mu-opioid processes also affect attachment-related behaviors. Mice lacking the mu-opioid receptor gene produce fewer distress vocalizations following maternal–infant separation (Moles, Kieffer, & D'Amato, 2004), perhaps because there is no longer distress at separation. Likewise, infant rhesus monkeys carrying a version of the mu-opioid receptor gene that is linked with increased physical pain sensitivity (Chou et al., 2006; Sia et al., 2008) also show increased distress behaviors upon separation from their mothers (Barr et al., 2008), and mothers who carry this same version of the gene are more likely to prevent their infants from separating from them (Higham et al., 2011), possibly because of the increased distress associated with separation. Together, these studies support the physical–social pain overlap by showing that opioids have similar effects on both physical and social pain.

Shared Neural Substrates

In addition to sharing neurochemical substrates, physical and social pain are also known to share neural substrates. As a bit of background, pain research has shown that physical pain can be subdivided into two components: (1) a sensory component, which codes for the localization, quality, and intensity of the nociceptive stimulus; and (2) an affective component, which is associated with the distressing experience of pain and the drive to terminate the painful stimulus (Price, Harkins, & Baker, 1987). Neuroimaging research has shown that these two components of pain map fairly well onto different cortical regions: the sensory component tends to be associated with activity in the primary and secondary somatosensory cortices (S1, S2) and the posterior insula (PI), whereas the affective component of pain tends to be associated with activity in the dorsal anterior cingulate cortex (dACC) and anterior insula (AI; Treede, Kenshalo, Gracely, & Jones, 1999; Apkarian, Bushnell, Treede, & Zubieta, 2005). Given that social pain does not have the same kind of nociceptive input as does physical pain, we have hypothesized that social pain shares the affective component with physical pain.

As evidence for this, lesioning certain regions known to play a role in the affective component of pain (dACC, AI) not only reduces the suffering component of pain (Foltz & White, 1962; Berthier, Starkstein, & Leiguarda, 1988), it also reduces social pain-related behaviors and experience. In animals, lesioning the anterior cingulate cortex (ACC; dorsal and/or ventral to the genu) in infant mammals reduces distress vocalizations upon mother–infant separation (Hadland, Rushworth, Gaffan, & Passingham, 2003; MacLean & Newman, 1988), whereas stimulating this region leads to the spontaneous production of these vocalizations (Robinson, 1967; Smith, 1945). Similarly, in humans, lesioning the dACC (through a surgical procedure known as a cingulotomy) can reduce shyness and lead to a reduced concern about the opinions or judgments of others (Tow & Whitty, 1953). Hence, across animals and humans, lesions to the ACC, known to play a role in the affective component of physical pain, reduce separation-distress behaviors in animals and concerns about social rejection in humans.

Neuroimaging research has also provided evidence that experiences of social pain rely on affective pain-related neural regions. Thus, various types of socially painful experiences (reviewed in Eisenberger, 2012) including social exclusion (Eisenberger et al., 2003), negative social evaluation (Eisenberger, Inagaki, Muscatell, Haltom, & Leary, 2011; Takahashi et al., 2009; Wager et al., 2009), viewing rejection-themed images (Kross, Egner, Ochsner, Hirsch, & Downey, 2007), reliving a romantic rejection (Fisher, Brown, Aron, Strong, & Mashek, 2010; Kross, Berman, Mischel, Smith, & Wager, 2011), and being reminded of a lost loved one (Gündel, O'Connor, Littrell, Fort, & Richard, 2003; Kersting et al., 2009; O'Connor et al., 2008) all activate the dACC and AI. In fact, one study demonstrated that subjects showed overlapping neural activity in the dACC and AI in response to both a physical pain task and a social pain task in which they relived a recent relationship breakup (Kross et al., 2011).

However, recent research has also suggested that there may be computational differences in the processing of social and physical pain, when looking at the level of multivariate patterns of neural activity (Woo et al., 2014; Wager et al., 2013). Thus, although physical and social pain activate overlapping neural regions (Kross et al., 2011), findings from multivariate pattern analysis (MVPA) show that physical and social pain rely on dissociable representations in these same regions. While it is possible that this is the case, these studies are hindered by the fact that they compare neural representations of live experiences of physical pain (e.g., subjects receive multiple trials of heat pain during the experiment) with memories of social pain (e.g., subjects are asked to think back to a prior experience of rejection multiple times). Hence, the differences observed in the multivariate patterns of neural activity could be due to real differences between physical and social pain or they could be due to more mundane differences inherent in the eliciting stimuli (real experiences vs. memories, etc.). Future studies are needed to address this confound and further examine the representational overlap between physical and social pain. Thus, though not conclusive, considerable research has shown that experiences of social pain activate neural regions often associated with the affective component of physical pain.

Functional Consequences

As further evidence that physical and social pain processes overlap, research has also confirmed some of the expected consequences of such an overlap. For example, one corollary of the physical–social pain overlap hypothesis is that individuals who are more sensitive to one type of pain should also be more sensitive to the other. Indeed, studies have shown that individuals who tend to be more sensitive to physical pain stimuli also go on to report greater social distress following social exclusion (Eisenberger, Jarcho, Lieberman, & Naliboff, 2006). Likewise, individuals who carry a variant of the mu-opioid receptor gene linked to increased physical pain sensitivity also report higher levels of rejection sensitivity and show greater activity in the dACC and AI in response to social exclusion (Way, Taylor, & Eisenberger, 2009).

A second corollary of the physical–social pain overlap hypothesis is that altering one kind of pain should alter the other in a similar manner, and studies have shown evidence for this as well. Factors that increase social pain, such as social exclusion or failure, tend to increase sensitivity to physical pain (Bernstein & Claypool, 2012; Levine, Krass, & Padawer, 1993; van den Hout, Vlaeyen, Peters, Engelhard, & van den Hout, 2000; cf. DeWall & Baumeister, 2006), whereas factors that decrease social pain, such as social support, reduce physical pain experience and pain-related neural activity in response to physically painful stimuli (dACC, AI; Eisenberger, Master, Inagaki, Taylor, Shirinyan, et al., 2011; Master et al., 2009; Younger, Aron, Parke, Chatterjee, & Mackey, 2010). Likewise, factors that increase physical pain, such as inflammatory processes, increase feelings of social disconnection (Eisenberger, Inagaki, Mashal, & Irwin, 2010) and are associated with greater dACC and AI activity to social exclusion (Eisenberger, Inagaki, Rameson, Mashal, & Irwin, 2009), whereas factors that decrease physical pain, such as the physical pain-reliever Tylenol, have been shown to reduce daily hurt feelings as well as pain-related neural activity (dACC, AI) to social exclusion (DeWall et al., 2010).

Summary

Together, this research provides solid evidence for the hypothesis that experiences of social pain may rely on the same neural mechanisms as those that process the distressing experience of physical pain. Given the importance of social connection for survival as well as the profound emotional impact that experiences of social pain have, it seems plausible that social pain represents a fundamental type of mammalian emotional experience.

Social Warmth and Physical Warmth

Similar to the insights we gain from examining the language of social pain, listening to the language of social pleasures, or the feelings that arise in response to feeling socially connected, may provide important information about these feeling states as well. Although there are many ways that people describe feelings of social connection, one common way is with words that reflect physical warmth, such as when individuals speak of "having *warm* feelings for someone" or of someone's actions "*warming* their hearts." (Another category of words used to describe social connection are those that indicate physical proximity—such as closeness: "I felt *close* to her." However, this category of linguistic processing is not reviewed here. See Parkinson, Liu, & Wheatley, 2014, for an insightful treatment of this topic.) Indeed, it has been suggested that the mechanisms involved in temperature perception and regulation may be involved in detecting and reinforcing social connection (Inagaki & Eisenberger, 2013; Panksepp, 1998). Specifically, the mechanisms underlying thermoregulation, the processes associated with maintaining our relatively warm core body temperature (including the motivation to seek out warm stimuli and the perceived pleasantness of physical warmth; Rolls, Grabenhorst, & Parris, 2008) may have been co-opted to maintain "social warmth"—the experience of feeling connected to and loved by others.

Physical and Social Warmth Are Associated Early On

In a very tangible way, physical and social warmth are associated from birth. Being close and (literally) connected to the mother before birth is associated with the physical warmth of the mother's womb. After birth, being held, rocked, or soothed by a caregiver is associated with increased physical warmth due to the close proximity of the caregiver. Hence, an early association is formed between physical and social warmth, the experience of being connected to and cared for by someone. Whether the association between physical and social warmth has been selected for over the course of evolutionary history or is learned within an individual's lifespan is not yet known.

This association between physical and social warmth appears to play out in multiple species. For example, in Harlow's (1958) early studies of infant rhesus monkeys' preference for cloth or wire monkey mothers, he found that infant rhesus monkeys preferred cloth mothers, which in addition to being soft, were also warmed by a 100-watt lightbulb. Moreover, monkeys paired with these warm, cloth mothers went on to show fewer emotional problems later on than those paired exclusively with wire monkey mothers (Harlow, 1958; Harlow & Zimmerman, 1959). Similarly, rat pups deprived of maternal care continued to develop normally if placed in a warm rather than a cold environment (Stone, Bonnet, & Hofer, 1976), suggesting that physical warmth may be substituting for the care or social warmth provided by the mother. Likewise, pups removed from their mothers evidenced less distress if placed in warm rather than cold or hot cages (Blumberg, Efimova, & Alberts, 1992).

Although the interaction between physical and social warmth has been less studied in humans, research has highlighted the importance of physical and social warmth (separately) for human infant development. Highlighting the critical need for physical warmth, premature infants placed in warmer, rather than cooler, incubators for the first 5 days of life were more likely to survive (Silverman, Fertig, & Berger, 1958). Highlighting the critical need for social warmth, children raised in institutional settings without a warm, nurturing caregiver show lifelong problems with physical, cognitive, and socioemotional development (Gunnar, Bruce, & Grotevant, 2000).

Behavioral Evidence for a Physical–Social Warmth Overlap

Emerging evidence stemming largely from the embodied cognition literature suggests that physical and social warmth rely on shared underlying mechanisms. One way that this has been demonstrated is by showing that altering one kind of warmth process can alter the other in a similar manner. For example, several studies have shown that increasing feelings of physical warmth can lead to corresponding increases in feelings of social warmth. Thus, holding a warm (vs. a cold) beverage increased self-reported feelings of social connection with a close other (IJzerman & Semin, 2009) as well as the tendency to act in socially warm ways (giving to close others vs. oneself; Williams & Bargh, 2008). Likewise, holding a warm (vs. cold or neutral) pack led to greater feelings of social connection (Inagaki & Eisenberger, 2013) and trust in others (Kang, Williams, Clark, Gray, & Bargh, 2011). Finally, being in a warm (vs. cool) room led to increased feelings of closeness with an experimenter (IJzerman & Semin, 2009). Conversely, reducing physical warmth can reduce social warmth; individuals who held a cold (vs. a warm or neutral) pack reported greater feelings of loneliness (Bargh & Shalev, 2012).

Reversing the causal direction of these effects, other studies have shown that altering social warmth can alter perceived physical warmth in a similar manner. Reading loving, socially warm (vs. neutral) messages from close others increased self-reported feelings of warmth (Inagaki & Eisenberger, 2013), and feeling more similar to interaction partners increased the perceived warmth of a room (IJzerman & Semin, 2010). Conversely, reducing feelings of social warmth have been shown to reduce feelings of physical warmth. Individuals who relived or faced an episode of social exclusion estimated the temperature of the room to be colder than those who relived or experienced social inclusion (Zhong & Leonardelli, 2008). Additionally, thinking about the many (vs. few) ways in which one is dissimilar from someone else led individuals to estimate the room temperature as colder (IJzerman & Semin, 2010).

Finally, as further evidence for this physical–social warmth overlap, human research has also shown that individuals may regulate their feelings of social warmth by substituting physical warmth. Thus, greater loneliness, or a lack of social warmth, is associated with taking more frequent warm baths/showers, taking longer warm baths/showers, and preferring the temperature of the water to be warmer (Bargh & Shalev, 2012). Similarly, after reliving a past rejection experience, holding a warm (vs. cold) pack reduced the need for affiliation or emotion regulation that typically follows rejection experiences (Bargh & Shalev, 2012).

Neural and Neurochemical Evidence for an Overlap

More recently, research has examined whether common neural structures underlie physical and social warmth. The few studies that have examined neural responses to warm thermal stimuli have highlighted a role for regions like the insula and ventral striatum (VS). Warm stimuli increase insula activity, a region associated with processing interoceptive cues (Becerra et al., 1999; Olausson et al., 2005; Rolls et al., 2008; Verhagen, Kadohisa, & Rolls, 2004), and lesions to the insula can result in the selective loss of nonpainful thermal sensation (Cattaneo, Chierici, Cucurachi, Gobelli, & Pavesi, 2007). Additionally, regions like the VS, pregenual anterior cingulate cortex (pACC), and orbitofrontal cortex correlate with the perceived pleasantness of warm stimuli (Rolls et al., 2008), suggesting that these regions may play a role in the pleasurable experience associated with warmth. Interestingly, similar regions have been implicated in viewing loved ones (Acevedo, Aron, Fisher, & Brown, 2012; Aron et al., 2005; Bartels & Zeki, 2000, 2004).

To examine whether experiences of physical and social warmth rely on similar regions, we examined neural activity as subjects completed physical and social warmth tasks (Inagaki & Eisenberger, 2013). During the physical warmth task, subjects held a warm pack on some trials (physical warmth) and a squeeze ball on other trials (control). During the social warmth task, subjects read loving messages written to them by their close family members and friends (seen for the first time in the scanner) on some trials (social warmth) and read neutral messages written by these same individuals on other trials (control). In addition to showing that the warm packs (vs. squeeze ball) made people feel more connected and that reading the loving (vs. neutral) messages made people feel warmer, results also showed that there was overlapping neural activity in the middle insula and the VS in response to both tasks. Hence, physical and social warmth may rely on common neural substrates.

Finally, physical and social warmth may also rely on some of the same neurochemical substrates. The regions that showed overlapping neural activity to physical and social warmth—the insula and VS—are known to have a high density of mu-opioid receptors, and thus opioids may serve, in part, to regulate physical and social warmth. Though complicated, mu-opioids have been shown to play a role in temperature regulation such that mu-opioid agonists, which enhance opioid processes, can increase body temperature (Clark, Murphy, Lipton, & Clark, 1983), whereas mu-opioid antagonists, which block opioid processes, can decrease body temperature (Handler, Geller, & Adler, 1992; Spencer, Hruby, & Burks, 1988). Interestingly, blocking mu-opioid processes in humans (through naltrexone) has been shown to reduce feelings of social connection in response to reading loving messages from close others (Inagaki, Ray, Irwin, Way, & Eisenberger, in press) and to reduce feelings of social connection in response to holding a warm pack (Inagaki, Irwin, & Eisenberger, 2015). In fact, Panksepp (1998) hypothesized that mu-opioids play a critical role in both the positive and negative socioemotional feelings that underlie social attachments, with increasing levels of opioids underlying the positive feelings associated with social connection and decreasing levels of opioids underlying the painful feelings associated with social separation.

Summary

In addition to a physical–social pain overlap, emerging evidence also highlights the shared mechanisms underlying physical and social warmth. Hence, mammalian species may have developed multiple insurance policies for maintaining social connection—relying on pain mechanisms to detect and avoid social separation as well as temperature regulation mechanisms to detect and reinforce social connection. Based on this, social pain and warmth may represent two fundamental emotional states—each associated with maintaining the critical mammalian goal of attaining social connection.

Why Have Social Pain and Social Warmth Been Overlooked as Fundamental Emotional States?

Given that emotions have been conceptualized as affective-motivational processes that reflect the function of circuits related to survival (LeDoux, 2012), social pain and social warmth, which are affective-motivational states stemming from the mammalian need for social connection, seem like shoe-ins for fundamental emotional states. However, typically, social pain and warmth—or even related terms that are more commonly used such as "hurt feelings" or "love"—have typically not been studied as fundamental emotions by the scientific community. Why is this? What might differentiate these emotional states from others and are these valid differences or faulty assumptions? Here, I review three possible reasons for why social pain and warmth may have been overlooked in the study of emotion.

- *Possibility 1: Early, influential models of emotion focused more on external cues of emotion.* Perhaps the main reason that social pain and warmth have been overlooked as fundamental emotions is that some of the early emotion research, which was influential in initially determining "what counts" as an emotion, focused more heavily on external cues of emotion. Thus, some early emotion research, inspired in part by Darwin's (1872) observations of emotional expressions in animals, focused on observable expressions of emotions, such as those found in facial expressions. For example, Paul Ekman (1993) used facial expressions to categorize emotions and determined, based on cross-cultural examinations of facial expressions, that there were six "basic emotions" that were universally recognized. These included fear, anger, sadness, disgust, happiness, and surprise. He then went on to posit that each of these basic emotions, which could be distinguished based on emotional expressions, also shared other characteristics such as specific triggers or antecedent events (distinct for each emotion), automatic appraisals, and a distinctive physiology (Ekman, 1992). This framework shaped much of the early thinking on emotion research and continues to influence emotion theory to this day, as evidenced by the common focus on the basic emotions of fear, anger, sadness, disgust, and happiness (Phan, Wager, Taylor, & Liberzon, 2002; Wager, Phan, Liberzon, & Taylor, 2003; Murphy, Nimmo-Smith, & Lawrence, 2003; Vytal & Hamann, 2010), with little focus on emotional states outside of this inventory.

Interestingly, although much of what is intriguing and unique about emotion is the quality of the experience associated with it; this early, influential framework focused very little on emotions "from the inside"—from the perspective of experience. Instead, the basic emotion approach focused largely on categorizing emotions based on external behavior: common facial expressions, physiological responses, and behavioral responses. Hence, this early and (still) influential view of emotion may have overlooked certain emotional states, not because they are not emotional, but rather because they lack a characteristic emotional expression or behavioral response or did not fit easily into this basic emotion schema.

However, shifting the way we categorize emotions—from a focus on external expressions and behaviors to a focus on internal feeling states—may change our understanding of emotion. Focusing on emotions from the inside may reshuffle the deck of basic emotions from a focus on emotions with discrete expressions (such as fear or anger) to a focus on more basic dimensions of human emotional experience (such as pleasure and pain). Perhaps this is the perspective that some emotion theorists had in mind when they suggested that the two most basic emotions were pain and pleasure (Mowrer, 1960; Panksepp cited in Phillips, 2003). Indeed, although pain and pleasure are not typically considered emotions according to the basic emotion approach, they are definitely considered fundamental categories of emotional experience when focusing on emotional experience. What might emotion research look like if the focus was on categorizing internal experience rather than external expressions and behavior?

Models that focus on the internal experience associated with emotions tend to focus more on the language people use to describe their emotional feelings rather than on characterizing emotional outputs (physiology, emotional expressions). For example, the circumplex model of emotion, which focuses on internal affective feelings, was developed, in part, by exploring how affective language naturally clusters. This was accomplished by having subjects or factor analytic techniques sort various affect labels ("alarmed," "depressed," "relaxed," "serene," "pleased," "tense") into categories, revealing a two-dimensional set of axes consisting of the categories valence (positive, negative) and arousal (low, high; Russell, 1980; Barrett & Russell, 1999).

Each of these axes relates more strongly to the experience, rather than the expression, of emotion: either positive or negative, arousing or calm.

Likewise, much has been learned about social pain and social warmth from the words used to describe the experiences that follow social rejection and connection. And it is interesting to note that the words that people use to describe these events are not necessarily standard emotion words, but words that reflect experiences of physical pain and physical warmth (MacDonald & Leary, 2005). Hence, focusing on emotions from the inside may provide different but important clues about the nature of emotional experience.

- *Possibility 2: Pain and temperature have been conceptualized as sensations, which are different from emotions.* A second reason that social pain and social warmth may have been overlooked as fundamental emotional states is that their hypothesized substrates—pain and temperature—have typically been conceptualized as sensory, rather than affective, processes. Hence, while it may seem quite logical that the painful feelings that follow from broken social bonds may have co-opted the pain system and that the warm feelings associated with feeling socially connected may have co-opted temperature regulation mechanisms, it may seem harder to imagine that physical pain and physical warmth are similar to emotional processes. Physical pain and warmth have typically been conceptualized as cutaneous sensations (like touch), which have been distinguished from emotional states. However, new research on the nature of pain and temperature processing has suggested that these processes may share more in common with emotional states than with sensations.

Early thinkers distinguished feelings related to the body's state (pain, temperature, flush) from the five senses (Weber, 1846). However, in 1948, Sir Charles Sherrington (1948), a Nobel Prize laureate in physiology and medicine, mistakenly categorized pain and temperature as aspects of touch, an exteroceptive sense. This mistaken classification still figures prominently in textbooks and highlights the fact that pain and temperature are assumed to be cutaneous sensations (Craig, 2002). Hence, many researchers and clinicians, and thus the broader public, have regarded pain and temperature as a submodality of cutaneous sensation or exteroception.

Recent work, however, has challenged the idea that pain and temperature are exteroceptively processed and has shown instead that both are interoceptively processed—that is, these feeling states result from homeostatic processes intended to regulate the condition of the body and signal when the organism is at risk (Craig, 2002). Thus, pain reflects an adverse condition of the body that demands a behavioral response and warmth (in most, though not all, cases) represents the rewarding attainment of the biological need for thermoregulation.

Notably, a key feature that distinguishes pain and temperature from touch is their inherent association with emotion. Painful or warm feelings have an affective-motivational component, whereas touch (noting whether something is rough, bumpy, smooth, etc.) does not (with the exception of gentle stroking or "affective touch"; see Olausson et al., 2002). While the affective-motivational aspects of pain are easy to see, the affective-motivational components of temperature are more often overlooked because feelings of temperature tend to be projected onto the objects being touched. However, temperature reflects the physiological condition of the body and generates an inseparable affective response (pleasantness or unpleasantness) that signals this homeostatic role. For example, when we are overheated, the feeling of cool water is experienced as pleasant. However, when the body is cold, that same cool water can feel intensely unpleasant. This example highlights the fact that temperature is homeostatically regulated and that the feelings of pleasantness or unpleasantness reflect the body's survival needs. Indeed, it has been suggested that these "bodily feelings" not only provide information about the homeostatic needs of the body but also underlie various mood and emotional states (Craig, 2003; Denton, McKinley, Farrell, & Egan, 2009; James, 1884).

Based on research showing that pain and temperature are processed interoceptively and thus, by definition, have an affective-motivational component, it may seem less surprising that pain and warmth represent the substrates for feelings of social rejection or social closeness. Even though pain and temperature are not classified as emotions, they have certain affective and motivational properties that position them as important precursors for the emotional states of social pain and social warmth.

Indeed, like the homeostatic processes of pain and temperature, which provide information about the condition of the body, social pain and social warmth are homeostatic emotions that provide information about the condition of one's social bonds. For example, in the same way that a cold breeze feels less distressing when one is already warm than when one is cold, social rejection may not be experienced as quite as painful if one already has strong social bonds. Indeed, research has shown that individuals who have higher levels of social support or who spend more time with their friends show less pain-related neural activity in response to social exclusion (dACC, AI; Eisenberger, Taylor, Gable, Hilmert, & Lieberman, 2007; Masten, Telzer, Fuligni, Lieberman, & Eisenberger, 2012). Likewise, an experience of social rejection may be even more painful and an experience of social connection may be even more pleasurable if one does not have strong social bonds. Consistent with this, individuals high in anxious attachment, who tend to worry about being rejected by close others and thus may experience less social connection, show greater activity in pain-related neural regions in response to social exclusion (DeWall et al., 2012). Likewise, individuals who score higher in loneliness—indicating a lack of felt social connection—show greater activity in the VS, a reward-related neural region, in response to viewing pictures of social support figures (Inagaki, Muscatell, et al., in press). Thus, social pain and warmth may represent homeostatic emotional states, which fluctuate based on whether the need for social connection has been met.

- *Possibility 3: Pain and temperature seem to primarily affect the body, whereas emotions seem to primarily affect the self.* Even after acknowledging that pain and temperature have an affective component and are not purely sensory, it might still seem strange to include social pain and social warmth as emotional states, because their substrates—pain and temperature—are still not typically conceptualized as emotional states even if they are affective in nature. One of the main differences is that physical pain and physical warmth appear to provide information about the state of the body, whereas emotions provide information about the organism's relationship to the environment (Denton et al., 2009; reviewed in Kleinginna & Kleinginna, 1981). Because of this, pain and temperature "feel" like they primarily affect the physical body, whereas emotions, because they provide information about the person's relationship to the environment, "feel" like they primarily affect the self.

This fundamental distinction between the body and the mind or self is one that has repeatedly emerged throughout psychology (Lieberman, 2007) and appears to be a fundamental way in which the brain is organized (Lieberman, 2007, 2009; Uddin, Iacoboni, Lange, & Keenan, 2007). Studies have shown that a right-*lateralized* frontoparietal network is involved in understanding the physical aspects of the self, such as recognizing one's face or voice or retrieving information about the body, whereas a more *medial* frontoparietal network is involved in understanding the psychological self, such as when thinking about one's traits, qualities, or preferences (reviewed in Lieberman, 2007). Likewise, thinking about others in terms of their bodies (e.g., in order to imitate them) leads to activity in the *lateral* frontoparietal network (Iacoboni et al., 1999), whereas thinking about others in terms of their minds or "mentalizing" (e.g., thinking about what others might be thinking or feeling) leads to activity in the *medial* frontoparietal network (Mitchell, 2008). Hence, pain and temperature, which typically reflect a focus on the physical body, may be differentiated in important ways from emotion, which may be more focused on the psychological self.

Still, *social* pain and *social* warmth, unlike physical pain and physical warmth, seem to be processed in such a way that makes them "feel" like they are primarily affecting the self rather than the body and thus may be more akin to other emotional states. Indeed, social pain, like other emotional states (anger, sadness, happiness) can be reexperienced and relived, perhaps because one can relive the thoughts and intentions of oneself and others (which results in the emotional response), whereas physical pain can not be easily relived (Chen, Williams, Fitness, & Newton, 2008), perhaps because there are not typically intentions to relive. A recent study confirms this hypothesis (Meyer, Williams, & Eisenberger, 2015). Hence, not only did reliving social (vs. physical) pain lead to greater reports of pain during the reliving episode, but reliving social pain led to enhanced mental state processing (for oneself and others) and increased activity in the medial frontoparietal regions (associated with processing the minds of oneself and others), whereas reliving physical pain led to enhanced body state processing and increased activity in lateral prefrontal regions (associated with processing the bodies of oneself and others). Moreover, when reliving social pain, activity in the medial frontoparietal regions was functionally coupled with increased affective pain-related activity (dACC, AI) and that pain-related activity was associated with greater self-reported pain. On the other hand, when reliving physical pain, activity in the lateral frontal regions was functionally coupled with sensory-related neural regions (S1), and these sensory-related regions were not associated with self-reported pain. Hence, even though social pain and social warmth may be rooted in the neural circuitry that regulates physical pain and temperature, there are still important differences that suggest that social pain and social warmth are more in line with emotional states.

Conclusions

Although the emotional states that arise in response to social connection or rejection are some of the most intense and memorable experiences of our lives, these emotional states have not typically been the subject of focus in emotion research. Here, I have suggested that social pain and social warmth may indeed be fundamental emotional states and that they may be so central to human emotional experience that they may have piggybacked onto other basic systems that regulate an organism's survival needs. Indeed, considerable evidence has now shown that social pain relies on neural systems that process the distressing experience of physical pain and that social warmth relies on some of the same systems that process thermoregulation (detecting and approaching the pleasant feelings associated with warmth).

Interestingly, by including social pain and social warmth into our emotional lexicon, we may expand our ideas about emotions. By listening to the language associated with the emotional experiences of rejection and connection, we find clues to an underlying reliance on neural systems involved in regulating pain and warmth. What if we did the same for other socioemotional states that have not been typically investigated or included in emotion research? What hints are we given about the nature of socioemotional experience when we focus on the language individuals use to describe the emotions that arise from social interactions?

Indeed, this approach may lead to several new questions, such as What does it mean to feel emotionally touched? To feel safe and secure in another's presence? To feel the chills at witnessing an act of true compassion or selflessness? Though none of these experiences are neatly carved into standard emotion categories, each of these emotional experiences are worthy of further investigation. Exploring the nature of these socioemotional experiences may not only further our understanding of emotional experience, but may also continue to reveal important information about the ways in which our emotions are shaped by our inherent need for others.

CHAPTER 26

Emotion Regulation

A Valuation Perspective

Gaurav Suri and James J. Gross

Imagine a golfer getting ready to putt on the deciding green of an important tournament. He feels nervous, and cannot quite keep his hands completely still. There is a pit in his stomach, and he worries that his mounting anxiety will interfere with the all-important final shot. If only he could find a way to calm down and regain control! Then, he has an idea. He decides to reinterpret his nervous arousal as something that will enable him to be even more focused than usual (as opposed to being a source of disquiet). Thinking about his physiological reactions in this way lessens his anxiety and he more feels more confidence as he gets in position to make the putt.

In this vignette, the golfer's anxiety arose because the golfer *valued* the consequences of a missed putt as being very negative. Many emotions can be similarly thought to result from positive or negative valuations. Emotional responses such as joy, fear, and disgust all have, at their core, a valuation of whether something is good for me or bad for me (see The Emergence of Human Emotions, Chapter 15, this volume). A valuation relevant to an individual's goals triggers a loosely coordinated set of experiential, behavioral, and peripheral physiological responses (Mauss, Levenson, McCarter, Wilhelm, & Gross, 2005). Together, these responses constitute an emotion.

Given the major role that emotions play in shaping how we feel about and respond to the world around us, it is no surprise that emotions themselves can become the target of valuation (Ochsner & Gross, 2014). In this vignette, for example, the golfer judged his emotion (anxiety) as having negative value and thereby energized processes that tended to lessen it. In this instance, he was engaging in emotion regulation. Emotion regulation refers to a valuation process that targets another valuation (the one that is generating emotion), assigns this valuation a positive or negative value, and takes action to make the emotion either more or less likely to occur.

In this four-part chapter, we consider emotion regulation from a valuation perspective. In the first part, we describe a multilevel framework that treats emotion as a type of valuation. The second part conceptualizes emotion regulation as a type of meta-valuation. In the third part, we describe the utility of this framework in exploring decisions related to emotion regulation. Finally, in the fourth part, we outline future directions in the field of emotion regulation, emphasizing areas where a valuation-based perspective seems likely to continue to yield exciting new results.

Emotion as a Type of Valuation

According to a valuation perspective, emotions are a particular type of valuation that (1) have a well-specified object (i.e., one is angry about something), (2) unfold over seconds to minutes, and (3) involve coordinated changes in subjective experience, behavior, and physiology (Feldman Barrett, Ochsner, & Gross, 2007; Scherer, Schorr, & Johnstone, 2001). Like other valuation systems, emotions can be said to consist of the four-stage cycle outlined in Figure 26.1 (Ochsner & Gross, 2014).

The *world*, whether external or internal, provides input into the *perception* stage, which takes various types of stimuli as inputs (e.g., sensory or physiological). A *valuation* stage dynamically evaluates the value of these stimuli given the current context (evaluations could range from reflexive/implicit associations to slow/deliberative computations), and an *action* stage consisting of valuation-appropriate responses ranging from covert adjustments of low-level sensory (e.g., increased pupil dilation) or higher-level cognitive processes (e.g., shifts in effortful attention) to overt adjustments of a wide range of response systems (e.g., facial behavior, postural adjustments, sympathetic nervous system activation). These action outputs frequently change the state of the world, and this new state of the world acts as an input for the next world–perception–valuation–action (W-PVA) cycle. Because multiple W-PVA systems are typically active at any given time, these systems interact, and it is these processing dynamics that give rise to behavior.

The World Stage

The changing state of the world provides input to subsequent stages. This input can vary in complexity from low-level perceptual features (e.g., a single musical note) or physiological responses (e.g., sweaty palms) to organized perceptual exemplars (e.g., a room full of people at a party) to abstract constructs such as the self. Targets of valuation range from primary reinforcers—objects that are innately seen as "bad" or "good," like a putrid smell or a sweet drink, to secondary reinforcers—objects that derive their negative or positive value from their association with primary reinforcers, like a wad of cash (Rangel, Camerer, & Montague, 2008; Rolls, 1999).

The Perception Stage

In the perception stage of the W-PVA cycle, sensory systems encode these types of sensory inputs and pass them along to systems for computing value (Kravitz, Saleem, Baker, & Mishkin, 2011).

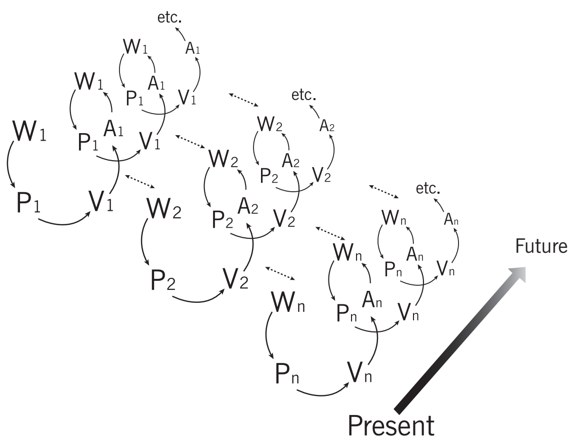

FIGURE 26.1. The perception–valuation–action (PVA) processing cycle that comprises the basic building block of emotion. Multiple PVA cycles can operate at once, here represented with subscripts 1 to *n*. Each cycle is comprises individual PVA sequences that iteratively feed into one another across time (shown here progressively spiraling from the present to the future), thereby comprising a PVA cycle. For each cycle, some set of internal and external stimuli comprising an initial state of the world (W) are represented perceptually (P), values are placed upon them (V), and associated action links (A) are activated that result in a new state of the world that feeds into the next iteration of the PVA processing cycle. PVAs can interact with one another, exciting or inhibiting each other's activation (schematically shown here by double-headed arrows between PVAs). Emotions are specific types of PVA sequences that involve specific types of perceptions, valuations, and actions. From Ochsner and Gross (2014). Copyright 2014 by The Guilford Press. Reprinted by permission.

The Valuation Stage

Valuations consist of a set of interacting processes that compute the badness or goodness of perceptual inputs (Hamann, Ely, Hoffman, & Kilts, 2002; Ochsner & Barrett, 2001; Rangel et al., 2008). Valuations provide a common currency for comparing various objects and events (Levy & Glimcher, 2011). Ochsner and Gross (2014) suggest that multiple valuations are computed for a given stimulus, and these vary along a continuum of representational complexity, with more complex valuations typically taking longer to compute than less complex valuations (Leventhal, 1984).

At the lowest level of this continuum, core valuations are made. These represent relatively direct associations between perceptual inputs and basic physiological and behavioral responses at the action stage (e.g., an approaching snake may often reliably induce a backward step). At an intermediate level, contextual valuations evaluate core inputs while factoring in the historical, social, and motivational contexts of the organism. For example, a familiar snake that is known to be harmless and is not inducing fear in anyone in the room may be valued as neutral (and not induce a backward step). At the highest level of this continuum, conceptual valuations represent appraisals of stimuli that are abstract and often verbalizable. By this we mean representations of evaluations and affective states that are abstracted across exemplars and contexts and are accessible to conscious awareness in the form of "belief–desire" language. For example, a conceptual valuation of a snake may involve activation of a conceptual representation of "fear," which one can verbalize using that word.

The Action Stage

At any given level of valuation, the action impulses associated with a W-PVA cycle can be either mental—like retrieving information from memory, forming a mental image, or introspecting about one's mood, or physical—including overt behaviors like shifts of gaze or starting to run, and autonomic/physiological responses, like heart rate increases or the release of stress hormones (Levenson, 1999).

At any given time multiple valuation computations may be concurrently active. Each valuation system has a particular target domain and creates action tendencies that operate with that particular domain. Sometimes valuation systems suggest complementary action tendencies and at other times they activate action tendencies that oppose each other. For example, a core valuation system may suggest approaching a plate of freshly baked cookies. A conceptual valuation system may support this tendency (if, e.g., one is celebrating a birthday) or oppose it (if, e.g., one is on a diet).

An Example of W-PVA Components Working Together

Imagine you are a passenger in an aircraft. Next to you sits a sleepy old man and a teenager. Suddenly, there is a spurt of turbulence and the plane loses altitude.

In our framework, emotional reactions to this change in the state of the world (altitude loss) can be conceived of as specific kinds of W-PVA sequences derived from particular perceptions, valuations, and associated action impulses (Ortony, Clore, & Collins, 1988). Thus, an initial response may reflect a core-level valuation of the dropping plane that triggers corresponding action impulses that mobilize you to avoid harm (e.g., increased heart rate, instinctively reaching for the seat belt; LeDoux, 2000; Phelps, 2006). As time passes, activation of the contextual level W-PVAs, which dictate other courses of action, can begin to build, and the initial valuation may evolve dynamic valuations of the altitude drop as relatively innocuous or highly dangerous, depending on whether you've previously experienced similar altitude drops (historical context), whether the drop elicits calm or anxious reactions from other passengers (social context), or you are stressed from a sleepless night or just had a great morning (motivational context). Then, at the conceptual level, the action outputs of activated contextual level W-PVAs are taken as inputs to systems that compute a valuation of the altitude drop in belief–desire terms that can—at the action stage—be introspectively accessed or reported to others as the thoughts and feelings you attribute to yourself or others, including, for example, the thoughts that you yourself are brave and that the sleepy old man and the teenager seem really anxious.

The order in which these valuation systems are activated, and their interplay, are not fixed and depend on the circumstances of your encounter with a stimulus. For example, if the pilot has already announced the potential of turbulence, then conceptual valuation systems might evaluate the threat (this will soon stop) and your own level of fear (I'm not scared—yet). As the turbulence continues and the steward straps himself to his seat, contextual systems might be most active as you evaluate the goodness or badness of potential courses of action based on your changing motivational state (increasing anxiety), recent history (the altitude drop is accompanied by an odd thudding sound), and the apparent anxiety of your fellow passengers (who look increasingly afraid). Finally, as the altitude drop suddenly deepens, and the threat level is very high, activation in core valuation systems may escalate to promote defensive actions like freezing, or bracing (Mobbs et al., 2009). The key idea is that taken together, all of these W-PVAs, however they were activated, and each with their associated mental and physical action tendencies, comprise an emotional response.

Emotion Regulation as Metavaluation

Just as emotion can be thought of as a W-PVA sequence, emotion regulation may also be conceptualized as a W-PVA sequence that takes as its input another W-PVA system, namely the one that is generating the underlying emotion. In the airplane example above, we might wish to protect our view of ourselves as unflappable, and thus as a consequence desire to decrease our fear responses. To do this, we can take as objects of valuation the action outputs of W-PVAs that comprise a fear response. When we do this—thereby activating a goal to influence the nature of the emotional response—we are engaging in emotion regulation.

In our framework, emotion regulation is initiated when a W-PVA cycle that gives rise to emotion becomes the object of valuation (see Figure 26.2; Gross & Ochsner, 2014). We propose that this typically happens across levels of valuation, as a higher-level W-PVA places a good or bad valuation on a lower-level W-PVA. It can also happen if there is a high level of conflict between active W-PVAs, such as whether the impulse to flee a potentially dangerous situation conflicts with the impulse to freeze, and a clear set of emotional responses is not activated. We propose that when that happens, the level of conflict constitutes an input to the next W-PVA cycle, and evaluation of that conflict triggers an appropriate course of regulatory action.

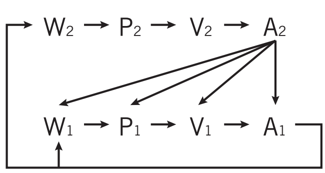

FIGURE 26.2. Emotion regulation is a functional relationship between two PVA sequences in which one (PVA_1) is "generating emotion" and the higher (PVA_2) is taking the first PVA as its "P," valuing it (negatively or positively), and targeting that first PVA for change via its "A." The "A" of PVA_2 enacts an emotion regulation strategy that influences one or more steps of PVA_1. From Ochsner and Gross (2014). Copyright 2014 by The Guilford Press. Reprinted by permission.

It is useful to consider the perception, valuation, and action stages of the higher-level regulatory W-PVA cycle. In the perception stage, the goodness or badness of underlying emotions is observed and emotions requiring regulation are identified. In the valuation stage, potential regulatory strategies are evaluated and an optimal regulatory strategy that best matches situational demands is selected. Finally, in the action stage, the particular tactics of the selected regulatory strategy are activated and implemented.

We have previously argued that emotion regulation processes can be differentiated into five families according to the stage of the emotion-generative process at which they have their primary impact (Gross, 1998). In the context of the present W-PVA framework, this idea may be expressed by suggesting that emotion regulatory processes differ in the stage of the W-PVA sequence at which they have their primary impact. Some strategies influence the state of the world (situation selection, situation modification) and perceptual inputs (attentional deployment). Others influence the valuation step itself (cognitive change). Still others influence the response output associated with activated action sequences (response modulation). By impacting different states of the W-PVA cycle, different strategies impact emotional responding in different ways, as detailed below.

Two complementary points should be made about this view of emotion regulation. First, although we make a PVA-focused distinction among emotion regulation processes, there are higher-order commonalities. For example, for some purposes, the first four emotion regulation families (situation selection, situation modification, attentional deployment, and cognitive change) may be considered antecedent focused, in that they occur before appraisals give rise to full-blown emotional responses. These may be contrasted with response-focused emotion regulation, which occurs after the responses are generated (Gross & Munoz, 1995).

The second point about these distinctions is that what someone does in everyday life to regulate emotions—such as going for a jog to cool down after a big fight with a supervisor—often involves multiple regulatory processes. Similarly, some regulatory processes do not neatly fit into any one of the PVA substeps. For example, in recent years, influential accounts from Eastern philosophy and Buddhism have introduced mindfulness as a form of emotion regulation. Mindfulness involves attending to emotional experiences by focusing on immediate here-and-now aspects with an orientation of curiosity, openness, and acceptance (Bishop et al., 2004). Mindfulness has proven to be an adaptive way to regulate negative emotions and has been incorporated into cognitive treatments of anxiety and depression (Goldin, McRae, Ramel, & Gross, 2008). Recent research suggests that the efficacy of mindfulness stems from increased executive control. This increased executive control is fostered by an improved response to incipient affective cues, which in turn is enabled by mindfulness (Teper, Segal, & Inzlicht, 2013). Despite these complexities, we believe that the W-PVA conceptualization provides a framework useful for understanding the causes, consequences, and mechanisms underlying various forms of emotion regulation.

In the following sections, we review research relevant to each of the five families of emotion regulation processes. Our focus is on emotion regulation processes in adults (see Gross, 2014b; Eisenberg & Morris, 2002; Gross & Thompson, 2007; Thompson, 1994, for a consideration of developmental issues; see John & Gross, 2004, for a consideration of individual differences in emotion regulation).

(State of the) World-Focused Strategies

Situation selection and situation modification are two families of strategies that are focused on the state of the world that leads to the emotion-generative process. Although they differ in important ways, they have in common the fact that they influence or modify the state of the world that acts as input to the emotion-generative W-PVA. *Situation selection* refers to altering the inputs to the W-PVA sequence through decisions about whether to expose oneself to a given situation/stimulus based on its projected affective impact. Thus, situation selection involves taking actions that make it more likely that we will be in a situation we expect will give rise to the emotions we would like to have (or less likely that we will be in a situation that will give rise to emotions we would prefer not to have).

We are often aware of the trajectory our emotions will likely take during a given period of time (e.g., a day) if we do not take steps to influence our emotions. This awareness may motivate us to take steps to alter the default emotional trajectory via situation selection. Thus, we may try hard to avoid situations we know will bring us face to face with an unpleasant acquaintance, or we may actively seek out situations that will provide us with contact with friends when we need a chance to vent and/or share positive emotions. Avoidance processes (such as those used in situation selection) function as a very strong regulatory option that intersects the emotion-generative process at the earliest point. Nevertheless, they can be clearly maladaptive if overused (Campbell-Sills & Barlow, 2007).

Of course, many of our everyday decisions about where to go to lunch and whether or not to go to a social event have implications for how we will later feel, but these decisions are not always determined by our estimates of the valuation of the emotions that these situations will engender. Situation selection refers only to the subset of these choices that consider the future consequences of our actions with respect to our emotional responses.

Situation modification refers to altering the situation one is in, thereby modifying the state of the world that is an input to the W-PVA sequence, and changing the potential emotion (e.g., shifting to a seat near the front of the aircraft where the effects of turbulence are relatively lower).

Similarly, imagine the case of not getting movie tickets to a long-anticipated new-release movie. This situation need not always lead to a negative emotional response. After all, one could always go to a nearby favorite restaurant and enjoy a meal with loved ones. Such efforts to directly modify the situation so as to alter its emotional impact are classified under the strategy of situation modification.

Given the vagueness of the term "situation," it is sometimes difficult to draw a clear distinction between situation selection and situation modification. This is because the W-PVA cycle of situation modification may effectively change the state of the world and call a new situation into being. Nevertheless, it is useful to separate the two strategies since situation selection often refers to entirely avoiding a negative W-PVA cycle, and situation modification often refers to changing some aspect of it. For a socially anxious person, for example, not going to an unwelcome party would be an example of situation selection, and going with a familiar friend would be an example of situation modification.

Perception-Focused Strategies

Attentional deployment refers to a family of perception-focused strategies that seek to alter the perception of the incoming input stream.

Specifically, *attentional deployment* refers to altering the inputs to the W-PVA sequence by increasing or decreasing attention to them (e.g., listening to loud music during turbulence or thinking about how one may remodel one's kitchen). In one form or another, attentional deployment is used from infancy through adulthood, particularly when it is not possible to change or modify one's situation (Rothbart, Ziaie, & O'Boyle, 1992). It is used, for example, by children who are waiting for delayed rewards, and spontaneous use of attentional deployment powerfully affects success during delay-of-gratification tasks (Mischel, Shoda, & Rodriguez, 1989). Attentional deployment may also include physical withdrawal of attention (such as covering the eyes or ears), internal redirection of attention (such as through distraction), and responding to others' redirection of one's attention (such as when a parent redirects a hungry child by having her listen to an interesting story). One of the best-researched forms of attentional deployment is distraction.

Distraction involves a shift in attention either away from emotional aspects of the situation, or away from the situation altogether, such as when an infant shifts its gaze during an overly intense emotional interaction (Stifter & Moyer, 1991). Distraction also may involve a change in internal focus, such as when an individual invokes thoughts or memories that are inconsistent with the undesirable emotional state. Distraction has often been studied in the context of pain, where it leads to increased activation of brain regions associated with cognitive control, such as lateral prefrontal cortical regions, and diminished activation of brain regions associated with pain generation, such as the insula (Ochsner & Gross, 2005).

Another attentional deployment strategy is rumination. Rumination involves directing attention inward, focusing on negative aspects of the self in an abstract, passive, and repetitive way (Nolen-Hoeksema, Wisco, & Lyubomirsky, 2008; Watkins, 2008). Rumination could be viewed as asking big "Why?" questions (e.g., "Why am I sad?" "Why do these bad things happen to me?") about the causes of negative events, without a translation into a concrete way to deal with things.

Valuation-Focused Strategies

Reappraisal is an important and extensively researched valuation-based strategy (Gross, 2002). It involves changing the situation's meaning in such a way that there is a change in the person's emotional response to that situation. For example, the golfer from the opening paragraph reappraised the nervous energy he was feeling to make his putt. Similarly, a reappraisal of the plane's drop in altitude may be interpreted as a preventative safety measure taken by the pilot.

To date, studies of reappraisal have focused on quantitative changes in emotion, particularly decreases in negative emotion. These studies have provided evidence that reappraisal leads to decreased negative emotion experience and expressive behavior (Dandoy & Goldstein, 1990; Gross, 1998). Reappraisal also has been shown to lead to decreased startle responses (Dillon & LaBar, 2005), decreased neuroendocrine responses (Abelson, Liberzon, Young, & Khan, 2005), and decreased autonomic responses (Stemmler, 1997). Importantly, comparable effects have been observed when research participants spontaneously use reappraisal, either in a negative emotion-eliciting situation in the lab (Egloff, Schmukle, Burns, & Schwerdtfeger, 2006), or in everyday life (Gross & John, 2003). These findings suggest that studies that manipulate emotion regulation have ecological validity, and provide insights into reappraisal as it naturally occurs in everyday life. Consistent with these behavioral and physiological findings, reappraisal in the service of emotion down-regulation is associated with decreased activation in subcortical emotion-generative regions such as the insula and amygdala (McRae et al., 2010).

Action-Focused Strategies

Response modulation is an action-focused strategy that refers to targeting manifestations of emotion (e.g., playing it cool by not showing fear of the plane's turbulence). Human research primarily has focused on one exemplar of this strategy—expressive suppression—which involves hiding behavioral manifestations of emotion (Gross, 1998). Examples of suppression abound, including our efforts to hide the anger we feel toward a boss, the anxiety we feel during an interview, or the amusement we feel at a coworker's decidedly non-politically-correct joke. Behaviorally, expressive suppression effectively reduces facial expressions of emotion, but the effort and attention required to do so triggers autonomic responses, impairs memory for visual cues, and can negatively impact social interactions (Gross, 1998; Richards & Gross, 2000).

These effects were measurably consequential: for example, the degree of memory impairment associated with suppression was as large as when we instructed participants to distract themselves as much as possible during the presentation of information (Richards & Gross, 2000). Similarly, suppression has been associated with important social costs. Partners of suppressors report less comfort and ease with their interaction partner (Butler et al., 2003). Importantly, the costs that have been associated with instructed suppression in the laboratory also seem to be evident when suppression is used spontaneously in the laboratory (Egloff et al., 2006), during an important life transition (e.g., the transition to college; Srivastava, Tamir, McGonigal, John, & Gross, 2009), and in everyday life (Gross & John, 2003).

The contrast between the outcomes associated with suppression and reappraisal has been extensively studied. The contrast is an interesting one because although both suppression and reappraisal are commonly employed to down-regulate emotion, suppression occurs in the action phase of the W-PVA module in which a person decreases emotion-expressive behavior while emotionally aroused, whereas reappraisal occurs in the earlier valuation phase in which a person tries to think about a situation in a way that alters the emotional response. Since suppression allows the underlying expression to fully develop, whereas reappraisal changes the valuation of the underlying emotion, we would expect the two strategies to have a range of differing outcomes.

Gross (2014b) notes that experimental studies—which allow one to make causal inferences—have shown different affective and cognitive effects of suppression relative to reappraisal. Affectively, suppression leads to decreased positive but not negative emotion experience (Gross, 1998; Gross & Levenson 1993, 1997; Stepper & Strack, 1993), increased sympathetic nervous system responses (Demaree et al., 2006; Gross, 1998; Gross & Levenson, 1993, 1997), and greater activation in emotion-generative brain regions such as the amygdala (Goldin et al., 2008). By contrast, reappraisal leads to decreased levels of negative emotion experience and increased positive emotion experience (Gross, 1998; Lieberman, Inagaki, Tabibnia, & Crockett, 2011; Wolgast, Lundh, & Viborg, 2011); has no impact on, or even decreases, sympathetic nervous system responses (Gross, 1998; Kim & Hammen, 2012); and leads to lesser activation in emotion-generative brain regions such as the amygdala (Goldin et al., 2008; Ochsner & Gross, 2008). Cognitively, suppression leads to worse memory for material presented during the regulation period (Johns, Inzlicht, & Schmader, 2008; Richards, Butler, & Gross, 2003). By contrast, reappraisal either has no impact on subsequent memory, or actually improves it (Richards & Gross, 2000; Hayes et al., 2011), and can be used to enhance performance on standardized exams (Jamieson, Mendes, Blackstock, & Schmader, 2010).

Using the W-PVA Framework to Analyze Emotion Regulation Decisions

At its core, the W-PVA framework focuses on valuation. Many decision-making frameworks also have a primary focus on how options are valued and selected. Not surprisingly, the W-PVA framework parallels several well-regarded frameworks in decision making. For example, Rangel et al. (2008) present a framework according to which (among other decision steps) viable selection options must be identified (representation phase), their value must be computed (valuation phase), and an appropriate action must be selected (action selection phase). March (1994) presents another decision-making framework with strong parallels to the W-PVA framework.

The presence of such decision-making frameworks suggests that it may be possible to use the W-PVA framework to analyze decisions and outcomes related to emotion regulation. There are two important decisions that we focus on in this section: (1) whether or not an emotional episode should be regulated (ER launch decision); and (2) if regulation is chosen, which regulation strategy should be selected for which types of emotion contexts (ER choice decision).

ER Launch Decision: To Regulate or Not to Regulate?

Let us revisit the golf vignette. Imagine that, as before, a golfer had launched a W-PVA sequence in which he negatively valued the consequences of missing the all-important final putt. The output of this W-PVA sequence is anxiety. He could now either launch another—higher-level—W-PVA sequence that takes the underlying emotion (anxiety) as an input, or he could stay with his default current state and leave the anxiety episode to unfold without intervening.

There are at least two ways to think about the golfer's decision. On one view, the golfer may decide based on benefits and costs of either action—regulating or doing nothing. Per this account, it stands to reason that the golfer will regulate his emotions if he derives a clear hedonic benefit from doing so (i.e., decreasing his anxiety that may interfere with his shot) and if the costs of regulation are low. This may often be how individuals approach emotion regulation decisions. On a second view, the golfer may decide to stick with the default (i.e., doing nothing) even if the benefits he derives outweigh the costs of regulation. Per this account, the golfer's default option is influential precisely because it is the default. A recent series of studies have shown that defaults can play an unexpectedly large role in shaping choices concerning emotion regulation initiation (Suri, Whittaker, & Gross, 2014).

Decision theorists have documented several decision contexts in which the default option is disproportionately chosen by decision makers (Dinner, Johnson, Goldstein, & Liu, 2010). A default option is defined as the option that is chosen if the decision maker does not act. Default preferences are seen as a bias because merely designating an option as the default increases the frequency of its selection even though its attractiveness remains unchanged. Such preferences have been observed in many decision domains including organ donation (Johnson & Goldstein, 2003) and patient compliance (Suri, Sheppes, Schwarz, & Gross, 2013). In the present case, the golfer may persist with the default because he did not launch the second-level W-PVA sequence that would have valued his anxiety.

To empirically determine what emotion regulators do in practice, researchers created a decision context in which participants were asked to watch negatively valenced affective images in a series of trials (Suri et al., 2014). On each viewing, they had the option of electing to reappraise in order to decrease negative affect and thus derive hedonic benefits. The cost of choosing to reappraise was a simple button press requiring negligible effort. The task was designed to ensure that participants had no instrumental motives to maintain negative emotion.

When doing nothing was the default option participants chose to regulate in only 16% of trials. However, when participants were required to explicitly choose between watching the image and regulating it (i.e., there was no default option present; participants were required to select one option or the other, each with a button press), their rate of regulation increased to nearly 50%.

When they did regulate, participants did derive hedonic benefits (measured by self-reported affect ratings). Thus it was the influence of the default, and not the absence of benefits from regulation, that (at least in part) drove participant behavior. The above results are consistent with the account that participants often did not launch the second-level W-PVA when doing nothing was the default. Had they launched a second-level W-PVA, they would have either regulated more frequently, or regulated trials would have indicated no benefits. In the context of everyday situations calling for explicit regulation, the default state—by definition—is to do nothing and experience the emotion. The above results suggest that many such everyday situations may go unregulated even though proactive regulation may have offered hedonic benefits.

Research on emotion regulation and psychopathology has suggested that compared with healthy controls, people who suffer from psychological disorders tend to regulate their emotions inadequately (e.g., Kring & Sloan, 2010). The above results suggest that the absence of emotion regulation may sometimes be driven by contextual variables—such as the presence of defaults. If an individual routinely lets emotions remain unregulated, he or she is less likely to overcome the default (of doing nothing), even in cases in which emotion regulation is proactively required. It is possible that there are intrinsic or environmental factors that create more inflexible default behavior in clinical populations.

ER Choice Decision: Which Regulation Strategy Should I Select?

Once again let us revisit the golf vignette. Now imagine that the golfer has decided that he needs to regulate his anxiety before attempting the final putt. What regulatory strategy, or combination of strategies, will he choose? Recent studies

(Sheppes, Schiebe, Suri, & Gross, 2011) have attempted to analyze this decision by limiting their analysis to two examined individuals' choice between two commonly used emotion regulation strategies: distraction and reappraisal.

For example, our golfer could attempt to distract himself by focusing on his breathing; alternatively, he could reappraise the meaning of his nervous energy by thinking of it as a source of focus rather than something that will detract from his shot. Part of his choice may hinge on context-specific factors, such as the type and intensity of his anxiety.

Sheppes and Gross (2011) hypothesized that in low-intensity negative situations, people would show a relative preference to choose to regulate emotions by reappraisal, which allows for emotional processing. However, in high-intensity negative situations, people would show a relative preference to choose to regulate emotions by distraction, which blocks emotional processing at an early stage before it gathers force. Thus, if our golfer was experiencing a low level of anxiety, he would be more likely to reappraise; otherwise he would be more likely to distract.

This hypothesis is consistent with the W-PVA framework. Distraction is a regulatory strategy operating in the perception phase, whereas reappraisal is a regulation strategy operating in the valuation phase. Thus, distraction acts as an "early filter" since it is used to block emotional information before it is represented in working memory for the valuation phase. On the other hand, reappraisal acts as a "late filter." It may be better to perceive and act on high-intensity stimuli before they gather force; lower-intensity stimuli may be better regulated by fuller engagement in the valuation phase.

The intensity hypothesis was empirically tested in decision contexts involving viewing images and receiving shocks. When the image or shock was of high intensity, participants, when asked to pick between reappraisal and distraction, frequently distracted. Conversely, when the image or shock was of low intensity, participants frequently reappraised (Sheppes et al., 2011).

These results as well as other theoretical accounts have emphasized the importance of flexible choice among emotion regulation strategies in the face of different situational demands (Kashdan & Rottenberg, 2010). A lack of flexibility in choosing emotional regulation strategies that are appropriate given contextual demands may result in psychopathology. For example, depression is thought to involve ruminative engagement with high-intensity negative emotional information, whereas anxiety is thought to involve an inflexible disengagement from low-intensity negative emotional information (Sheppes et al., 2011).

Although emotional intensity appears to be a key determinant of emotion regulation choice, other (noncontextual) factors may also play a role. For example, some people have incremental beliefs about emotion, and see emotions as things that can be changed. Others have entity beliefs about emotion, and see emotions as relatively immutable (Gross, 2014a). Those with incremental beliefs seem to utilize emotion regulation more effectively relative to those with entity beliefs. For example, in one study, college students who had incremental beliefs about emotion made greater use of reappraisal, and had a more positive adjustment to college than those with entity beliefs (Tamir, John, Srivastava, & Gross, 2007).

Other determinants of emotion regulation choice likely include person-specific factors such as the availability of cognitive resources, as well as situation-based factors such as situational nudges that may make some forms of emotion regulation easier to implement than others. We believe that the W-PVA framework could be useful is analyzing both types of factors.

Emerging Directions in the Study of Emotion Regulation

This is a time of unmatched excitement for the field of emotion regulation (Gross, 2014b). There has never before been such a focused scientific effort to examine emotion regulation processes, nor has there been such a variety of perspectives brought to bear.

In the following sections, we consider three promising new directions for research in emotion regulation, each of which seems likely to broaden and extend the way we think about emotion regulation, and each of which are informed by the valuation perspective we have adopted in this chapter. The first considers a valuation perspective on other forms of self regulation (not including emotion regulation), the second considers the neural bases of valuation, and the third considers how what we know about emotion regulation can be used to design effective interventions. While by no means exhaustive, these three selections exemplify the promise of emotion regulation research.

Links to Other Forms of Self-Regulation

Emotion is only one type of impulse that must be regulated. People often must also regulate their affect, moods, appetitive impulses, and learned responses. It certainly appears that a valuation framework can be applied in each of these cases. However, are the underlying W-PVA components in these domains similar to those in emotion regulation, or are there crucial differences?

Accounts from the ego control (Block & Block, 1980) and impulsivity (Newman et al., 1993) literatures suggest that there are crucial similarities across domains. Indeed, in the domains of affect and mood, it is possible that superordinate models of affect regulation may be substantially similar to models of emotion regulation.

However, it is less clear how processes that regulate emotional impulses should be distinguished from those that regulate impulses associated with hunger, thirst, aggression, and sexual arousal (Buck, 1985; Loewenstein, 1996). Presumably, the valuation components postulated in emotion are absent, or present in a simplified form, in the context of these appetitive impulses. The similarities and differences across these domains are certain to attract continued interest as researchers from a variety of domains (e.g., weight loss, substance abuse, aggression, emotion regulation) investigate links across different forms of self-regulation. One important way to understand these links is investigate the neural bases of valuation. We next turn to this topic.

Neural Bases of Valuation

Ochsner and Gross (2014) have outlined the brain systems that drive the multiple valuation systems in the context of emotion and emotion regulation discussed in this chapter. Their account leverages recent neuroscience research that has made great strides in describing the neural systems that give rise to emotional responses and those that permit their regulation. It is becoming evident that the neural systems implicated across various literatures—including those concerned with emotion and emotion regulation—are strikingly similar. While some progress has been made in identifying these systems, it is likely to be an area of growing focus. Future work should clarify the number and kind of valuation systems, as well as the rules that govern their engagement in particular contexts. A related direction concerns the inputs and outputs of valuation systems.

In this chapter, we have suggested a class of W-PVA sequences whose inputs are other W-PVA sequences, and whose outputs include the engagement of regulatory processes. However, the range of relevant inputs and outputs and the dynamics of input–output relationships require further study. In particular, it is yet to be understood the factors that contribute to the (nondefault) launching of a second-level W-PVA sequence.

A related direction concerns the efficacy of various forms of value regulation, and how they are intermixed in everyday life. Which "pure" or "hybrid" forms of value regulation are most effective? Other than intensity, what are the contextual variables that shape the effectiveness of particular regulation strategies? Another direction for future research concerns the translation of what we learn to illuminate individual differences. There are many potential sources of individual differences that are suggested by the W-PVA framework. These include (1) the level of initial valuations, (2) the speed with which these valuations are made, (3) the efficiency of conflict resolution among different valuation systems, (4) the process with which learning processes update these valuations, and (5) the capacity and ability to deploy top-down control systems to implement these strategies. One important direction for future research is examining how each of these differences—and others—may interact to produce various forms of psychopathology.

As we deepen our understanding of the neural underpinnings of regulatory processes, we become better positioned to design effective interventions that are driven by emotion regulation.

Emotion Regulation Interventions

Research on regulation, while rapidly growing, must still tackle a number of important questions regarding the psychological processes that are necessary for skillful and flexible emotion regulation. However, what is already known does give us some important starting points for helpful interventions. We consider interventions at the individual, couple, and group levels.

One type of application is individual-level interventions designed to teach healthier patterns of emotion regulation (Gross & Munoz, 1995). Such interventions may focus on both the "why" (creating awareness of the importance of skillful emotion regulation) and the "how" (providing practical skill sets to increase emotion regulation efficacy) of emotion regulation. They may take the form of widely distributable instruction materials or they may include more focused inperson workshops and/or classes designed to improve well-being in the classroom or the workplace.

More specific interventions could target individuals who have clinical diagnoses. For example, recent research suggests that how we view stress (as an enabler or a inhibitor) is a distinct and meaningful variable in determining the stress response (Crum, Salovey, & Achor, 2013). This suggests that future interventions designed to alter stress-related mind-sets may prove fruitful. Similarly, attention bias modification interventions that are designed to directly modify attention and interpretation biases via repeated practice on cognitive tasks are showing promise in the treatment of anxiety and mood disorders (Beard, 2011).

Another type of intervention is applicable to couples and/or to small groups of individuals. Many marriages and romantic relationships are important contributors to well-being. Researchers used a reappraisal-based intervention to attempt to arrest the normative decline in marital quality over time (Finkel, Slotter, Luchies, Walton, & Gross, 2012). The effectiveness of a brief (21-minute) intervention was mediated through reductions in conflict-related distress over time. This study suggests that theory-based, social-psychological interventions may preserve the quality of intimate relationships over time.

A third type of application involves making larger changes in the physical and social worlds in which we live. An example of this class of interventions comes from applying an emotion regulation perspective to seemingly intractable global conflicts (Halperin & Gross, 2011). These conflicts are characterized by high levels of negative emotions that powerfully shape attitudes and behaviors of each of the parties to the conflict. In particular, negative group-based emotions—emotions that arise as a result of belonging to a certain group—can lead to the commencement and maintenance of hostilities, and then block progress toward a peaceful solution to the ongoing conflict. Our prior W-PVA analysis has focused on the individual as the value-computing unit. However, it is possible that W-PVA analysis may focus on the group as the unit of analysis. Taking this approach may help yield valuable insights into how group-based emotions arise, and how they might be regulated.

Group-based emotion and emotion regulation certainly seem to be important factors in contemporary conflicts. For example, in the ongoing Israeli–Palestinian conflict, a nationwide survey of Jewish Israeli adults was conducted during one of the wars between Israelis and Palestinians. This survey assessed both reappraisal use and attitudes toward providing humanitarian aid to Palestinian citizens. Findings indicated that Israelis who regulated their negative emotions during the war by using reappraisal were more supportive of providing humanitarian aid than Israelis who did not use reappraisal (Halperin & Gross, 2011). Overall, these findings suggest that interventions based on an emotion regulation perspective can be helpful to individuals, couples, and groups.

Summary

Emotions have been said to represent the "wisdom of the ages" (Lazarus, 1991, p. 820), and many theoretical approaches to emotion have rightly emphasized its many adaptive benefits. But emotions are not always helpful, and in the last two decades, there has been a dramatic increase in the attention that's been given to how emotions can be regulated so as to help people benefit from what is useful about them, but avoid what is not useful.

In this chapter, we have conceived of emotion as a type of W-PVA sequence, in which a particular state of the world constitutes a perceptual input that is valued (negatively or positively), leading to an impulse to alter ongoing behavioral or cognitive responses. We have conceived emotion regulation another W-PVA sequence that takes the emotion-generation W-PVA as its "W" and "P," valuing it (negatively or positively), and targeting that first W-PVA for change via its "A." This W-PVA conception allowed us to classify the five families of emotion regulation strategies as being either concerned with modifying the state of the world (situation selection and situation modification), the perception of the emerging emotion (attentional deployment), changing its valuation (cognitive reappraisal), or altering action (response modulation). Additionally we were able to analyze decisions related to emotion regulation (i.e., whether to regulate or not and which regulation strategy to select) using the perception, valuation, and action components. Finally, the W-PVA framework was a useful tool in analyzing emerging directions in the growing field of emotion regulation.

CHAPTER 27

Expression of Emotion

Dacher Keltner, Jessica Tracy, Disa A. Sauter,
Daniel C. Cordaro, and Galen McNeil

The study of emotional expression has long been the provenance of scientific discovery and heated controversy. It has spurred advances in studies of emotion-related physiology (Matsumoto, Keltner, Shiota, O'Sullivan, & Frank, 2008), mammalian social behavior (Snowdon, 2003), cultural variation in emotion (Matsumoto, Olide, Schug, Willingham, & Callan, 2009), and evolutionary treatments of emotion (Shariff & Tracy, 2011). Alongside these discoveries are controversies that have propelled the science of expression forward. Questions persist about what kind of information expressions signal—feeling states, intentions, or both (Fridlund, 1991); the inferences to be drawn from emotion recognition data (Barrett, 2011; Russell, 1994); and the extent to which subjective feeling necessarily accompanies expressive behavior (Mauss, Levenson, McCarter, Wilhelm, & Gross, 2005). More recently, attention has turned to how contextual factors shape the interpretation of emotional expression (Barrett, Lindquist, & Gendron, 2007; Barrett, Mesquita, & Gendron, 2011).

In the last edition of this volume, this review centered on what has been learned about expression from a basic emotions perspective (Matsumoto et al., 2008). That review summarized discoveries related to the display of emotional behavior in other species; the covariations among expressive behavior, subjective experience, and physiology for a limited set of emotions; and the universality and cultural variations in labeling expressive behavior. Advances continue in those areas of inquiry, but in many ways the past 10 years has seen the study of expression broaden in consequential ways.

In the present review, we bring into focus these new directions in the study of emotional expression, concentrating on four emergent themes. A first is that signalling behavior is associated with a broader array of emotions than initially considered in early studies of emotional expression (e.g., Ekman, 1992). A second is the interest in new modalities of expression: studies of facial muscle movement and emotional speech prosody are increasingly complemented by an attention to vocal bursts, bodily movement, tactile contact, autonomic responses, and artistic forms of expression, including dance, music, and drawing. Our third focus is on how expressions of emotion shape social interactions. This idea traces back to ethologists' observations of how emotional expressions structure ritualized social interactions in remote peoples in the naturalistic contexts of their daily living, and is being actively pursued in laboratory research. And finally, we explore new advances in studies of the inferences that people draw in judging emotional displays. New theoretical developments have sought to capture how the perception of expressive behavior is shaped by contextual, cultural, and individual difference factors, a theme we bring into focus in the last section of this review (Barrett et al., 2011).

New Expressions of Emotion: A Widening Landscape of Emotional Expression

In 1872, Charles Darwin published *The Expression of the Emotions in Man and Animals*, which influenced profoundly the scientific search for the characteristic patterns of behavior that signal different emotions, their universality, and their origins in display behaviors of mammalian species (Ekman, 1998; Barrett, 2011; Shariff & Tracy, 2011). In Table 27.1, we represent the specific behaviors Darwin observed to be associated with positive emotional states (see Keltner, 2009).

One sees that Darwin (1872/1998) concerned himself with a wide array of states; in fact, over 40 in all (those in Table 27.1 are just the positive ones he referred to in his analysis). These states may cluster in emotion families, and represent variations or subtypes of one emotion (e.g., Ekman, 1992; Sauter, Gangi, McDonald, & Messinger, 2014). But clearly, Darwin cast his net much more

TABLE 27.1. Darwin's Descriptions of Expressive Behaviors Associated with Positive States

Admiration	Eyes opened, eyebrows raised, eyes bright, smile
Affirmation	Nod head, open eyes widely
Astonishment	Eyes open, mouth open, eyebrows raised, hands placed over mouth
Contemplation	Frown; wrinkle skin under lower eyelids; eyes divergent; head droops; hands to forehead, mouth, or chin; thumb/index finger to lip
Determination	Firmly closed mouth, arms folded across breast, shoulders raised
Devotion (reverence)	Face upward, eyelids upturned, fainting, pupils upward and inward, humbling kneeling posture, hands upturned
Happiness	Eyes sparkle, skin under eyes wrinkled, mouth drawn back at corners
High spirits, cheerfulness	Smile, body erect, head upright, eyes open, eyebrows raised, eyelids raised, nostrils raised, eating gestures (rubbing belly), air suck, lip smacks
Joy	Muscle tremble, purposeless movements, laughter, clapping hands, jumping, dancing about, stamping, chuckle/giggle, smile, muscle around eyes contracted, upper lip raised
Laughter	Tears, deep inspiration, contraction of chest, shaking of body, head nods to and fro, lower jaw quivers up/down, lip corners drawn backward, head thrown backward, shakes, head/face red, muscle around eyes contracted, lip press/bite
Love	Beaming eyes, smiling cheeks (when seeing old friend), touch, gentle smile, protruding lips (in chimps), kissing, nose rubs
Maternal love	Touch, gentle smile, tender eyes
Pride	Head, body erect, look down on others
Romantic love	Breathing hurried, faces flush
Surprise	Eyebrows raised, mouth open, eyes open, lips protruded, expiration, blowing/hissing, open hands high above head, palms toward person with straightened fingers, arms backward
Tender (sympathy)	Tears

broadly than the six or seven states that were of intensive focus in the early literature on facial expression.

In the past 10 years, scientific progress has been made in charting expressive behaviors of a wider array of emotions. Some studies have documented the expressive behaviors that covary with the experience of a specific emotion (see Matsumoto et al., 2008, for a review). Other studies have examined the patterns of behavior individuals emit when given different emotion concepts (e.g., "awe" or "love") and asked to express the emotion using their face, voice, or body. And emotion recognition studies have ascertained whether naïve observers can reliably identify emotions from patterns of expressive behavior.

From evidence generated by these methods, a case can be made for several "new" displays beyond the six traditionally studied. Here we profile a few more specific studies (see Table 27.2, for a synthesis of the literature). To establish whether self-conscious emotions would elicit unique nonverbal displays, Keltner (1995) coded muscle-by-muscle actions of participants who became embarrassed after making a silly face on camera. Careful frame-by-frame analysis uncovered a fleeting but highly

TABLE 27.2. Evidence Related to the Expression of Emotion in Different Modalities

Emotion	Face	Voice	Touch	Music	Dance
Amused	Yes[a,b,d,i]	Yes[y,z,bb]	n/a	n/a	Yes[gg]
Anger	Yes[d,w,x]	Yes[y,aa,bb]	Yes[dd,ee]	Yes[ff]	Yes[gg]
Awe	Yes[a,c,d]	Yes[y]	No	n/a	Yes[gg]
Boredom	Yes[n]	Yes[aa]	n/a	n/a	n/a
Confused	Yes[n,u]	n/a	n/a	n/a	n/a
Contempt	Yes[v,w]	Yes[y,aa]	n/a	n/a	n/a
Content	Yes[d]	Yes[z]	n/a	n/a	Yes[gg]
Coy	Yes[e,f,g]	n/a	n/a	n/a	n/a
Desire	Yes[h,i]	No[y]	n/a	n/a	n/a
Disgust	Yes[d,w,x]	Yes[y,aa,bb]	Yes[dd,ee]	n/a	Yes[gg]
Embarrassed	Yes[d,i,j,k,l]	Yes[y]	No[ee]	n/a	Yes[gg]
Fear	Yes[d,w,x]	Yes[y,aa,bb]	Yes[dd,ee]	Yes[ff]	Yes[gg]
Gratitude	n/a	No[y]	Yes[dd,ee]	n/a	n/a
Happiness	Yes[i,w,x]	Yes[aa]	Yes[dd]	Yes[ff]	n/a
Interested	Yes[i,m,n]	Yes[y]	n/a	n/a	n/a
Love	Yes[d,i]	No[y]	Yes[dd,ee]	Yes[ff]	Yes[gg]
Pain	Yes[o,p,q,r]	Yes[cc]	n/a	n/a	n/a
Pride	Yes[a,i]	No[y]	No[ee]	n/a	n/a
Relief	n/a	Yes[y,z,aa,bb]	n/a	n/a	n/a
Sadness	Yes[d,w,x]	Yes[y,bb]	Yes[dd,ee]	Yes[ff]	Yes[gg]
Shame	Yes[d,i,t]	No[y]	n/a	n/a	Yes[gg]
Surprise	Yes[w,x]	Yes[y,bb,ee]	No[ee]	n/a	n/a
Sympathy	Yes[i]	Yes[y]	Yes[dd,ee]	n/a	n/a
Triumph	n/a	Yes[y]	n/a	n/a	n/a

coordinated 2- to 3-second display, which involved gaze aversion, controlled smiles, and partial face covering with one hand (Edelmann & Hampson 1979; Harris, 2001).

Other experiments sought to analyze self-conscious displays that accompany gaining or losing status (Tracy & Robins, 2004, 2007; Tracy & Matsumoto, 2008). Tracy and Robins (2004, 2007) documented expansive postures coincident with the emotion of pride, as well as head movements up and back, and expansive arm thrusts upward, or outward in an akimbo position with hands on hips. This expansive display, reliably recognized as pride by children and adults (Tracy, Robins, & Lagattuta, 2005), is the direct opposite of the shame display, which involves head tilt downward, eye gaze downward, and posture turned inward (Keltner, 1995; Haidt & Keltner, 1999; Izard, 1971; Tracy & Matsumoto, 2008). Images of both pride and shame displays were reliably recognized in both industrialized cultures and remote small-scale societies in Burkina Faso and Fiji (Tracy & Robins, 2008; Tracy, Shariff, Zhao, & Henrich, 2013). These expressions of pride and shame are also reliably displayed in response to success and failure, respectively, by children and adults (Lewis, Alessandri, & Sullivan, 1992).

Conceptual analyses of attachment processes emphasize distinctions among love, desire, and compassion or sympathy that enable specific attachments to reproductive partners and offspring (Bowlby, 1969). Guided by these claims, studies have found that when feeling romantic love, individuals show coordinated sequences of genuine smiling, mutual gaze, affiliative hand gestures, open posture, and leaning forward (Gonzaga, Keltner, Londahl, & Smith, 2001), a pattern of behavior found to covary with oxytocin release (Gonzaga, Turner, Keltner, Campos, & Altemus, 2006), and to occur when people are given the term "love" and asked to express or embody it in nonverbal behavior (e.g., Campos, Shiota, Keltner, Gonzaga, & Geotz, 2013). By contrast, individuals' reports of desire correlate with a different pattern of behavior that includes lip licks, bites, and puckering. Reactions to the suffering of others and experiences of sympathy are correlated with oblique eyebrows, concerned gaze, and approach behaviors such as forward leans (Eisenberg et al., 1989; Goetz, Keltner, & Simon-Thomas, 2010).

Still other studies have identified facial displays of awe (Campos et al., 2013), coyness (Reddy, 2000), pain (Prkachin, 1992; Grunau & Craig, 1987; Botvinick et al., 2005), and amusement (Ruch & Ekman, 2001). Different smiles accompany different positive states (Sauter et al., 2014). For example, in one recent study participants were given descriptions of eight different positive emotions—amusement, awe, interest, joy, love, pride, gratitude, and contentment—and asked to express these emotions nonverbally (Campos et al., 2013). Coding of these patterns of behaviors with Ekman and Friesen's (1978) Facial Action Coding System (FACS) found distinctions in the displays of all these emotions except gratitude, and several of the expressive behaviors observed in this paradigm replicated those observed in other investigations (see also Mortillaro, Mehu, & Scherer, 2011; Sauter, 2010).

Building upon studies of emotional prosody (Nelson & Russell, 2011a; Banse & Scherer, 1996), a similar broadening of the range of states shown to have signals has emerged in the study of emotion-related vocalization (Sauter & Scott, 2007; Sauter, Eisner, Calder & Scott 2010; Simon-Thomas, Keltner, Sauter, Sinicropi-Yao, & Abramson, 2009). In one illustrative study, participants read descriptions of 22 different emotions, and then produced "vocal bursts"—sighs, growls, grunts, and laughs—to convey each emotion (Simon-Thomas et al., 2009). Naïve observers could reliably identify several understudied emotional states, including awe, interest, relief, sensory pleasure, enthusiasm, sympathy, triumph, and contempt, from these vocal bursts. Other studies have documented similarly high rates of identification of emotion vocal bursts conveying triumph, amusement, contentment, sensory pleasure, and relief (Sauter & Scott, 2007).

Sauter, Eisner, Ekman, and Scott (2010) performed a two-way cross-cultural vocalization experiment with U.K. participants and members of the Himba, a culturally isolated group in Namibia. The vocal bursts collected from both cultures were decoded bidirectionally with above-chance accuracy ratings for anger, disgust, fear, sadness, and surprise. In addition, vocalizations of amusement were recognized across cultures, and relief expressions were similar, although not bidirectionally recognized. These findings have recently been replicated and extended by Laukka and colleagues (2013), who recorded emotional vocalizations of 18 emotions from actors in India, Kenya, Singapore, and the United States. Swedish participants performed well in identifying emotions that had been well recognized in Sauter, Eisner, Ekman, et al.'s (2010) study, and also could identify interest, lust, relief, and serenity from brief vocal bursts (but see Gendron, Roberson, van der Vyver, & Barrett, 2014; Gendron, Roberson, & Barrett, 2015).

Synthesizing these new studies, in Table 27.2 we present the states that can be signaled with reliable patterns of behavior, at least in one modality. It is clear the field is moving beyond the original six or seven emotions so sharply in focus in early studies of expression to a much broader landscape of emotion, one that likely includes over 10 signals each of positive and negative emotion.

Beyond the Face and Voice: Toward a Science of Multiple Modalities of Emotional Expression

Emotional expression is a multimodal phenomenon. Darwin (1872/1998) himself referred to facial muscle movements and vocalizations, but also autonomic responses (the blush, pupil activity), movements of the arms and hands (clapping), shifts in posture, head movements, gestures, respiration, and full-body actions like jumping and dancing about. Darwin's emphasis on dynamic behavior is also of note. With a few notable exceptions (see Krumhuber, Kappas, & Manstead, 2013; Nelson & Russell, 2011a, 2011b, for a review) though, the literature on facial expression has focused on static photos. Yet a great deal of information is likely contained in dynamic movement.

For the most part, however, the empirical literature on expression has removed the body from systematic inquiry (but see Atkinson, Dittrich, Gemmell, & Young, 2004; Kret, Pichon, Grèzes, & De Gelder, 2011, for exceptions) and focused narrowly on facial muscle movements or vocalizations. Attention to emotions like pride and embarrassment has necessitated the study of head, gaze, and bodily movements (Keltner, 1995; Tracy & Robins, 2004, 2007). There are select studies of other channels of nonverbal behavior, such as how emotions are communicated in patterns of posture (Dael, Mortillaro, & Scherer, 2012; Gross, Crane, & Fredrickson, 2010) and gaze (Graham & LaBar, 2007; Lobmaier, Tiddeman, & Perret, 2008; Sander, Grandjean, Kaiser, Wehrle, & Scherer, 2007). Clearly, Darwin's (1872/1998) more comprehensive analysis suggests that there should be signal value in how emotions are communicated in a vast array of communicative behaviors, from simple movements of the hands to shifts in body posture to head movements. Relatively little is known about these intriguing possibilities.

Several recent studies have begun to capture how people convey emotion in tactile contact (Hertenstein & Weiss, 2011). Studying touch poses methodological challenges. Touch is dyadic, involves multiple regions of the body, and has many dimensions, including pressure, duration, location, and intensity. Touch does not lend itself to portrayals in classes of stimuli that can be used in typical emotion recognition paradigms. Notwithstanding these methodological issues, progress is being made in understanding which emotions have tactile signals.

Hertenstein and colleagues (Hertenstein, Keltner, App, Bulleit, & Jaskolka, 2006; Hertenstein, Holmes, McCullough, & Keltner, 2009) have begun to ascertain which emotions can be conveyed by touch. In a first study, an encoder (the person charged with touching another person to convey emotion) and decoder (the person being touched) sat at a table, separated by an opaque black curtain, which prevented communication other than touch. The encoder was given a list of emotions and asked to make contact with the decoder on the arm to communicate each emotion, using any form of touch. The decoder could not see any part of the touch because his or her arm was positioned on the encoder's side of the curtain. After each touch, the decoder selected from 13 response options the term that best described what the person was communicating. In this study, participants could reliably communicate anger, disgust, and fear with a brief 1- or 2-second touch of another's forearm, as well as love, gratitude, and sympathy (see also Piff, Purcell, Gruber, Hertenstein, & Keltner, 2012, for replication). Emotions like embarrassment, awe, and sadness were not reliably communicated via touch. In other research, people prove to be better able to communicate emotion through touch when allowed to touch other regions of the body than the arm (Hertenstein et al., 2009), and there is cross-cultural similarity in which emotions can be conveyed in tactile contact (see Hertenstein et al., 2009).

There are also emerging literatures on potential autonomic signals of emotion. The blush arises during experiences of embarrassment (Shearn, Bergman, Hill, Abel, & Hinds, 1992) and has clear social signal value. The chills, or goosebumps, refer to the sympathetically mediated contraction of the muscle surrounding the hair follicles, and arise during the appreciation of music and art (e.g., Grewe, Kopiez, & Altenmüller, 2009). In nonhuman species, this action, piloerection, is thought to signal threat behavior toward conspecifics. Recent work by Maruskin and colleagues (Maruskin, Thrash, & Elliot, 2012) has mapped the emotional correlates of two kinds of chills, which they posit have different evolutionary origins in mammalian behavior. One variant of chills, goosebumps, covaries with experiences of awe (see also Campos et al., 2013). Another kind of chills response, shivers, involves more pervasive muscle contractions like those observed during experiences of cold, and covaries with social disgust and fear.

Alongside the blush and the chills, another autonomic response with almost certain signal value is a tearing response. Studies of tears—a chemosignal response—have recently examined the chemical content of tears and their effects, when displayed by women, upon males' sexual response (Gelstein et al., 2011). It will be interesting to determine whether the addition of tears to different facial expressions (e.g., to facial muscle configurations of sadness or laughter or pain) changes the inferences drawn from the expression (e.g., Provine, Krosnowski, & Brocato, 2009).

As scientists have begun to understand more richly how bodily responses express emotion, they also have turned with more focus to the artistic expression of emotion. The voice and music share many emotionally expressive properties (i.e., tempo, loudness, and timbre) that account, in part, for how instruments can resemble the human voice (Gabrielsson & Juslin, 2003; Juslin & Laukka, 2003). In an analysis of the cues that people use to infer emotion from speech prosody and music, Juslin and Laukka (2003) found that people vary their tempo, loudness, and pitch in similar ways to communicate emotion (see also Zentner, Grandjean, & Scherer, 2008). And scientific studies find that listeners can reliably discern distinct emotions from different musical performances. In music–emotion recognition studies, performers sing a brief melody with no words and attempt to communicate anger, fear, happiness, sadness, joy, and on occasion, tenderness or love. The listener is then asked to choose the word from a list of words that best matches the emotion conveyed in the musical performance. Across over a dozen studies of this kind, listeners on average achieved accuracy rates of about 70% (Gabrielsson & Juslin, 2003; Juslin & Laukka, 2003). Recent evidence suggests that at least a few basic emotions may be universal to the perception of music in radically different cultures (Fritz et al., 2009).

What about emotional expression in other art forms? One recent study ascertained whether Western observers could reliably identify the emotion conveyed in traditional Hindu dance (Hejmadi, Davidson, & Rozin, 2000). In the Hindu Indian *Natya Shastra*, from around the second-century B.C.E. (Bharata Muni, 200 B.C.E.), specific writings detail how actors and dancers are to express emotions in movements in the face, body, and with hand gestures. Hejmadi and colleagues presented participants in India and the United States with videotapes of Hejmadi's own renditions of anger, disgust, fear, heroism, humor, love, peace, sadness, embarrassment/shyness/modesty, and wonder (Hejmadi performed as a dancer in India for 20 years). Based on video clips only lasting between 4 and 10 seconds, observers achieved accuracy rates between 61 and 69% in judging the 10 emotions communicated through dance and gesture.

These growing literatures on emotional expression in art bring into focus an important theme: that emotional expression is not limited to how humans signal internal states with the communicative systems shaped by evolution and culture. Emotional expression is part of all forms of art and other creative acts. And emotions are likely to be expressed in other sensory modalities, including through scent (Delplanque et al., 2012), color (Palmer, Schloss, Xu, & Prado-León, 2013), and natural scenes (e.g., Zhang, Piff, Iyer, Koleva, & Keltner, 2014). These new areas of inquiry raise the deeper question of how emotions are expressed in cultural artifacts like painting, sculpture, dance, music, poems, and architectural design—a question we believe is ready for synthetic theorizing.

Table 27.2 represents the current state of knowledge with respect to which emotions can be signaled in the five modalities of expression with substantive literatures: face/body, voice, touch, music, and dance. "Yes" in the columns signify that either in production or perception evidence, the emotion was found to have a distinct display.

The study of emotional expression has broadened in the past 10 years. Signals for at least 24 states have been identified. New modalities and the temporal dynamics of expression are increasingly considered. The promise of new areas of inquiry that are likely to yield new empirical insights is great. For example, there is good evidence for the association between subjective experience and emotion-related behaviors for "basic" emotions like anger, fear, disgust, or happiness (see Lench, Flores, & Bench, 2011, for a meta-analysis). This sort of evidence is needed for more recently investigated emotion displays.

A continued focus on the mammalian parallels of these "new" expressions will yield intriguing insights into the functional origins of these displays (Shariff & Tracy, 2011). As one example, shivering and piloerection are common responses in mammals; their study is germane to understanding the origins of human goosebumps and emotions like awe.

As the study of these new signals progresses, we foresee several important issues on the horizon. A first is to study emotional expression across multiple modalities (e.g., Aviezer, Trope, & Todorov, 2012; Campos, Campos, & Barrett, 1989). That science will likely reveal the relative contribution of different modalities to the experience and signal value of distinct emotional displays (e.g., see App, McIntosh, Reed, & Hertenstein, 2011; Flack, 2006; Scherer & Ellgring, 2007). Table 27.2 hints at the possibility that certain emotions may be robustly signaled across modalities (e.g., anger), whereas others may privilege select modalities of expression (e.g., embarrassment, awe). For example, sympathy, or compassion, is reliably signaled in touch and the voice, but less so, in the face (Goetz et al., 2010). Studies of multimodal expressions will bear upon debates about the degree to which emotions are expressed in patterns of behavior (Barrett, 2011; Russell, 1994). Cross-modal integration of expressive stimuli has a long history of producing additive effects in emotion recognition accuracy (Vroomen, Driver, & de Gelder, 2001; Paulmann & Pell, 2011). The distinct possibility is that as studies examine multimodal expressions of emotion—involving face, voice, body, tactile contact, and gesture—those signals may prove to be more recognizable than static photographs of facial expressions or snippets of vocalizations.

It will be important to explore universals and cultural variations in these expressions (e.g., Russell, 1994; Nelson & Russell, 2013). There is already evidence suggesting that the Japanese privilege the voice in inferring intention and emotion (Tanaka et al., 2010). This raises the question that some cultures may privilege the face in inferring emotion, some the voice, some touch, and some bodily responses—all intriguing possibilities awaiting empirical inquiry.

It will also be important to continue the study of remote peoples. In work attempting to differentiate beyond the basic six emotions, there is a dearth of research on culturally isolated groups. Basing our knowledge on findings from participants from a culturally narrow range of groups limits the inferences that can be drawn from such findings (Henrich, Heine, & Norenzayan, 2010). The influence of cultural input emerges early: Recent work has documented the impact of cross-cultural differences in parenting behaviors on the development of emotional expression beyond the commonly studied emotional states (Wormann, Holodyski, Kartner, & Keller, 2014). The limited available evidence suggests that the role of culture-specific social learning is likely highly variable across emotions (Sauter, Einser, Ekman, et al., 2010).

Critically, it will be important to extend this research further to special samples of individuals with reduced cultural input, such as people who lack vision. In one example of this approach, Tracy and Matsumoto (2008) coded the pride and shame displays of sighted and blind—including congenitally blind—athletes from 37 different countries at the 2004 Olympic Games judo competition. Both sighted and blind winners showed expansive posture, smiles, head up, and arms in the air; sighted and blind losers showed slouched posture, shoulders slumped, and chest caved in. Interestingly, the tendency to display pride in response to success was found in all cultural groups examined. Shame displays, by contrast, were reliably shown in response to failure by individuals from all cultural groups except those that were particularly high in individualism and self-expression values—that is, North American and Western European cultures.

Finally, the work we have reviewed points to several states that do not figure in the classification schemes of theorists influential in the development of the science of emotion (see Keltner & Lerner, 2010, for synthesis). As the list of emotional displays expands, it will be important to consider how some states and their accompanying displays may fall within the same overarching emotion category (see Scarantino, 2012, for a discussion). For example, recent evidence points to distinct displays for fear and anxiety (Perkins, Inchley-Mort, Pickering, Corr, & Burgess, 2012). Other research, however, suggests that two variants of pride—labeled "authentic" and "hubristic"—share the same nonverbal display, and thus must be distinguished from contextual information (Tracy & Robins, 2007; Tracy & Prehn, 2012). However, as research on other modalities continues, perhaps these distinct forms of pride will be linked to distinct vocal, or even musical, displays.

Emotional Expression and the Coordination of Social Interaction

Based on his years of intensive observation of preindustrial people, Irenäus Eibl-Eibesfeldt (1989) posited that emotional expressions are like a grammar of social interaction. Facial expressions, vocalizations, patterns of bodily movement, gaze, gestures, and touch bind people into dyadic and group-based interactions—the soothing of a distressed child, the flirtation between potential suitors, sexual interaction, the play of young siblings, the aggressive encounters of rivals, or status conflicts in groups.

A corollary to this analysis is that emotional expressions trigger systematic inferences and behavioral responses in others. This thinking requires that we shift a level of analysis, and look at individuals' expressions of emotion at the dyadic or even group level (Tiedens & Leach, 2004), as has been done in the study of emotional mimicry (Hess & Fischer, 2013).

Consider the recent theorizing of Paula Niedenthal, Ursula Hess, and their colleagues concerning how different smiles evoke different inferences and responses in others (Niedenthal, Mermillod, Maringer, & Hess, 2010). Within 500 milliseconds, this theorizing posits, a warm smile of enjoyment triggers neural processes that lead the perceiver to seek more information about the smiler through eye contact, which in turn evokes feelings of pleasure, mimetic behavior, and the experience of positive emotion and approach behavior. A proud, dominant smile, by contrast, triggers the same automatic search for information about the smiler, along with neural activation that leads to a sense of threat and avoidant behavior.

Or consider a recent study of touch among members of professional basketball teams (Kraus, Huang, & Keltner, 2010). Drawing upon the new science of emotional touch, these researchers coded all observed touches in an entire game of each team in the National Basketball Association at the start of the 2008 season. Over 25 kinds of celebratory and encouraging touch were coded: high-fives, fist bumps, chest bumps, arm embraces, bear hugs, and the like. On average, each player touched his teammates for about 2 seconds during each game. The more a team's players touched each other at the beginning of the season, the better the team played at the end of the season, according to sophisticated basketball statistics, even when controlling for whether or not the team was winning, their preseason expectations, and how much money they were making.

So how do emotional expressions coordinate social interactions? Three ideas have emerged (Keltner & Kring, 1998; van Kleef, 2009). A first is that emotional expressions rapidly provide important information relevant to perceivers, useful in guiding subsequent behavior. For example, emotional expressions signal more trait-like tendencies of individuals, including the tendency to be dominant (Knutson, 1996), to be of upstanding character (Feinberg, Willer, & Keltner, 2012), and the degree of strength within a negotiation (van Kleef, De Dreu, Pietroni, & Manstead, 2006). Pride displays promote automatic, cross-cultural judgments of high status in the displayer—judgments that are strong enough to counter contextual information indicating that the displayer in fact merits low status (Shariff & Tracy, 2009; Tracy et al., 2013).

Emotional expressions also signal the trustworthiness of the sender. For example, Krumhuber and colleagues (2013) have found that people trust interaction partners more, and will give more resources to those partners who display authentic smiles (which have longer onset and offset times) than fake smiles, which have shorter onset and offset (Krumhuber et al., 2013). Social perceivers infer trustworthy intentions from people who spontaneously display intense embarrassment, and are more likely to cooperate with individuals who express embarrassment than other emotions (Feinberg et al., 2012). Pride displays direct social learning by providing information to others; individuals motivated to attain the correct answer to a difficult trivia question were found to selectively copy the answer provided by others showing pride, suggesting that pride displays communicate expertise or knowledge (Martens & Tracy, 2013).

Emotional expressions convey information about the environment, allowing individuals to coordinate their responses to outside opportunities or threats (e.g., Klinnert, Emde, Butterfield, & Campos, 1986). For example, parents use touch and voice to signal to their young children whether other people and objects in the environment are safe or dangerous (Hertenstein & Campos, 2004), using vocal cues that are consistent across cultures (Bryant & Barrett, 2007).

Emotional displays coordinate social interactions in a second way, by evoking specific responses in social perceivers. Early studies in this tradition found that some emotional expressions trigger complementary emotions in social perceivers: facial displays of anger enhance fear conditioning in observers, even when the facial displays are not consciously perceived (Ohman & Dimberg, 1978); expressions of distress can evoke sympathy in observers (e.g., Eisenberg et al., 1989); and displays of dominance trigger more submissive expressive behavior (Tiedens & Fragale, 2003). More recently, van Dijk and colleagues (van Dijk, de Jong, & Peters, 2009) have documented that social observers respond with more positive emotion to individuals who blushed after they made mistakes than if they showed other display behavior.

Finally, emotional expressions structure social interactions by serving as incentives for others' actions, by rewarding specific patterns of behavior in perceivers. Early studies on this notion focused on how parents use warm smiles and touches to increase the likelihood of certain behaviors in their children (e.g., Tronick, 1989) and the incentive value of laughter, and how it triggers cooperative interactions between friends (Owren & Bachorowski, 2001).

This analysis of the rewarding properties of emotional expression likewise sheds light on some of the direct effects of emotional touch upon recipients of touch. Gentle, pleasing touch triggers activation in the orbitofrontal cortex, a brain region involved in the representation of secondary rewards (Rolls, 2000). Given the rewarding quality of being touched, it has been claimed that touch motivates sharing behavior in others' altruism (De Waal, 1996). This may help explain why a warm touch increases compliance to requests (Willis & Hamm, 1980) and cooperation toward strangers in economic games (Kurzban, 2001).

Clearly, these studies on how expressions coordinate social interactions are in their infancy. Many of these studies have focused on the face; it will be important to extend this line of reasoning to studies of the voice, touch, body movement, gaze, and other modalities. This work has focused on a more limited set of emotional displays: smiles, anger displays, disgust expressions, and fear expressions. It will be important to examine how less-studied expressions of emotion—for example, of interest (in the voice), gratitude (in touch), sympathy (in the voice or touch), or awe (in the voice)—coordinate social interactions.

Studies of the social functions of emotional expressions have set the stage for new theorizing. One recent line of argument has outlined how emotional expressions evolved to serve these informative, evocative, and incentive-signaling functions, perhaps in the "second stage" of their evolution (see Shariff & Tracy, 2011). This account dates back to Darwin (1872/1998), and argues that internal physiological regulation was likely the original adaptive function of emotion expressions, which later evolved to serve communicative functions (e.g., Chapman, Kim, Susskind, & Anderson, 2009; Eibl-Eibsfeldt, 1989; Ekman, 1992; Shariff & Tracy, 2011).

To take the classic example of fear, the facial muscle movements that constitute a fear expression likely originally emerged as part of a functional response to threatening stimuli; widened eyes increase the scope of one's visual field and the speed of eye movements, allowing expressers to better identify (potentially threatening) objects in their periphery (Susskind et al., 2008). In contrast, the "scrunched" nose and mouth of the disgust expression results in constriction of these orifices, thereby reducing air intake (Susskind et al., 2008; Chapman et al., 2009). Given that disgust functions to alert expressers of the potentially noxious nature of the eliciting stimulus, and thereby disincline them from ingesting it (Rozin, Lowery, & Ebert, 1994), the reduced inhalation of airborne chemicals can well be considered part of the same adaptive response. In more recent work, these authors have shown that the opposing eye movements involved in fear and disgust expressions (i.e., widening vs. narrowing) function to increase visual sensitivity (localizing an object) and acuity (determining what the object is), respectively—further supporting the argument that these two expressions initially evolved to serve opposing yet equally important functions for the expresser.

However, these original physiological benefits experienced by the expressers eventually became transformed into communicative signals, which benefit both expressers and observers in terms of the more efficient and coordinated interactions. Over time, the facial and bodily behavioral components of certain emotions came to signal those emotional states to observers, through processes of ritualization, wherein mammalian nonverbal displays become exaggerated, more visible, distinctive and/or prototypic, and ultimately, more recognizable.

Beyond these theoretical implications, this new emphasis on how expressions coordinate social interactions has inspired studies of how the abilities to express and detect emotions predict positive social outcomes. For example, the ability to read emotions effectively predicts positive negotiation outcomes (Elfenbein, Der Foo, White, Tan, & Aik, 2007). The extent to which a person's felt positive emotion is expressed in positive social behaviors predicts better social connections and reduced symptoms of depression (Mauss et al., 2011). These two skills—to express emotions clearly and read others' emotions effectively—are correlated (see Elfenbein & Eisenkraft, 2010, for a meta-analysis) and central to conceptualizations of emotional intelligence, which consistently predicts increased social adjustment (see Brackett et al., 2013; Mayer, Salovey, Caruso, & Sitarenios, 2003, for a review).

Beyond Single-Word Emotion Recognition Paradigms: Context and Inference in Emotion Perception

The first wave of science on emotional expression—in particular, that on the face—involved emotion recognition studies that most typically entailed that participants match an emotion term from a list of options to a specific expression (see Elfenbein & Ambady, 2002). A meta-analysis of 182 independent samples examining judgments of emotion in the face and other nonverbal stimuli yielded an average accuracy rate of 58.0% (a notably large effect size), after correction for chance guessing (Elfenbein & Ambady, 2002). With respect to vocal expressions of emotion, in a review of over 60 studies largely using single-word emotion recognition paradigms, Juslin and Laukka (2003) concluded that listeners can judge five different emotions in the voice—anger, fear, happiness, sadness, and tenderness—with accuracy rates that approach 70% (see also Scherer, Johnstone, & Klasmeyer, 2003). There is continued debate about the meaning of these levels of accuracy, and the degree of universality they imply (Barrett, 2011; Russell, 1994).

Of course, emotion perception involves more than labeling expressive behaviors with single words, and the study of emotion perception has advanced in two new directions. A first is to begin to systematically examine the inferential processes by which individuals interpret expressive behavior. When people encounter expressive behavior in another person, or target, the inferential processes they likely engage in involve more than the ascription of single-word labels; they almost certainly make inferences about the target's desires and intentions, trait-like tendencies, strategic motivations, and surrounding context. This common-sense analysis begs two questions: What other sorts of inferences do people make in interpreting expressive behavior? and How do perceivers arrive at attributions of emotions to targets?

In work on this latter question, Scherer and colleagues propose that perceivers first infer specific appraisals upon observing expressive behavior (Scherer & Grandjean, 2008)—that is, if a person sees another person express anger in the face, or interest in the voice, or sympathy in a pattern of postural movement and tactile contact, the social perceiver first infers a pattern of appraisals that would lead the individual to express emotion as he or she has done. And from these inferred appraisals, the social perceiver would then infer the experience of specific emotions. Seeing someone express anger might lead to initial inferences that the person has been treated in an unpleasant, unfair, intentional, and immoral fashion, which in turn would increase the likelihood of attributing anger to the target. It may be that the first inferences perceivers draw on seeing others' expressive behavior is a pattern of appraisals, rather than distinct emotions, a notion in need of systematic study, and one that could shed light on cultural variations in attributions of emotion to individuals' expressive behavior (Fontaine, Scherer, & Soriano, 2013).

Another area of growth in the study of emotion perception is in the understanding of how the context influences how people perceive emotional expression (Barrett et al., 2011). How do emotional expressions vary in their meaning from one context to another? A pattern of touch will vary in the inferences it evokes depending on whether the people are friends or strangers, at work, or on a date. A laugh can be perceived as an expression of affection or sarcastic critique depending on the context. A blush could be read as a sign of self-conscious inhibition or flirtatious interest, again depending on the context.

In their constructivist account of emotion perception, Barrett and colleagues (2011) offer a theoretical synthesis for how to approach contextual variations in the meaning social perceivers derive in perceiving emotional expressions, highlighting three kinds of context. A first is called stimulus context, which refers to the surrounding stimulus features that accompany the expressive behavior. Most of the work on emotional expression has isolated specific display behaviors in the face or voice, largely for purposes of experimental control. But expressions of emotion in the real world most typically occur in multimodal patterns of behavior: A facial expression, or vocalization, is accompanied by other behaviors (gestures, bodily movements, intentional actions unrelated to emotion, gaze—static features of appearance—physical size, beauty, and even patterns of dress). These behaviors that accompany an expression of emotion are likely to shape the interpretation of the focal expression in interesting ways; something for which the field is turning its attention to.

In one line of work inspired by this analysis, studies are finding that the accuracy in labeling facial expressions of emotion varies according to other physical actions of the individual expressing emotion (see Barrett et al., 2011, for a review). When observers are given more than a decontextualized static facial expression to judge, they tend to take into account the surrounding contextual information in making their judgment. For example, Aviezer and colleagues (2008) presented a classic facial expression of disgust in one of four stimulus contexts, in which the person expressing disgust was engaged in different actions. Participants labeled the expression as disgust 91% of the time when the individual was holding a soiled article of clothing, 59% of the time when the person displayed fearful hand and arm movements, 33% of the time when the same person was clasping his or her hands sadly to the chest, and 11% of the time when the person was poised with fist clenched to punch.

A second kind of context highlighted is perceptual context. Perceptual context refers to the mental states within the perceiver's mind that shape his or her inferences upon observing expressive behavior. A person's current goals, intentions, values, emotions, physical state, and the like give rise to context-specific interpretations of social stimuli, and one would imagine, expressive behavior. Little is known about how a person's goals, current state, or values and ideals shape the perception of expressive behavior, although that is starting to change thanks to Barrett et al.'s (2011) constructivist theorizing. For example, recent studies find that the likelihood that participants will label a disgust expression (nose scrunch) rises when an anger expression precedes the presentation of the disgust expression, but drops when no anger expression precedes the target disgust expression (Pochedly, Widen, & Russell, 2012). The clear implication is that the perceiver's judgments of emotional expressions will be shaped by his or her encounters with stimuli that precede his or her judgments of the expressive behavior.

In another series of studies on perceptual context, Lindquist and colleagues induced participants into a state of what is known as semantic satiation by having them repeat an emotion word (e.g., "sadness") 30 times (Lindquist, Barrett, Bliss-Moreau, & Russell, 2006). This repetitive process makes specific emotion words less accessible, and less likely to be used in interpreting emotionally expressive behavior. Indeed, this semantic satiation slowed participants' identification of anger, disgust, sadness, surprise, and happiness, but did not influence their levels of accuracy.

A third kind of context is culture. In early studies in this tradition, researchers documented cultural differences in the accuracy of emotion perception (e.g., Russell, 1994) and cultural variations in attributed intensity to emotional displays (Biehl et al., 1997). More recently, studies have begun to explore cultural variations in the more complex inferences that perceivers make in perceiving expressions of emotion. For example, when compared with members of East Asian cultures, Americans indicate that the external display of emotion is more intense than the inner experience, consistent with the emphasis in the United States on expressing one's feelings (see also Matsumoto, Olide, & Willingham, 2009).

Still other findings suggest that cultures vary in their attention to the surrounding context of an expression. In one paradigmatic experiment, Masuda and colleagues showed Japanese and American participants cartoon figures with various expressions on their faces (Masuda, Ellsworth, Mesquita, Leu, & van de Veerdonk, 2004). The central, target face was always surrounded by smaller, less salient faces, with expressions that were dissimilar to those of the target. Japanese participants' judgments about the central target's facial expression were more influenced by the surrounding faces than were judgments made by Americans. In a similar vein, Kraus and colleagues (Kraus, Côté, & Keltner, 2010) have found that lower-class individuals—more oriented to the social context than upper-class individuals—also incorporate contextual information into their judgments of expressive behavior.

This new focus on the complex interpretations placed upon emotional expression represents one of the exciting areas for further inquiry. The general promise is to begin to understand the meaning attributed to expressive behavior beyond labels or relatively scripted stories, and to understanding systematically how interpretations of expressive behavior are similar across individuals, cultures, and contexts, and how they vary in their meaning.

Conclusions

Our review has focused on four emergent themes in the study of emotional expression. We have seen impressive advances in the study of new states that had only received scant attention in the past. The field is moving beyond the face and voice, to study other signaling modalities. We are learning how a pattern of emotionally expressive behavior might change from one context to the next. And the field is revealing how emotional expressions shape social interactions of all kinds. Throughout the review, we have highlighted promising lines of future inquiry represented by these four new developments and how they interact.

CHAPTER 28

Emotional Body Perception in the Wild

Beatrice de Gelder

The study of cognition and emotion is a very broad area of research and it is fair to say that it is still expanding. New methods have become available for researchers and in part as a consequence of that, the age-old wall between emotion and cognition is rapidly crumbling. The classical picture of posterior to anterior processing in the cortex and the feedforward push of information from the simple to the more complex is gradually replaced by a combination of feedforward and feedback projections. The rich connectivity of the brain areas, not to forget their connections with subcortical structures, offers an exciting new perspective to see how emotion and cognition are intertwined.

Still, it often seems that emotion research is an area where scientists are divided by barriers of methods as well as by questions. Focusing on the search for integration of findings in the specific field of human emotion, or even more narrowly within that, the field of threat perception, it is easy to find examples of research endeavors that have proceeded unrelated to one another. It therefore seems remarkable that one barrier that does not seem to exist, or at least that does not appear to be experienced as a barrier by researchers in the field, is that of language. Across vastly different theories and models, the language used to talk about and investigate emotions is remarkably similar. But does this mean that the phenomena and underlying explanations are similar?

Let us continue with the example of fear and threat perception. Whichever aspect of threat perception is being considered—at the individual or group level and whether the threat is triggered by natural, social, or symbolic factors—studies tend to speak the same language and use the same core notions. This suggests that whatever the level of analysis (from behavioral to molecular) or whatever the level of detail, we are somehow talking about one and the same phenomenon, of fear or threat-of-fear experience, and we are talking about it in the same way, that is, by using the same central concepts that are understood similarly by all.

Is this indeed the case? In the spirit of other recent work discussed below, this chapter reconsiders emotion language as a blueprint for the neural basis of body language at the subpersonal level and the phenomena it covers by focusing on one specific area of research: that of body expression perception. In the course of a decade of researching the perceptual and neural basis of bodily expression of emotion, some basic assumptions have been challenged and some certainties have become unhinged.

This chapter is devoted to the current understanding of emotion and body expressions. It does not review systematically the studies on this topic from our own lab or from others. Such reviews have been done recently on other occasions (de Gelder, 2016; de Gelder, de Borst, Watson, 2014). Here I take a further theoretical step and one that mostly remained implicit in previous work. In reviewing our current understanding of the perception of body language, this chapter argues that our findings necessitate a revision of a core notion of many familiar and classical emotion theories, which is the dogma of the conceptual and categorical continuity across levels of analysis. I challenge the notion that the brain is integrated in such a way that across levels of descriptions I refer to the same holistic process. My rejection of this integrative dogma follows from evidence indicating that the brain processes body language in two different ways and that each of these requires a different account, with different ontologies. The first section of the chapter sets out the findings. The second, more theoretical section, describes what the distinctions are and why we can probably not ignore them. The third section develops the issue of threat perception as an example, sketches two ways to talk about threat signals, and considers body language from these two different perspectives.

Body Expression Perception: The Body as Object of Representation

In the few years that emotional body language has been studied, some interesting findings have come to the fore. These are, first, that the results on the perception of emotional body expressions seem more difficult to fit what is commonly assumed about the primacy of category-specific areas in the brain. What we have learned about bodily emotion perception does not square easily with the role assigned to the extrastriate body area (EBA), or to its twin brother, the fusiform body area (FBA), in studies of category representation in the temporal cortex. Second, significant activation has been found in other areas than the temporal cortex that are specifically important for emotion but do not depend on stimulus processing in the temporal cortex body areas. Third, these activations are earlier than the time courses typically associated with category perception. Fourth, there appear to be strong effects of congruency between a body expression and the natural and social context in which it is seen. Finally, body expressions are multisensory events not involving only putative visual recognition of body form. I review these findings in turn.

Body Area(s) and Encoding of Body Expression

The exact role of the body area(s) is still a matter of debate. The notion that there is an area whose function it is to assign category membership and thereby to be the gateway to subsequent attribute processing is borrowed from classical models of face perception. In this perspective, the emotional information is processed based on links between the body area and the amygdala (AMG), as envisaged for the case of some facial expressions like anger or fear, and this influences the activation level of the face category selective area(s). Support for this explanation was provided, for example, by a study on a direct AMG–fusiform gyrus (FG) connection (Vuilleumier, Richardson, Armony, Driver, & Dolan, 2004). To anticipate the arguments provided below, note though that a similar explanation would require that an EBA–AMG connection exists, which is not clear (Peelen, Atkinson, Andersson, & Vuilleumier, 2007). The debate has become more complex with the localization of a secondary body area in the FG (the FBA), and then with later studies providing evidence for a more fine-grained representation of bodies in the temporal cortex. In view of the uncertainty about function, one reasonable position is that the area that presumably is the gateway to body perception and body attribute recognition, the EBA, is itself not directly involved in representing the emotional information of body images (Downing & Peelen, 2011).

There are different types of findings here that speak to the notion of the body area as a category-specific area endowed with this gateway function. Admittedly, most of the relevant studies that have investigated body processing have used functional magnetic resonance imaging (fMRI) and cannot easily or directly provide a causal link between an area and its gateway function. However, some studies used transcranial magnetic stimulation (TMS) in normal controls and some were done with brain-damaged patients. The simplest and most conventional prediction, in line with standard models of hierarchical visual processing, is that the first stage of body perception is the one during which the overall body shape is encoded.

Our first fMRI study (de Gelder, Snyder, Greve, Gerard, & Hadjikhani, 2004) found a number of areas that react selectively to fear expressions, which included the FG, but the EBA was not among them. However, we did report an increased activation in FG as well as AMG activation. The studies used a whole-brain analysis and passive viewing without any requirement to name or even recognize explicitly the emotions expressed in the body images. In a later study, we used specific category localizers for face and body areas. When comparing activation in these areas (EBA, fusiform face area [FFA], posterior superior temporal sulcus [pSTS]) we did indeed observe that their level of activation was higher when the images were showing fear rather than being neutral (van de Riet, Grèzes, & de Gelder, 2009), as is consistent with the explanation based on an FBA–AMG connection.

One may ask whether some of these findings might in part be artifacts resulting from the use of still images. How would this pattern change when dynamic images are used? There is reason to believe that the use of dynamic stimuli would not radically change this picture (De Winter et al., 2015; de Gelder & Van den Stock, 2011). We undertook a systematic comparison of still and dynamic images (Grèzes, Pichon, & de Gelder, 2007) and found that the areas where there is a critical difference in activity level between fear dynamic and fear still images are the superior temporal sulcus (STS) and the premotor (PM) cortex, but not areas directly related to emotion perception such as the amygdalae. Interestingly, EBA activity was neither influenced by movement nor by emotion.

Critical Activation Outside Temporal Cortex Areas

TMS is a technique that allows the researcher to establish a direct relation between a specific brain area and its function so it should enlighten us on the role of the body category area in the temporal cortex. TMS studies targeting EBA present a complex and interesting picture.

A few TMS studies have focused on the role of the EBA in comparison with the FBA (Pitcher, Charles, Devlin, Walsh, & Duchaine, 2009; Pitcher, Goldhaber, Duchaine, Walsh, & Kanwisher, 2012) but did not engage directly in the neutral versus emotion comparison. As with fMRI studies, for TMS-based conclusions we ideally need studies that have directly compared neutral and expressive bodies. Three studies from our lab used TMS for this purpose. The first study (Candidi et al., 2011) showed that applying TMS to the EBA did not influence the task results of the participants when recognizing small changes in posture in two successive frames taken from a video clip. Instead, only stimulation to the pSTS clearly modified performance and this effect was specific for the fearful body expressions. The second study (Candidi, Stienen, Aglioti, & de Gelder, 2105) used a different technique, as the focus was on conscious versus nonconscious perception of face and body expressions. A third study (Engelen, de Graaf, Sack, & de Gelder, 2015) compared the effects of TMS on V1, the EBA, and the inferior parietal lobule (IPL). Here also, no effects were seen for EBA stimulation, while IPL stimulation improved expression recognition performance.

The Matter of Time Course

There are currently only a few studies that have looked into the time course of body expression perception. Stekelenburg and de Gelder (2004) found that fearful body expressions are processed holistically and show the same inversion effect in the N170 (a component of the event-related potential observed in the window of 150–200 ms after stimulus onset) that was originally thought to reflect specifically the neural processing of faces. As we showed, it also reflects upright body perception. Depending on one's view about the source of the N170, this activation could be seen as corresponding to the increase in activation in the FFA typically observed in many fMRI studies. But there was no posterior activation that could possibly be seen as related to the EBA. Instead, fearful body expressions triggered a sustained frontocentral potential at a longer latency. Using a more sensitive method, Meeren, Hadjikhani, Ahlfors, Hämäläinen, & de Gelder (2016) recently reported in a magnetoencephalography (MEG) study that the first time window corresponding to the presentation of fearful, as contrasted with neutral body expression, was 80–100 milliseconds. And this activity was located in the posterior parietal cortex (IPL), not in the ventral cortex area. Thus, there was no earlier emotion-specific activity in visual areas or in the EBA. This role for the IPL is compatible with findings that fearful body expressions rely on activity in the IPL shown in the TMS study by Engelen et al. (2015).

Context Influences Body Expressions

Emotional body expressions take place in natural environments. Our actions reflect our understanding of the environment. Thus, there has to be a close link between our understanding of a scene and the behavior. In a recent fMRI study, the relation between natural scenes and body expressions was investigated (van den Stock, Vandenbulcke, Sinke, & de Gelder, 2014). The participants were shown images of various categories of natural scenes. They consisted of natural landscapes or objects, each shown in a neutral and in an emotionally laden variant (a car or a crashed car, a quiet streetscape and one devastated after a storm). These images were either shown alone or were used as backdrop for neutral or fearful body expressions. In the latter case, the scene–body combination had either a congruent or incongruent valence for the body. An analysis focusing on the EBA shows an increased response to threat signals displayed by the body, whereas response to threat in the scenes is only seen when no body is present and when the body expression in the foreground is neutral. This intricate pattern reveals that scenes on their own can trigger activation in the body area, as happens in the face area (Sinke, Sorger, Goebel, & de Gelder, 2010), and that the information provided by the scene influences how neutral body images may be colored by the affective meaning of the scene (Hortensius et al., 2016). More research is needed to understand how these effects arise in real life.

Body Expressions Are Multisensory Events

We not only see people, but we hear, feel, and smell them. We still know very little about the way affective signals operate in these different modalities, and how they connect with information residing in the brain and are constantly reactivated in imagination (Bertelson & de Gelder, 2004). So far the standard way to investigate the issue of affective signaling in different sensory modalities is to present a stimulus in each of the different modalities and asking for a recognition judgment. A recent fMRI study explored modality-independent representations of emotion (Peelen, Atkinson, & Vuilleumier, 2010) by having participants evaluate the intensity of the emotion expressed by body movements, facial movements, or vocal intonations. They then utilized multivoxel pattern analysis to search for brain regions in which emotion-specific patterns in one modality (e.g., bodies) could predict emotion-specific patterns in a different modality (e.g., voices). Interestingly, they found modality-independent activity patterns in the medial prefrontal cortex (mPFC) and left STS. This leaves open the question of which aspects of modality-specific representations exist when no explicit emotion judgment is requested from the participants. Does the EBA then figure as a critical area for the visual modality (Watson & de Gelder, 2014)?

The Matter of Development

So far there is little research on the development of body representation during infancy, childhood, and adolescence. There is evidence from electroencephalogram (EEG) measurement that around 7 months infants react selectively to body images (Filippetti, Lloyd-Fox, Longo, Farroni, & Johnson, 2014). On the other hand, fMRI studies of youngsters and adolescents show that the body areas are not fully developed until adulthood (Ross, de Gelder, Crabbe, & Grosbras, 2014).

In contrast, few parents or educators, cartoonists or painters, would doubt that at a very early age children perfectly understand bodily expressions for what they are, that they convey their meaning unambiguously and trigger adaptive reactions in the youngsters. Clearly, the notion that body expressions are recognized in infants and children before full maturation of the cortical areas pinpointed for body categorization in an adult brain may be consistent with the notion that body categorization is a prerequisite for the recognition of body expressions of emotion.

Conscious or Not?

Body expressions are also processed when one is not attending to them and without being aware of it. The behavioral studies that have established this have been reviewed elsewhere (de Gelder, 2015). Here I review evidence only for the involvement in the body areas provided by fMRI and patient studies. Let us first consider the role of attention deficit related to a right parietal lesion. Tamietto, Geminiani, Genero, and de Gelder (2007) tested three such patients with hemispatial neglect in visual awareness for fearful, happy, and neutral bodily expressions. When fearful bodies were presented in the contra-lesional visual field together with neutral bodies in the ipsi-lesional visual field, they were detected more frequently than happy or neutral bodies in the contra-lesional visual field. This shows that the presence of a salient signal such as a full body fearful expression reduces the attention deficit. This result was followed up in an fMRI study of one of the cases in order to pin down which areas are specifically related to conscious emotional body perception (Tamietto et al., 2015). Interestingly, the EBA and FBA did not show a different pattern of activity depending on whether the image was perceived and consciously reported or not. Conscious perception of fearful bodies was uniquely associated with activity in the anterior insula; the somatosensory, motor, and premotor cortex; and in the cerebellum. These areas are implicated in interoception, the perception of sensory–motor changes in the organism. Of course, in my view one cannot conclude from this that these are the structures that play a crucial role in bridging the gap between nonconscious and conscious processes.

Visual unawareness due to attention disorders like neglect is a condition quite different from that caused by cortical blindness because only in the latter case is processing in the striate cortex ruled out. Functionally and anatomically, the role of body areas may thus be different depending on the processing route. Furthermore, whether or not the whole-body images provide emotional information, may make the difference between attentional blindness and cortical blindness more radical in the case of cortical blindness. To give one example, Van den Stock, Tamietto, et al. (2014) observed activation triggered by the presentation of neutral body images in the EBA without visual awareness of the stimuli in a bilaterally blind patient.

To conclude this section, current evidence suggests that the body areas, which are the putative loci of the body concept as the basis of conscious perception, may not be critically involved in the perception of body expressions and may not be the stage through which further processing of body information needs to be gated. If so, what is the neural basis of our recognition of and reaction to emotional body expressions?

Personal or Subpersonal?: The Importance of Making Distinctions

In the above studies, researchers have used notions such as perception, recognition, and action, and the various terms referring to the processing of emotions, in the same way and presumably therefore meaning the same reality. But is this the case?

There are a number of traditional, updated, and recent emotion theories around, but remarkably, most of them adopt the same explanatory schema and center on very similar central issues; the reasoning goes as follows. A description of the stimuli is a (set of) processing stages in the individual and a decision behavior. All along this chain of transformation from stimulus perception to behavior, the same concepts figure and language is used from the lowest (i.e., physiological) to the highest (i.e., cognitive) level to refer to what is processed (an affective stimulus) and who processes it (a subject). The intuition is that these levels hang together, building upon the same core concepts, referring to the same "natural kinds," and the same conceptual apparatus applies. When distinguishing between subpersonal and personal processes, or between individual or social processes, the validity of the personal-level language is usually not questioned. But this is more than we can assume or accept without argument.

Barrett (2009) discussed and summarized the situation of the diversity of behaviors that expresses anger as the *emotion paradox*. There are fundamental difficulties with this familiar picture, as has been shown in a series of arguments by constructionist theorists like Lisa Barrett and her group. Noteworthy, constructionist theories of emotion explicitly do not take an S → O → R approach to emotion (Barrett & Simmons, 2015). Nor do constructionist views assume that emotions are natural kinds and the basic building blocks of the emotional brain. In this sense, constructionist theories address some long-standing controversies in the human emotion literature and may be symptomatic of deeper problems. I consider two of them, as they are directly relevant to theories of body expression recognition. One is the old but still active debate about whether basic emotions actually exist; the other is the issue of whether emotion perception depends on the conceptual category representation that is available, as previously discussed in the section "Body Expression Perception."

Basic Emotions?

As is well known, most of the research on facial expression has been conducted from the vantage point of the central hypothesis of basic emotions. It seemed obvious for the new field of bodily expressions to take the same point of departure and assume that there are also six basic body expressions. Multisensory research has been conducted along these lines. If the same emotion is conveyed similarly by the face and the voice, there is reason to expect that information from each sensory input converges rapidly, as I showed originally for face–voice combinations (de Gelder, Böcker, Tuomainen, Hensen, & Vroomen, 1999) and as has been replicated by different researchers (Collignon et al., 2008; Hagan et al., 2009; Jessen &

Kotz, 2011). Reasoning along these lines, researchers have investigated the perception of emotion from the face, voice, and body and concluded that what is underlying the perception of these different inputs is a common core emotion substrate that qualifies as the abstract representation of the emotion in the brain.

Will this approach withstand close scrutiny? What if either current critiques are correct or future research establishes that there are no "basic" facial expressions? In the area of emotion research, the debate has centered on the existence of a few basic emotions originally opposing Ekman (1984) and Russell (2003). We can simplify the debate in the following way. Defenders of basic emotions argue for a bottom-up approach to cataloging emotions. Basic emotions are present in the organism at birth in whatever conceptual format, neurobiological substrate, or physiological engram. Much as the notion of basic emotions has triggered debates by Ekman himself in later statements (Griffiths, 1997, 2002) all versions of this basic emotion approach share the bottom-up picture about a circumscribed set of affective states. We may not know just how to characterize them, but across the different levels at which we describe the emotional life of the mind, the same familiar common-sense pillars are holding the organism together, from basement to roof. And, most importantly, these affective states are something very similar to what we mean in ordinary language by fear, anger, happiness, and so forth.

By contrast, we sketch the alternative view as a top-down approach. Basic emotions, viewed as biological entities or natural kinds, are the opposite of experiential, social, or interactive constructions (Hacking, 1999). A major argument of the opposition to basic emotions is that whether by the power of language or by that of culture, it is the conceptual apparatus of familiar emotion labels that allows us to cast a net over the ensemble of affective phenomena and characterize them in a more or less stable way. Constructivists argue that in the course of this procedure we created the impression that there are basic emotions in the brain while, in fact, emotions exist only in our way of talking about our experience. A recent argument in favor of this position was developed by Barrett (2009). It is important to note that recently the constructivist position has received a boost from meta-analytic studies of fMRI data, which may be considered as illustrating that there is remarkably little consensus on the neurofunctional basis of emotions in the brain (Lindquist, Wager, Kober, Bliss-Moreau, & Barrett, 2012).

Admittedly, this is an oversimplification of positions that have been formulated with much more nuance by their defenders. For example, the approach elaborated by Barrett and Satpute (2013) is different from the position originally argued for by Russell (2003). In line with some view about constructivism in other social science disciplines, emotion constructivism was associated with personal-level experience. But my goal in drawing this sketch is to bring out what in fact both positions have in common. This is adherence to a *unitarian* notion of the subject of emotions. It is the fundamental presupposition in all our thinking about emotion that the "I" or the self, the person or the subject of the emotional experience, is always present and understanding. To paraphrase in the simplest terms, if one does not feel it (or cannot verbalize, testify to it, communicate or otherwise express), then it is not an emotion and he or she cannot explain the affect. The notion that we are conscious of our emotions and intentions and that our conscious feelings and intentions cause, and therefore explain, our actions are at the core of how we conceive of human beings.

We cannot use this familiar framework and its conceptual categories to understand subpersonal processes, which are *de jure* the processes that are currently targeted by the scientific methods of affective science.

The distinction between personal and subpersonal explanations has been present in contemporary philosophy of mind, since at least the 1970s (Dennett, 1969). The distinction is easy to grasp but its consequences for scientific theories of the mind are vast. In a nutshell, at the personal level theories use the familiar and common-sense notions about mental processes, action, thinking, goals, and most relevant here, about emotions and emotional experience (see Metzinger, 2011, for fine analyses). But none of those concepts are applicable at the subpersonal level—that is, when we talk about brain areas, physiological processes, and so forth.

Now, in the present context, the issue is whether—given that we accept the distinction between personal and subpersonal processes—it is actually conceptually coherent to talk about conceptual representation at the subpersonal level. If not, theories of emotion addressing processes, mechanisms, and explanations at this level need a radically different conceptual apparatus in which the ontology of daily experience is not altogether deterministic vis-à-vis our scientific hypotheses about the brain. The familiar approach of emotions as motivational feelings and states or as explanatory constructs, around which both basic and constructivist emotion theories are built, is not applicable to the description and explanation of humans at the reflex-like behavior level.

First, experiencing fear or reacting to threat are states that can be well described at the personal level, and are the ingredients of explanation of someone's actions. But this is not the case when we consider the subpersonal level. We simply cannot take for granted that there is or must be a correlate of personal and conscious experience in the subpersonal affective mechanisms.

Second, on the cognitive process model side, the conceptual apparatus used to describe and explain emotional experience are models that are built on the familiar daily object categories.

In the context of this chapter I make the case with findings from studies on body expressions. If one maintains the notion of basic emotions in the biological sense, the issue is whether and how these translate at the personal level in the observable behavior. Can we classify the bodily expressions along those basic categories, or, more pertinently, is this a good way to investigate how the brain deals with body expressions?

Body Expression Perception as Action and as Experience

Here is a sketch of the approach. As already implied, a crucial notion is that of multiple processing streams. For the sake of the argument in this chapter we use a model of dual-processing streams. But this is not to be taken as a theoretical position carved in stone, it is only a simplification reflecting current understanding. The organism reacts to the sight of body expressions along separate but parallel routes that were previously referred to as reflex-like and reflective behaviors (de Gelder, 2006). With that approach as background, we can now clarify some further aspects of each route in relation to the processing of bodily signals. The reflex-like processing route is based on activation of *immersive scenarios* or scenarios where the context and the action are welded together—for example, the scenario of running from the sight and smell of fire. One could call these scenarios immersive because the perceiver is immersed in the context reality and is not in a mode of analytically dealing with separate components of the environment and adding them together to get at the meaning of the scene. The other route is by activating concept-based representations (the category body) and subsequently (as a matter of logical requirement, a matter of time course of both) combining them. Here the perceptual process is first and foremost a matter of object categorization. This category representation stage is followed by further processing consisting of object attribute decoding and context decoding. The bare bones of this model of emotion perception as cognitive (re)description of physiological reactions is already found in James (1884). To put this traditional contrast in the most simplistic formulation, top-down or constructivist theories envisage projection of higher-order concepts onto lower-level descriptions. Bottom-up theories postulate content-preserving redescriptions translating from organismic processes to cognitive descriptions and onto explanations of behavior.

Contrary to the bottom-up and top-down theories, I argue here that the two processing streams coexist and are involved in most of the processing history of an affective stimulus. An essential aspect of this approach is that the two processing routes are normally both active and trigger independently. The personal and the subpersonal simply do not map onto each other; these two worlds do not meet. But I return to that matter below. This means that the lower levels of organismic responses are not automatically preserved and represented through successive cognitive descriptions. There is no transparency or content-preserving transformation from low-level physiological responses to phenomenal experience and to the upper levels of cognitive appraisal. This implies that the organismic processes like freezing, for example, cannot be described with the use of cognitive language consisting of concepts that have cash value in only personal and cognitive levels of analysis.

A position like the one just sketched has recently been described very clearly by LeDoux (2012) and, along somewhat similar lines but in a different framework, by Panksepp (1998). This means that, for example, even for the case of fear, which is presumably the one candidate emotion concept that can be "translated" most closely in organismic reactions, we cannot really identify a fear circuit or project the conceptual content of the conscious fear experience on the organismic reactions.

No Basic Emotions at the (Sub)personal Level

For an outsider, it must surely be bewildering that activations of brain areas as discovered with sophisticated fMRI have not yet led to clear function assignments that would take the formula of one emotion: one brain area (a few, a network). The areas that were originally pinpointed as the seat of fear (the amygdalae), disgust (anterior insula), sadness (anterior cingulate cortex), and anger (orbitofrontal cortex) have come under attack from the experimental data, even in studies that are restricted to the cortex. The field is moving away from the original notions where one emotion concept and its perceived function (including the typical behavior and experience) could be pinned down to one area. Recent meta-analyses (Vytal & Hamann, 2010; Lindquist et al., 2012) have provided new evidence that there is no such thing as a 1:1 relation between a specific emotion and its corresponding brain area (the fear area in the AMG) or even a corresponding brain network (the fear network). The fact that this one emotion:one brain area type of relation between a familiar object of emotion and its neurofunctional correlate now seems increasingly unlikely, does not stop optimists from arguing that there are differences in stimuli, methods, analysis techniques, and tasks across the different studies. The consequence is that we do not yet know exactly which area does what and that the search for a 1:1 relation is still on. More advanced fMRI methods like high-field scanning and analysis methods like multivoxel pattern analysis (MVPA) and searchlight techniques may still contribute data that support this classical emotion picture.

Depending on one's viewpoint there are different ways to deal with the current picture. Traditional constructivism argues, often convincingly, that one emotion:one area is the wrong agenda for emotion research. Alternatively, networks may replace emotion modules, and emotion labels themselves may disappear at the brain level to be replaced by structure–function mappings that are domain general and shared by different brain functions whether they are predominantly cognitive, social, or emotional (Barrett & Satpute 2013).

Is there then a better chance of finding and naming basic emotions when the theory is restricted to the subpersonal level? The answer depends on whether we can develop a methodology to investigate subpersonal processes that does not depend of a predefined cognitive categorical system.

No Body Representation at the (Sub)personal Level?

At the subpersonal level the affective brain is built of integrated perception–action scenarios. What this means is that an element in the environment triggers a scenario or a program, not a single representation that would require extensive processing and interpretation by cognitive structures. For example, seeing a whole-body expression of fear triggers a scenario of escape or escape preparation. Different fear situations trigger different fear scenarios. Similarly, hearing a loud noise triggers a survival scenario. One can think of these as integrated body–environment scenarios, or face–body scenarios, face and/or face and body–voice or –sound scenarios. They correspond to organism-specific interaction patterns and survival scenarios of the actions of the individual organism, its interactions with others, and the actions of the group of conspecifics in their natural environment. They do not require higher-level reflection or decision and are not dependent on cognitive control, mental state attribution or theory of mind, cognition, decision, or action–intention understanding on the part of the conscious agent.

Disconnection: The Methodological Conundrum

Historically, the earliest approaches to the scientific study of human emotions were already confronting the issue of the interface between the newly gained scientific language to investigate correlates of affective processes and the commonsense language of emotional experiences. In the human emotion literature, physiological processes and the notion of arousal presented the interface that links the conscious individual to its organismic roots. For example, physiological arousal supposedly lowers the threshold for awareness, making us aware of salient and relevant aspects of the environment that would otherwise go unnoticed or remain within the realm of nonconscious processes. But attributing this content-delivering role to physiological processes flies in the face of evidence. Indeed, it has long been known that physiological arousal carries no specific identifying label about its causes.

What about an interface then? Is there an interface between levels and mechanisms, between the raw emotions and the cognitive processes, as is usually assumed in cognitive theories of emotion perception and appraisal? The logic of the distinction between personal and subpersonal level compels us to reject the notion of an interface in the sense of an automatic mapping of subpersonal states and processes to personal states, processes, attitudes, and so forth. At the subpersonal level there is no epistemic agency and there is no thinking autonomous agent willfully planning his or her actions and initiating behaviors. At the personal level there is cognitive accountability exercised with intentions, plans, and concepts. It is not a translation but an active representation by a "self" with the aid of a model of its actions.

Art and Emotion: An Illustration

One may argue that, of the various art forms, dance combines a few characteristics that make it among the most basic and ancient forms of art. Watching dance creates emotion in the observer; it moves the observer often literally and always metaphorically. For example, people report being brought to tears by the choreographies from Pina Bausch. Yet the dance movements we are watching, the patterns making the dance "language," are utterly unfamiliar. Not only is it not feasible for nonprofessionals to mimic the movements of the dancers without extensive training, but the movements do not have referents in the motor repertoire of nonprofessionals, nor do they have a clear meaning that is activated in watching a performance. Yet it is the meaning of the movements that moves us, such that some spectators are brought to tears. No concept is expressed or represented in these movements yet they stir clear and strong emotions in the observer. These facts are a challenge for explanations that view concepts like motor perception, imitation, and motor contagion as central. In contrast, one can take the emotional impact of watching unknown dance movements as an indication that at the subpersonal level bodily movements are not necessarily perceived with the help of the well-known conceptual categories and do not correspond to known or canonical descriptions of body movements associated with each everyday emotion.

The concept of fear seems fully transparent in the sense that everybody knows what it means and what experiences and behaviors it is about. But at the same time this concept covers a wide variety of fear triggers, behaviors, and experiences. Social fear versus environmental fear is just one very superficial distinction. Still, phenomenologically, they are all experienced as fear. Introspectively, they may all feel like fear and therefore be lumped together. Hence the notion is that there is a fear system in the brain that represents all these variants and that is their common core. We are beginning to understand, so far mainly from animal experiments, that there are as many kinds of fear as there are contexts, behaviors, types of attacking, or conditions for self-defense. For example, animal studies adapt the distinction between social fear versus predator fear (Gross & Canteras, 2012; Silva et al., 2013).

The issue addressed in these last paragraphs is discussed with a different terminology than used here in a number of papers by Jaak Panksepp (2011) in the context of animal feelings and consciousness.

The implications of the distinctions I just made for understanding emotional body expressions are straightforward. I have argued that the question of whether there are basic body expressions is not easy to answer. Whether there ultimately are basic body expressions will depend on whether it is useful to describe and categorize the vast number of bodily expressions encountered in real life along some organizing and explanatory lines. But the prediction is that once such a research program becomes more advanced, we will see that these will not be the same at the subpersonal and at the personal level. The point is well illustrated with the example of defensive behavior. The following is far from an exhaustive list of common ways to behave in the presence of an aggressive person. Defensive behaviors can vary among at least all of these: running away, grabbing any tool to attack, looking for cover; hiding and covering oneself, typically by holding the hands in front of the face; adopting a nonaggressive face expression; making oneself disappear; protecting vulnerable things in the environment (children, wallets, telephones, etc.); or submitting to the attack, giving in, and showing surrender in voice, posture, and so forth. All of these behaviors would in the appropriate circumstances qualify as adaptive behavior. But two things stand out when we consider the variety of such defensive behaviors. First is that in order to be adaptive or to explain that they are adaptive, people do not necessarily need to assume they are under cognitive control, initiated by higher-order cognitive processes, or following so-called processes of mentalizing. Subpersonal-level explanations involving sensorimotor loops embedded in specific contexts and responding to characteristic adaptive demands go a long way toward understanding such behaviors. There are as yet not many examples of studies that have investigated emotion-related behavior from that perspective—that is, unbiased by the traditional conceptual apparatus and conceptual categories of the conscious intentional mind. The second aspect that stands out is that it does not add anything to what needs to be understood or explained to view any of these behaviors as derived from fear in the mind. Of course, one can view all of these behaviors as manifestations of fear, but it does not add anything new to our understanding to do so.

The distinction between personal and subpersonal descriptions can be illustrated with an analogy. In the literature on body awareness and its disorders in brain-damaged patients a contrast emerged quite early on between body schema and body image (see, e.g., Paillard, 1999). The first refers to a sensorimotor map of the body space that is mainly based on proprioception. The second refers to the mostly explicit description of the body as based on external information. The neuropsychological literature is rich in examples illustrating how these two notions of the body do not map onto each other (e.g., Berlucchi & Aglioti, 2010). In the same vein, bodily expressions in the wild may not correspond to body expression as described from the perspective of a conscious willful and intentional agent.

CHAPTER 29

Form and Function in Facial Expressive Behavior

Daniel H. Lee and Adam K. Anderson

Facial expressions of emotion are a salient and important means of social communication (Ekman, 1973; Fridlund, 1994; Izard, 1977). Visually, the face is the most important part of an individual's identity. So it is not surprising that how our facial information changes by its expressivity captures our attention (Vuilleumier, Armony, Driver, & Dolan, 2001) and serves as an important source of nonverbal communication (Bruce & Young, 1986; Calder & Young, 2005). Among the various expressive forms the human face can take, researchers have found six expressions that are recognized as communicating distinct mental states (fear, disgust, surprise, anger, happy, and sad) consistently across cultures, literate and preliterate (Ekman, Sorenson, & Friesen, 1969; Ekman & Friesen, 1971). The most likely explanation for these expressions' cross-cultural consistency is a common point in their evolutionary selection that passed them down to all humans, rather than the less likely, independent emergence of them within each culture. These categories of facial expressions have been labeled "basic expressions" (Ekman, 1973, 1999; Izard, 1977, 1994), and over time, their recognition has been found to be reliable (e.g., Etcoff & Magee, 1992; Scherer & Wallbott, 1994; Young et al., 1997; see Elfenbein & Ambady, 2002, for a definitive meta-analysis), with the pattern of their forms being recognized similarly in machines as in humans (Susskind, Littlewort, Bartlett, Movellan, & Anderson, 2007).

Providing balance to this view, some of the stronger inferences made based on the evidence for basic expressions have been criticized, mainly against the notion that basic expressions might be "universal" in a strong sense, rather than a more relativistic, "cultural universality." Critics emphasizing socially and psychologically constructivist influences over absolute universals suggest a weaker form of basic expressions in that they are not fixed categories, nor immutable readouts of our internal states. In the argument against strong categories of expressions, constructivists note: the variance of facial expression space, of which six expressions capture a small fraction; the psychological tendency to impose distinct categories within this multidimensional space (Barrett, 2006a, 2006b); and that these basic and other expressions become susceptible to higher-order associations for social and contextual utility (Fridlund, 1997). Evidence supporting this view has shown basic expressions' cultural (Jack, Garrod, Yu, Caldara, & Schyns, 2012) and contextual variance (Aviezer et al., 2008; Aviezer, Trope, & Todorov, 2012), and that our faces are able to communicate more than just six mental state categories (Baron-Cohen, Wheelwright, Hill, Raste, & Plumb, 2001; Baron-Cohen, Wheelwright, & Jollife, 1997; Du, Tao, & Martinez, 2014).

With the empirical evidence supporting culturally invariant and culturally variant expression forms, one theory that incorporates both sides is the dialect theory of expressions (Elfenbein, 2013). It considers cultural variations in expressions form as "accents" and "dialects" that emerge as socially learned ingroup advantages (Elfenbein & Ambady, 2003; Marsh, Elfenbein, & Ambady, 2003) that developed atop a global grammar of culturally invariant basic expressions (Elfenbein & Ambady, 2002). The application of a language metaphor (Tomkins & McCarter, 1964) to the nonverbal medium of facial expression communication connotes the utility of understanding the invariant grammar and lexicon of English, as well as the variant accents and dialects that emerge within local regions of England.

Taken together, much evidence and theory has been accrued in accounting *what* our culturally invariant and variant forms of expressions are. However, a notably neglected line of research in our understanding of expressions forms is *why*—that is, *why* do our expressions look the way they do? One reason for the paucity of research understanding why certain culturally variant expressions exist may be the challenge in theorizing their abstract, emergent origins. However, we are better positioned to understand the origins of our culturally invariant basic expressions for two reasons. First, we have an evolutionary theory that accounts for their cultural invariance. While our facial expressions are now used primarily for communicative purposes, Darwin (1872/1998) theorized that their forms originated for sensory function for the expresser, which were then co-opted for social function. Second, because this theory is grounded in a primitive sensory function, rather than a more abstract communicative function, we are equipped to test such specific hypotheses of function. Investigating the origins of these nonverbal communicative forms is worthwhile, considering that their cultural invariance encompasses a wider scope than the etymology of any spoken word.

In this chapter, we discuss research inquiring into the evolutionary origins of our common expression forms and examine evidence for their origins grounded in Darwin's (1872/1998) theories of egocentric function. Afterward, we take a preliminary look at how some of these egocentric functional forms may have been co-opted for allocentric function.

In his book *The Expression of the Emotions in Man and Animals*, published in 1872, Darwin posited his theories on the origins of our emotions. He proposed three principles by which emotional expressions may be understood: the principle of serviceable associated habits, the principle of antithesis, and the principle of direct action (or expressive discharge) of the nervous system. The first two of these principles addressed how nature shaped and organized our expressions and are relevant here. The first principle argues that expressions originated for some immediate egocentric functional benefit, rather than their modern, allocentric communicative purpose. Thus, an emotional expression's appearance is not arbitrary but was selected for its congruent adaptive function with its emotion. The second principle of antithetical form argues that expressions can be understood as originating from opposing actions. Thus, an expression may have another that is opposite in appearance for an opposing function.[1] And because the face contains many of our key sensory apertures (e.g., eyes, nose, mouth, ears), Darwin (1872/1998) theorized that the function of emotional expressivity was to adaptively modulate sensory intake, such as lowering of the brows to reduce the eyes' exposure to sunlight.

Darwin's (1872/1998) principles are less concerned with expressions' explicit categories and their immutability from higher-order social associations. Instead, he placed emphasis on the bottom-up expressive features that once served the animal for some sensory function (i.e., *why* they appear the way they do). From this perspective, a basic "fear" expression represents not so much a universal ideal but rather a probable grouping of facial action tendencies that cohere toward some sensory function (e.g., vigilance toward threat in fear; Whalen, 1998). Then, the basis of these expressions, which were originally predicated on utility for the expresser, would have been co-opted as communicative signals for utility for the expressions' receiver (Andrew, 1963; Shariff & Tracy, 2011). In the following, we discuss a series of studies that examined Darwin's principles, toward understanding facial expressions' form and egocentric function, and how they may have undergone social exaptation for allocentric function. We begin with basic expressions' form.

Form

A useful starting point for understanding expression form is to be impressed by the sheer physical breadth of the facial musculature that supports it—our potential expression space. Based on the taxonomy of our facial muscle units, the Facial Action Coding System (Ekman, Friesen, & Hager, 1978), we computed that a conservative estimate of our possible expression space amounts to 3.7×10^{16} possibilities.[2] To put this number in perspective, it means that correctly identifying an expression in this space is the probabilistic equivalent of a person winning two Powerball jackpots.[3] This combinatorial complexity affirms the multidimensional nature of our expression space, which cannot be fully captured by six distinct categories, and leave ample possibility for higher-order expressive associations for social utility, whether as ingroup dialects (Elfenbein, 2013) or complex mental states (Baron-Cohen et al., 1997, 2001; Du et al., 2014). At the same time, it provides a statistically appropriate context for affirming the cross-cultural consistency of basic expressions. If our expressions were purely higher-order associations, each shaped arbitrarily for social communication, there could not be any recognition of expressions across cultures. We would instead be left with sets of arbitrary expressions that would have to be translated across cultures, akin to the symbolic associations of verbal languages. Thus within this expressive framework, basic expressions need not be universal in the strong sense but in having maintained statistical stability across the myriad influences of culture and context they would indicate a common ancestry.

It is daunting to try to understand the raw complexity of this expressive space, and how our basic expressions fit in it. A dimensional perspective (Oosterhof & Todorov, 2008; Plutchik, 1980; Rolls, 1990; Russell, 1980; Russell & Barrett, 1999; Watson & Tellegen, 1985) is helpful in keeping some of this variance tractable, but we still require a theory to organize and interpret those dimensions. Moreover, familiar dimensions of psychological experience (Rolls, 1990; Russell, 1980; Russell & Barrett, 1999; Watson & Tellegen, 1985) or physiological changes (Bradley, Codispoti, Cuthbert, & Lang, 2001; Cacioppo & Berntson, 1994), such as valence and arousal, may not be the most applicable way to frame dimensions of physical form, in particular if the physical forms have been evolutionarily selected for survival. A more aptly organizing perspective may be that evolutionary selection implies function, and when it comes to nature's selection of behaviors or features that interface with the physical world, form follows function.[4] We thus applied Darwin's (1872/1998) principles as a framework for understanding basic expression form.

Framed by Darwinian principles, the cross-cultural consistency of basic expressions (Ekman et al., 1969; Ekman & Friesen, 1971) may be important as reference points that reveal how natural selection organized those expressive features as probable action tendencies rather than categorical ideals. Then, toward uncovering these natural origins, basic expressions' features may be useful to consider as anchors, without which we would find ourselves adrift in facial expressions' combinatorial complexity. Darwin's second principle of antithesis also provides an organizing influence toward aligning opposing expressions and dimensional continua of expression variance based on appearance and function. Applying these ideas may reveal a more predictable pattern for understanding the basic expressions that anchor our vast expressive space.

Indeed, while facial action units may be taxonomized independently, our basic expressions appear to have systematic relationships in activation and thus expressive appearance (Dailey, Cottrell, Padgett, & Adolphs, 2002; Susskind et al., 2007). To concretely examine these facial action tendencies, we applied a computer graphics model of facial appearance (Cootes, Edwards, & Taylor, 2001) to the six basic expressions from a standard cross-cultural dataset (Matsumoto & Ekman, 1988). The appearance model allowed us to create a prototype for each basic expression as vector representations that coded its expressive shape. This revealed an important dimension of expressive action of widening versus narrowing of the sensory apertures across a number of basic expressions. For example, fear and surprise demonstrated expressive widening, while in opposition, disgust and anger demonstrated expressive narrowing (Susskind & Anderson, 2008). These similarities in expression form were corroborated by similarities in expression perception, where fear and surprise were perceived alike, and disgust and anger were perceived alike, and each pair was perceived highly unlike the other pair (Susskind et al., 2007). Of these expressions along this dimension, we focused our examination on the two that occupied the extremes of expressive widening versus narrowing: fear and disgust (Susskind et al., 2008).

Based on these vectorized models of facial form, we first tested a prediction of this widening versus narrowing expressive dimension. We generated computerized fear and disgust "antiprototypes" by reversing the direction of the facial action vectors of the fear and disgust prototypes, predicting that these antiprototypes would be perceived as its prototype's dimensional opposite. Indeed, participants perceived antifear most strongly as disgust and antidisgust most strongly as fear (Susskind et al., 2008). These vectorized facial models also indicated the expressive directions that represented these action tendencies that either stretched or compressed features of the face. To visualize the action tendencies of these expressions, we generated vector flow diagrams of these expression prototypes relative to their antiprototypes (Figure 29.1). They demonstrated expanding versus compressing longitudinal actions of the muscular frames around the mouth, nose, and eyes (Susskind et al., 2008; Susskind & Anderson, 2008), suggestive of Darwin's (1872/1998) theories of expressive form and its opposition.

Beyond just demonstrating opposition in form, if these actions that widen versus narrow the sensory apertures were indeed selected for function (Darwin, 1872/1998), they should cohere with theorized functions of the emotions associated with the expressions. Next, we examine Darwin's principles on whether these forms confer sensory benefits to the expresser.

Egocentric Function

A prominent theory of the function of fear is vigilance toward threats (Öhman & Mineka, 2001; Whalen, 1998). For an animal confronted with immediate potential threats in its environment, survival would be enhanced by increasing its sensitivity toward detecting and locating those threats (even if they turned out to be benign, false positives). Thus, congruent with fear's theorized function, we predicted that widening of sensory apertures, such as the eyes and nasal passages, would promote the gathering of relevant sensory information. Conversely, disgust is theorized to be an emotion of rejection toward threats of a different kind (Rozin & Fallon, 1987; Rozin, Haidt, & McCauley, 2000; Chapman & Anderson, 2012). Potentially originating in older principles of distaste and rejection of chemosensory stimuli (Chapman, Kim, Susskind, & Anderson, 2009), expressions of disgust may reflect a different response, such as a deliberate discrimination (Anderson, Christoff, Panitz, De Rosa, & Gabrieli, 2003; Sherman, Haidt, & Clore, 2012) of threats of a more proximal, stationary kind. Thus, in addition to fear and disgust expressions potentially serving as anchoring ends of a widening versus narrowing facial expressive dimension (Susskind

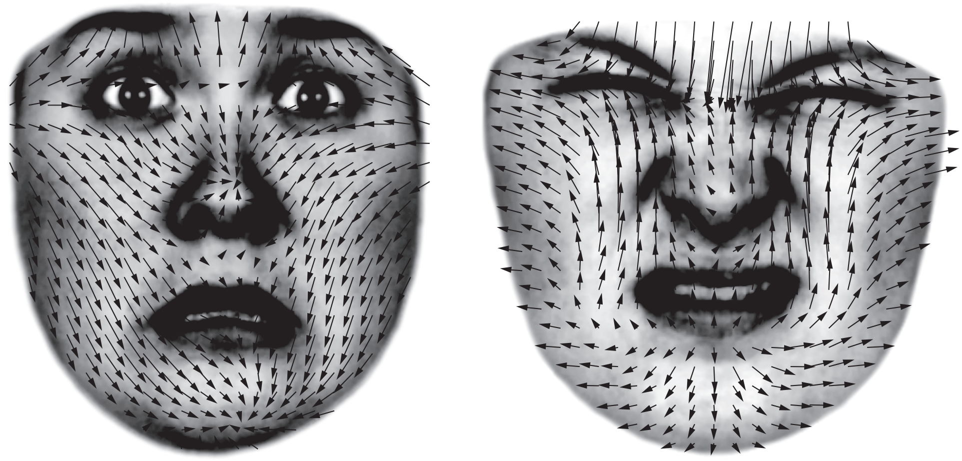

FIGURE 29.1. Opposition in facial actions of fear and disgust expressions. Arrows depict vector flow fields of skin surface deformations of an expression prototype from its corresponding antiprototype. Visualizing these underlying facial–action patterns indicates the opposing expansion in fear (left) versus compression in disgust (right) along the longitudinal axis emanating from the bridge of the nose, resulting in raised versus lowered brows, increased versus decreased eye aperture, and vertical elongation versus compression of the nose associated with raised versus lowered lips. Adapted from Susskind et al. (2008).

et al., 2008), these independently theorized functions of fear and disgust emotions provided specific hypotheses of egocentric function to test about their sensory consequences.

We tested this thesis of facial form's function using a variety of experiments on how expressive actions functionally influence two conspicuous sensory apertures: the nose and the eyes. Participants posed expressions in a directed facial action paradigm as we measured various sensory functions and perceptual consequences. The use of directed facial actions (instructions for fear: raising the eyebrows and drawing them together, opening the eyelids, letting their mouths drop open and stretching their lips horizontally; for disgust: raising their upper lips, wrinkling their noses and raising their cheeks[5]; for neutral: relaxing the facial muscles; Ekman et al., 1978) rather than inducing fear or disgust was important in being able to isolate the sensory effects of facial expressions through facial form, independent from the cognitive influences emotions can have at the level of the central nervous system (e.g., enhancing attention; Vuilleumier et al., 2001).

Nose

Beginning with nasal effects of expressive action, we acquired nasal respirometry, nasal temperature, and abdominal–thoracic respiratory measures during a controlled instructed breathing cycle. Given equal duration of inspiration (2.2 seconds in/out per breath), fear was associated with an increase in air velocity and volume relative to neutral and disgust expressions, even when corrected for respiratory effort (Figure 29.2a; Susskind et al., 2008).

Altered air intake may reflect a variety of factors rather than genuine structural changes in sensory capacity afforded by facial expression form. We thus directly examined whether fear and disgust altered the underlying structure of the nasal passages in opposing manners. High-resolution magnetic resonance images of the nasal passages were acquired during the directed facial action task, which resulted in nasal passage volume significantly modified by expression (Figure 29.2b; Susskind et al., 2008). More specifically, these structural images revealed that fear expressions resulted in a dilation of the entry to the inferior nasal turbinates of the respiratory mucosa, consistent with horizontal mouth stretching and lowering facilitating nasal passage dilation; in contrast, disgust resulted in a sealing off of this normally open passage, consistent with upper lip raising and nose wrinkling (Figure 29.2c).

Eyes

Moving on to visual function, we examined how expressions influence the visual field. First, testing subjective measures of visual field change, participants reported seeing farther out into the periphery of a visual grid space while posing fear relative to neutral as well as disgust (Figure 29.3a; Susskind et al., 2008). Next, testing objective measures of visual field change, we used two kinds of stimuli in separate experiments. In a simple dot target detection task, fear widened the peripheral visual field relative to neutral and disgust (Susskind et al., 2008). This visual field expansion of fear was similarly found in a rigorous psychophysical task where participants identified orientations of Gabor gratings that were controlled for visual angle size (Figure 29.3b; Lee, Susskind, & Anderson, 2013). In the latter psychophysical study, eye widening of fear expressions enhanced the effective visual field of the expresser 9.4% farther out in the available periphery compared with neutral (Lee et al., 2013). These visual field changes were direct physical effects of opening versus occluding of the upper visual periphery by eye opening, as corroborated by the larger effect in the vertical rather than oblique meridians (due to the morphology of our vertically opening eyes) and an opposing visual periphery reduction for eye-narrowing disgust expressions.

Although we found visual field enhancements along the vertical and oblique meridians and not the horizontal, participants maintained central fixation in order to test their peripheral, and not foveal, vision. However, in the real world, eye movements are critical for gathering information about one's visual surroundings. In another experiment, we examined whether fear expressions facilitate muscle units for eye scanning. We found that horizontal saccades to peripheral targets (27° apart) were faster for fear relative to neutral and disgust, for both, average and peak speeds (Susskind et al., 2008).

These visual field effects were due to a basic sensory gating mechanism, involving simple retraction of eye features that occlude the visual periphery. But beyond peripheral occlusion effects we theorized that expressive eye opening may fundamentally influence how light is gathered along a functional dimension seen throughout the visual system. Although facial muscles that reconfigure superficial eye features should have no direct influence on the pupil or the accommodative lens behind it, approximately two-thirds of the eye's full refractive power comes from the cornea (Duke-

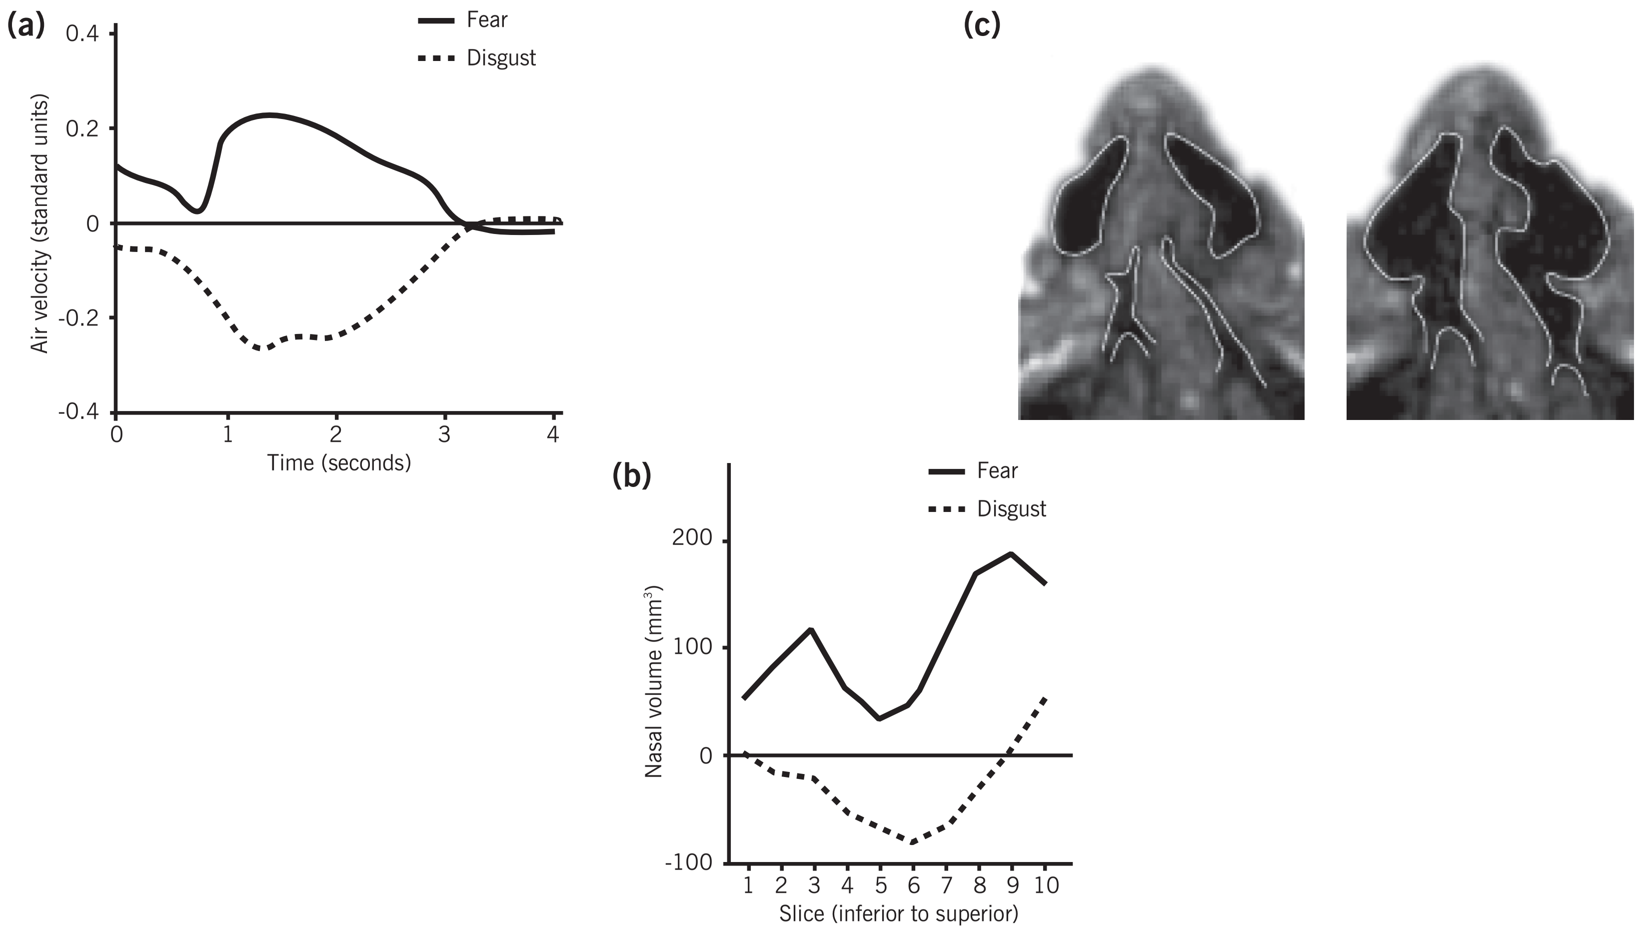

FIGURE 29.2. Nasal effects of fear and disgust expressions. (a) Mean air-flow velocity (in standardized units) for fear and disgust expressions relative to neutral during inhalation over time (2.2 seconds). (b) Volume of air cavity of the ventral portion (12 millimeters) of the nasal passages for fear and disgust expressions relative to neutral. Each slice was 1.2-millimeters thick with an in-plane resolution of 0.86 × 0.86 mm. (c) Passageways to the inferior turbinate of the respiratory mucosa from magnetic resonance imaging. Expressions of disgust (left) and fear (right) resulted in closure and dilation, respectively. Adapted from Susskind et al. (2008).

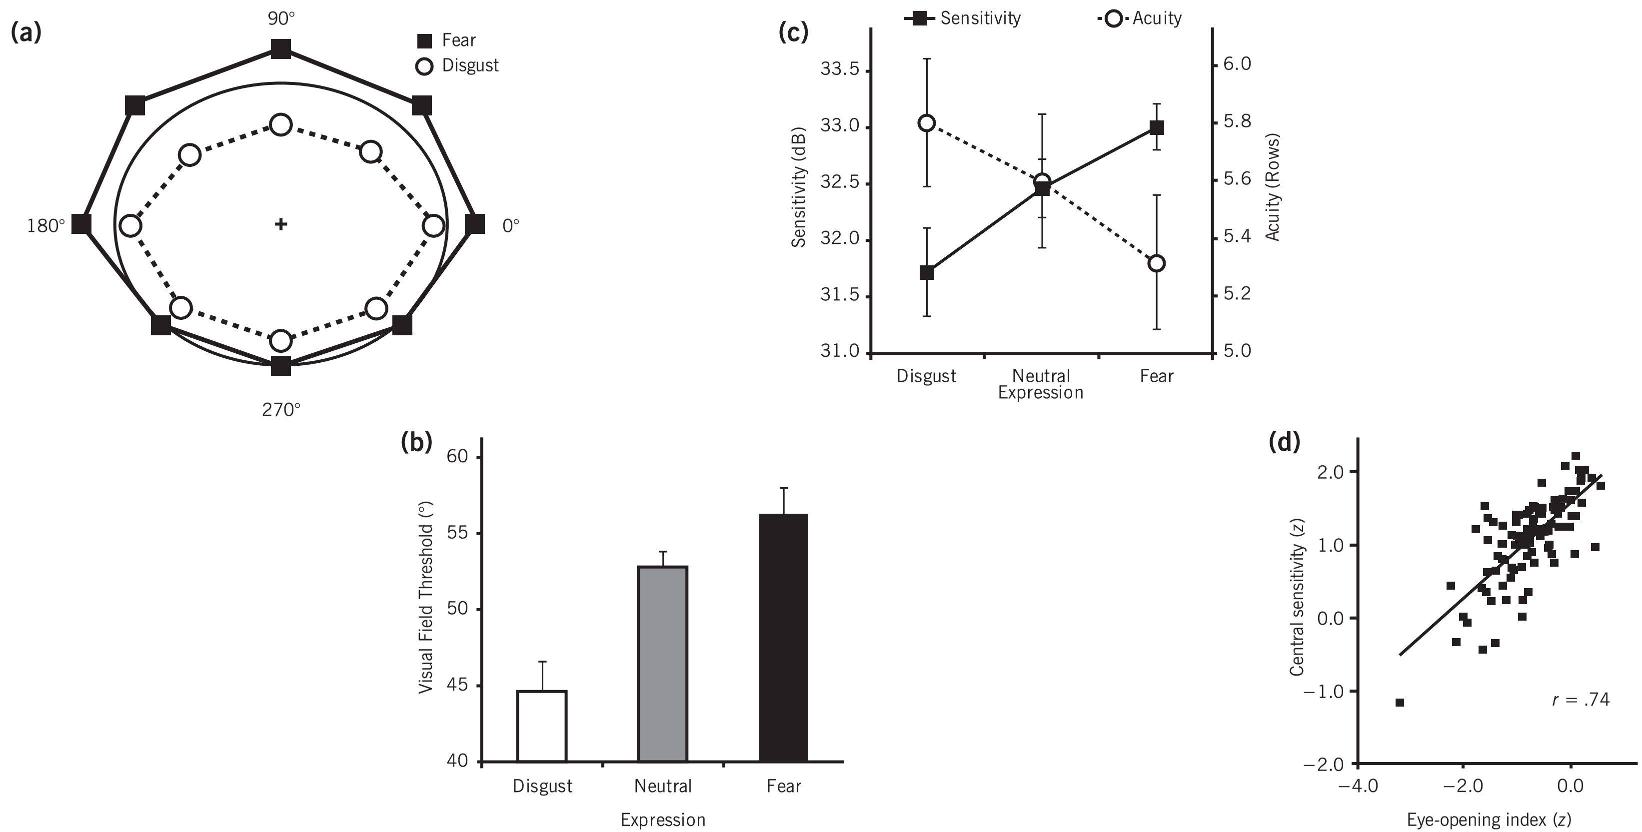

FIGURE 29.3. Visual effects of eye widening and narrowing in fear and disgust expressions. (a) Subjective visual field changes in visual field estimation along horizontal, vertical, and oblique axes. Central ellipse is neutral baseline. (b) Objective visual field thresholds for identifying Gabor orientations for each expression. Fear expanded the visual field relative to neutral and disgust expressions. Error bars represent SEM. (c) Visual sensitivity (left *y*-axis) and visual acuity (right *y*-axis) effects of expression. Sensitivity scores are restricted to the central visual field (4.2° visual angle from fovea). Acuity scores are the number of correctly read rows of eye-chart letters. Higher scores indicate greater sensitivity or acuity. Error bars represent SEM. (d) Relationship of central visual field sensitivity to degree of eye opening, indexed by visual sensitivity measured at the peripheral visual field (mean visual angle from fovea = 20.6°, SD = 2.1°). Expression effects on visual sensitivity in the periphery are due to light occlusion by eyebrow and eyelids, whereas central visual field is due to light refraction. Adapted from Susskind et al. (2008) and Lee et al. (2013, 2014).

Elder & Abrams, 1970). We thus predicted facial expressive behaviors that expose or conceal the cornea to have adaptive consequences on the eye's optics. Specifically, an optical model predicted eye widening to increase light gathering and enhance sensitivity over acuity, prioritizing fear's function for vigilance of threat detection and localization (Öhman & Mineka, 2001; Whalen, 1998). Conversely, eye narrowing would focus light more sharply to enhance acuity over sensitivity, prioritizing visual discrimination of different kinds of threat, such as contaminated foods or disease vectors (Chapman & Anderson, 2012; Rozin et al., 2000; Sherman et al., 2012).

This functional tradeoff between sensitivity and acuity is a familiar division in the visual system, from retinal rods and cones to the crude but fast magnocellular and slow but sharp parvocellular systems (Livingstone & Hubel, 1987), which are carried on to the dorsal and ventral streams for processing "where" and "what" information, respectively (Ungerleider & Mishkin, 1982). The optical tradeoff suggested by our model predicted that expressive actions that alter the eyes' capacity to gather and focus light may have arisen from a differential need to filter light information toward the "where" (magnocellular) versus "what" (parvocellular) channels, in a situation-appropriate manner.

We tested this optical tradeoff hypothesis in experiments that used standard optometric measures of visual sensitivity and visual acuity. In a psychophysical contrast-sensitivity task, eye-widening fear expressions enhanced visual sensitivity, whereas disgust reduced it. Conversely, in a visual acuity task using standardized eye charts (Bailey & Lovie, 1976), eye-narrowing disgust expressions enhanced acuity, whereas fear reduced it (Figure 29.3c; Lee, Mirza, Flanagan, & Anderson, 2014).

Continuous Physical Dimension

Across the nasal and visual experiments, we also found reliable, linearly increasing effects from disgust to fear (Susskind et al., 2008; Lee et al., 2013, 2014). The clearest demonstration of this was in the sensitivity measures eye aperture, where degree of eye opening across participants and conditions was directly related to central sensitivity effects (Figure 29.3d). This suggests that these sensory effects are tied to a continuum of expressive action tendencies rather than discrete facial configurations, emphasizing the underpinning of a physical nature, rather than psychological categories. The physical underpinning of these sensory effects, which can occur in the absence of their discrete emotions, such as fear and disgust and their associated autonomic expression, suggest that the egocentric functional dimension of eye opening may extend to other expressions (e.g., raising eyebrows in surprise or lowering them in anger; Susskind & Anderson, 2008). This availability of continuous physical form and the degrees of influence on egocentric changes also leaves open a potentially wider and more complex window into the intentions of the expresser (Baron-Cohen et al., 1997, 2001; Du et al., 2014) and cultural variance in their interpretation and emergence (Aviezer et al., 2012; Elfenbein & Ambady, 2003; Marsh et al., 2003; Fridlund, 1997; Jack et al., 2012; Russell & Barrett, 1999).

Increasing evidence suggests that emotions influence the central nervous system at multiple levels to alter perception (e.g., Krusemark & Li, 2011; Li, Howard, Parrish, & Gottfried, 2008; Sherman et al., 2012; Todd, Talmi, Schmitz, Susskind, & Anderson, 2012). The collective evidence here shows that emotional expressions can exert potent effects at the earliest stage of sensory encoding. These effects are consistent with the theorized functions of fear and disgust (Chapman & Anderson, 2012; Öhman & Mineka, 2001; Rozin et al., 2000; Sherman et al., 2012; Whalen, 1998) and the distinct processing dynamics proposed for fear and disgust (Anderson et al., 2003), as the opposing sensory and perceptual effects discussed in this chapter shed light on why these two negatively valenced and avoidance action-related emotions are associated with opposing facial actions (Susskind et al., 2008) and opposing effects on the autonomic nervous system (de Jong, van Overveld, & Peters, 2011; Levenson, 1992). For example, specific to the eyes, the functions of their expressive widening and narrowing may converge with the sympathetic dilation and parasympathetic constriction of the pupil (Beatty & Lucero-Wagoner, 2000), potentially acting as the initial filters toward the magnocellular (dorsal) and parvocellular (ventral) visual streams (Ungerleider & Mishkin, 1982).

It is important to note that the expressive effects here are attributable to direct sensory differences rather than indirect effects of facial feedback (e.g., Strack, Martin, & Stepper, 1988) or emotional embodiment (Niedenthal, 2007). In the sensitivity experiment, measurement of pupil size found no differences during posing expressions (indicating a lack of autonomic feedback) and no differences in behavioral tendency, measured by fixations away from center to peripheral targets (Lee et al., 2014). However, in full-fledged emotional expressions, we would expect these egocentric sensory functions to be further augmented—for instance, in fear, its eye-widening light sensitivity may be amplified by an increase in sympathetic autonomic tone (Levenson, 1992) that dilates the pupils, and the further conjunctive retracting of the eyelids through the involuntary, sympathetically innervated Müller's muscle (Brunton, 1938).

While expressive forms may have been functionally shaped to modulate the expresser's sensory intake, the modern utility of our expressions extends beyond the self to serve as social signals. We next examine evidence on how such allocentric function may have been co-opted from egocentric functional forms.

Allocentric Function

To examine how expressions' interpersonal function may have been co-opted from personal function, we focused on the eyes. The eyes are an important source of social information (e.g., Marsh, Adams, & Kleck, 2005; Smith, Cottrell, Gosselin, & Schyns, 2005), with the capacity to communicate a wide variety of complex mental states (Baron-Cohen et al., 1997, 2001). Indeed, circumscribed brain regions in the superior temporal sulcus and gyrus, which are responsive to eye information (Allison, Puce, & McCarthy, 2000; Calder et al., 2007), neighbor regions supporting how we read the mental states of others (in the temporoparietal junction; Saxe & Powell, 2006). Convergently, increasing failure to use the information conveyed by the eyes has been positively related with degrees of autism, a disorder tied to failures in the ability to understand the expresser's mental states (Baron-Cohen, 1995).

Prior work has also examined how emotional expressions influence processing of eye gazes. For instance, fear expressions facilitate faster judgments of averted gaze compared with direct gaze (Adams & Franklin, 2009) and, inversely, that averted gaze enhances the perceived intensity of fear (Adams & Kleck, 2005). Fear expressions' directional eye gazes have also been shown to deploy additional attention in the context of an attentional cueing paradigm (Putman, Hermans, & van Honk, 2006; Tipples, 2006). These eye gaze effects are hinged to the communicated emotion and illustrate a congruent social utility of eye gazes with fear expressions in facilitating a state of vigilance in the observer as well as fear's expresser—the state of alarm whose reverberation in the observer acts as the catalyst (e.g., Harrison, Singer, Rotshtein, Dolan, & Critchley, 2006).

Physical Signal

In our examination, we tested the benefits of fear expressions on the eye gaze signal at a more basic, physical signal level. We predicted that wider fear eyes would capitalize on the morphology of our eyes, such as the additional contrast provided by our white sclera thought to have coevolved with our social nature (Kobayashi & Kohshima, 1997). The enhancement of this physical signal in expressive eye widening would serve as the most expedient social signal of a significant event's location by way of a clearer "look here" gaze signal. Thus, the potential personal sensory benefit of eye widening would be directly conferred interpersonally prior to, or independent from, the need for the communicated emotion of the expresser.

We created schematic eye stimuli using modeled (Cootes et al., 2001) expressions of fear and disgust, and removed the rest of the face, which reduced their emotional perception (Lee et al., 2013) in order to impoverish any emotional influence of the full expressions while retaining the basic physical features. We then created four different eye sizes, from narrowest disgust to widest fear (Figure 29.4a), of which participants judged the gaze directions. We found accuracy of gaze direction judgment linearly increased with increased eye widening (Figure 29.4b).

Given that mere greater exposure of eye whites can activate the amygdala (Adams, Gordon, Baird, Ambady, & Kleck, 2003; Whalen et al., 2004) and widened eyes are sufficient to recognize fear (Smith et al., 2005), the recruitment of emotional circuitry as well as some degree of emotion contagion (Harrison et al., 2006) in modulating these effects was possible. To control for this, we used the same eyes inverted, as inverted fear expressions have demonstrated reduced fear perceptions (McKelvie, 1995), reductions in amygdalar activity (Sato, Kochiyama, & Yoshikawa, 2011), and attentional orienting (Bocanegra & Zeelenberg, 2009; Phelps, Ling, & Carrasco, 2006; although they have been shown to retain some of their affective influences; Lipp, Price, & Tellegen, 2009). Indeed, the inverted schematic eyes reduced the perception of fear but provided the identical physical gaze signal and retained the same enhancement in gaze

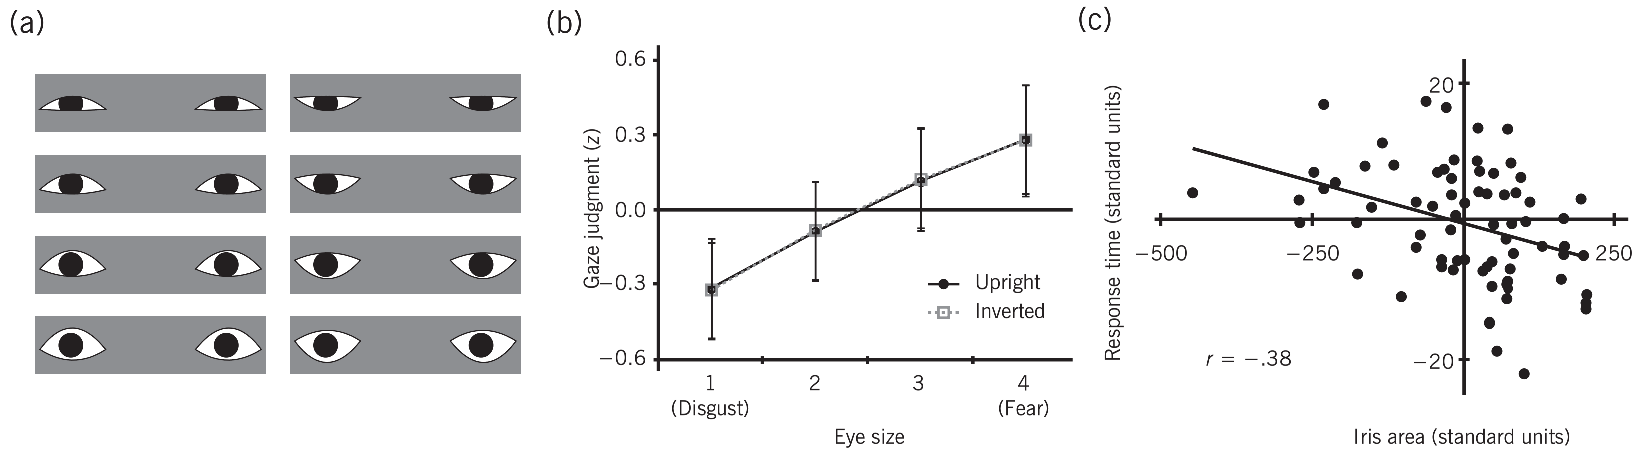

FIGURE 29.4. Allocentric physical signaling effects of eye widening. (a) Schematic eyes were modeled from participants who posed disgust expressions (top images; Size 1) and fear expressions (bottom images; Size 4). Intermediate Sizes 2 and 3 were interpolated linearly from Size 1 to 4 in equal steps of vertical aperture. Eyes in the right column are inverted versions of eyes in the left column. All eyes are gazing the same degree, slightly left of center. (b) Plot shows standardized scores of logistic regression slopes for each eye size for upright and inverted eyes. Accuracy of gaze direction judgments increased with eye widening, but not eye inversion. Error bars represent SEM. (c) Plot shows response time negatively correlated to visible iris information. Participants responded faster to peripheral targets cued by wider eye gazes that revealed more iris. Adapted from Lee et al. (2013).

judgment accuracy for wider eyes (Figure 29.4b; Lee et al., 2013).

Separately, we examined whether fear eye widening would directly facilitate observer responsiveness in locating peripheral targets (i.e., to “look here”). In a gaze-cueing experiment, we used the same schematic eyes and found that participants responded faster to cued peripheral targets, with response speed related to key physical features of the eyes, contrast, and amount of visible iris (Figure 29.4c; Lee et al., 2013). Further, we found no attentional biasing effect of wider eyes, which further suggested that the effects of the emotionally impoverished gaze stimuli were not due to the communicated emotion, as full fear expressions and their gazes have been shown to bias attention (Vuilleumier et al., 2001; Putman et al., 2006; Tipples, 2006).

The importance of the physical signal of our eye gazes is highlighted in the features that are enhanced in fear’s eye widening, which provide no direct function for the expresser. For example, the additional exposure of our physically salient white sclera, unique among primates (Kobayashi & Kohshima, 1997), suggests an additional social function supported by expressive eye widening. Thus the egocentric sensory benefits of fear may have had a direct influence in shaping their allocentric benefits—by the single expressive action of eye widening that augments its physical saliency, fear’s sensory function may be directly linked with that of the observer. In this way, the functional benefit of expressive fear at its basic sensory level in locating potential threat is passed on to the observer through transmission of a clearer “look here” gaze signal, highlighting the coevolution of egocentric and allocentric sensory functions of expressions.

Retracting the eyelids and eyebrows has likely resulted from multiple selective pressures. One such pressure may be the coevolution of an enhanced processing of events in the visual field of the expresser passed on to the observer. The basic, physical utility of this function may have been selected prior to expression’s modern utility of communicating a particular emotion or mental state (Shariff & Tracy, 2011). Convergent evidence also suggests the interaction of these pressures toward a congruent social function, such as the emotionality of full fear expressions enhancing averted gaze direction processing (Adams & Franklin, 2009). Further linking allocentric to egocentric function, fear expressions have also shown to improve early vision for observers (Phelps et al., 2006), specifically along lower spatial frequency channels (Bocanegra & Zeelenberg, 2009), which is aligned with fear expressions’ prioritized perception and action via the low-spatial-frequency-tuned-magnocellular pathway, projecting to the dorsal stream (Vuilleumier, Armony, Driver, & Dolan, 2003; West, Anderson, Bedwell, & Pratt, 2010).

Summary

The purpose of this chapter was to bridge a gap in our understanding of facial expressions: why they look the way do and how they were shaped to be the varied social communicative signals of today. Our thesis is that of Darwin (1872/1998), who posited that our facial expressions originated for sensory function to provide egocentric benefits to the expresser, which were then socially co-opted for allocentric function to the expressions’ observers.

In the broader context of facial expression research, this egocentric-to-allocentric functional perspective supports an integration of categorical and dimensional views. It holds the categorical view of expressions (Ekman, 1999; Izard, 1994) to the degree that basic expressions such as fear and disgust represent higher-order probabilities organized by lower, adaptive actions as opposites along a dimension of an expressive continuum (Oosterhof & Todorov, 2008; Russell & Barrett, 1999; Susskind et al., 2008). Thus, basic expressions are not considered strong universal categories, but the evidence for their functional origins provides a parsimonious, empirical account of their cultural consistency (Ekman et al., 1969; Ekman & Friesen, 1971). Then, rather than the emergence of new and variant sets of expressive forms across different cultures, it is likely that these invariant, adaptive action tendencies were socially co-opted for communication (Andrew, 1963; Shariff & Tracy, 2011), serving as anchoring sources of invariance in expression perception across cultures and contexts.

The facial actions we tested for egocentric function fell on a sensory regulatory dimension of widening versus narrowing expressive form. The variance afforded by this dimension makes available a variety of facial expressions that can be interpretable as signals of different mental states (Baron-Cohen et al., 1997, 2001; Du et al., 2014) and cultural dialects of expressive communications (Elfenbein, 2013). This perspective accommodates the constructivist view in that the labels that define specific facial actions and their degrees of expressivity (i.e., what the expressions are) is left up to social interpretation and context (e.g., Aviezer et al., 2012; Fridlund, 1997; Jack et al., 2012; Russell & Barrett, 1999). However, an important consequence of this functional perspective is how it may provide guiding constraints for understanding why our expressions as social signals look the way they do. While features could be arbitrarily mapped for communication, they cannot be arbitrarily mapped for function (Darwin, 1872/1998; Susskind et al., 2008). For example, from a strictly constructivist perspective (Barrett, 2006a, 2006b), widening and narrowing of the eyes may not universally characterize fear and disgust expressions, especially given the powerful influences of culture (Jack et al., 2012) and social context (Aviezer et al., 2008, 2012) on perception of facial expressions. So if fear and disgust expressive forms were swapped, they would serve equally well as social signals of mental states but have misaligned functional consequences (e.g., reducing acuity in disgust, or making it harder to tell where someone is gazing during fear). Evidence that these functionally driven features serve as guides for social interpretation is supported by the fact that powerful contextual effects do not cause narrow-eyed expressions to be judged similarly to wide-eyed ones, and vice versa (Aviezer et al., 2008).

We found adaptive sensory effects for both fear-widening and disgust-narrowing expressions, aligned with their theorized emotion functions. However, despite symmetrical opposing form, they did not necessarily exhibit symmetry in function. For example, in contrast to a visual field enhancement in fear, its reduction in disgust arguably confers no functional benefit. And anatomically, while a sympathetically innervated Müller's muscle may further retract the eyes, there is also no opposing, parasympathetically innervated muscle that further closes the eyes. This asymmetry in functional needs was also seen in the utility of these expressions to their receivers, as only wider fear eyes conferred the benefit of enhanced gaze judgment. Physically speaking, fear and disgust both communicate negative emotional states, thus being equal potential targets for attention, but the salience of the signal transmitted by their eyes is biased toward fear. This asymmetric salience of eye widening may also enhance detection of these expressions from afar (Smith & Schyns, 2009), in addition to transmitting a clearer "look here" signal, both aligned with fear's selective pressures toward rapid processing of distal, moving threats, as compared with disgust that tracks proximal, stationary ones (Anderson et al., 2003). That is, fear and disgust are both threat responses of different kinds, with the former more appropriate for a potential predator or looming threat and the latter for a potential disease vector (Chapman et al., 2009; Chapman & Anderson, 2012; Rozin & Fallon, 1987; Rozin et al., 2000). Further social exaptation of fear's association with sensitivity and immediacy in action is evidenced in fear expressions' relationship with the magnocellular system, in their perceptual prioritization (West et al., 2010), and low-spatial-frequency tuning (Bocanegra & Zeelenberg, 2009; Vuilleumier et al., 2003). In contrast, we predict that encoding of disgust expressions would be slower and more attentionally gated (Anderson et al., 2003), dependent on the ventral parvocellular system and high-spatial-frequency analysis.

Looking forward, this functional perspective of expression form may further serve as a useful guide for navigating the complex ways that facial information can interact with our social nature. For instance, neuroimaging evidence has shown that amygdala activations toward fear expressions are enhanced for members of one's own culture, suggesting greater saliency attributed to potential threats toward ingroup members (Chiao et al., 2008). Also, the pedomorphic features of fear's wide eyes have been shown to solicit more socially sympathetic responses from neighbors (Marsh, Ambady, & Kleck, 2005), thereby reciprocating the signaling function transmitted by the expresser. The overlearning of these socially coopted expressive facial features (Zebrowitz, 1997) can also convey traits that are more enduring than transient mental states, such as sexual orientation (Rule, Ambady, Adams, & Macrae, 2008) and political affiliation (Rule & Ambady, 2010). These overlearned features combined with how our social nature feeds back on itself may explain the self-fulfilling prophecies of how faces that communicate competence can predict election outcomes (Todorov, Mandisodza, Goren, & Hall, 2005) and financial measures of success (Rule & Ambady, 2008).

Notes

1. It is worth noting that Darwin (1872/1998) stated that these opposing forms sometimes may not serve any function.
2. Using 20 facial action coding units, bilaterally where applicable, each of which may contract independently at five different levels of intensity.

3. The odds of winning the jackpot is one in 2.9×10^8. Winning two jackpots is the number squared: one in 8.5×10^{16}.
4. An immediate physical utility distinguishes itself from the more distant social utility. Expression forms selected for social utility could also be considered "evolutionary" and functionally "egocentric." However, purely symbolic associated forms for social utility need not have any physical utility.
5. For some visual experiments, we left out the facial actions of the lower face in fear and disgust, to maintain fixation and head stability on the chin rest (Lee et al., 2014).

PART V

Cognitive Perspectives

CHAPTER 30

Emotional Intelligence

Marc A. Brackett, Susan E. Rivers, Michelle C. Bertoli, and Peter Salovey

A quarter of a century has passed since Salovey and Mayer (1990) introduced the first formal model of emotional intelligence into the scientific literature and demonstrated how aspects of it might be measured (Mayer, DiPaolo, & Salovey, 1990). Synthesizing research from developmental and social psychology with an emerging literature on mental abilities, they defined emotional intelligence as "the ability to monitor one's own and others' feelings and emotions, to discriminate among them and to use this information to guide one's thinking and actions" (Salovey & Mayer, 1990, p. 189). Today, several thousand publications have cited that article. Research on emotional intelligence, its correlates, and its applications has flourished, and efforts to enhance individuals' emotional intelligence have proliferated across the globe. Former British Prime Minister Tony Blair recently asserted that "one big change in what kids should learn is the need to nurture creative thinking and emotional intelligence" (Global Ed & Skills, 2014). High-ranking business schools have added emotional intelligence screenings to their battery of entrance assessments to help determine which students are likely to be top performers (Korn, 2013). The University of Málaga in Spain now offers a master's degree in emotional intelligence.

These developments belie the construct's initial reception. At first, the concept that individuals might differ in their ability to reason adaptively with and about emotions did not sway many within academia; in fact, it elicited criticism (see Mayer & Salovey, 1993). For one thing, as emotion researcher Joseph LeDoux (2000, p. 156) noted, "emotion research was a victim of the cognitive revolution" of the mid-20th century. For some time, the cognitive psychological approach to explaining human behavior overshadowed interest in emotion (Neisser, 1967). The 1980s and 1990s saw a surge of interest in affective science (Barsade, Brief, & Spataro, 2003), but even then, the idea of an emotional intelligence—with its emphasis on individual differences—ran counter to existing trends in emotion research. Only within the last decade, roughly, have neuroscientists increasingly begun to appreciate the value of individual neurobiological differences in emotion processing (e.g., Eugène et al., 2003; Hamann & Canli, 2004). Prior to that, neuroscience tended to focus on universal processing trends, considering individual differences to be statistical "noise" (Hamann & Canli, 2004; Plomin & Kosslyn, 2001). Such "noise" distracted from a century-long endeavor to first agree upon the provenance of emotions within the human organism (i.e., the brain as opposed to visceral organs) and then to map the general neural circuitry underlying emotional experience in animals and humans (see Davidson, Jackson, & Kalin, 2000, for a concise historical summary). Moreover, theories and measures of intelligence had long been concerned mainly with the *g* factor (Spearman, 1904), general intelligence conceptualized as interrelated cognitive capacities like abstract and mathematical reasoning (e.g., Sattler, 1982; Spearman, 1927; Wechsler, 1939). Finally, emotional intelligence had to overcome an entrenched view of emotions as destabilizing, disorganized forces that prevent logical reasoning (e.g., Lefford, 1946; Young, 1943). That mistrust of emotions has roots in Stoic philosophy, which presumed that the self-centeredness of emotional experience precluded its leading people to act in rational (i.e., moral, altruistic) ways (see Lyons, 1999).

However, an undercurrent of insight into the possible existence of distinct intelligences, including social intelligence (Thorndike, 1920), gained momentum as the latter part of the 20th century drew to a close. It manifested in the proposal of a "cognitive loop" among mood and judgment (Isen, Shalker, Clark, & Karp, 1978), Gardner's (1983/1993) theory of multiple intelligences, and Sternberg's (1985) triarchic theory of intelligence. By questioning the view that IQ was the prime determinant of success in life, these and other investigations into the link between emotion and cognition (e.g., Damasio, 1994) laid the groundwork for the "affective revolution" some argue is now under way (Barsade et al., 2003).

The book *The Bell Curve* (Herrnstein & Murray, 1994) may have pushed the tipping point; it lent a particularly controversial voice to the argument that IQ is preeminently predictive. The authors linked IQ to social class and race in a manner that sparked considerable backlash (see Lynn, 1999) and prompted the American Psychological Association to assemble a task force on the state of intelligence research (Neisser et al., 1996). One year after the publication of *The Bell Curve*, psychologist and reporter Daniel Goleman (1995) published a trade book—*Emotional Intelligence*—that provided a unique counterpoint to *The Bell Curve*'s polemic assertions (see Cartwright & Pappas, 2008; Matthews, Zeidner, & Roberts, 2002). Goleman presented a persuasive articulation of what audiences inflamed by *The Bell Curve* likely wanted acknowledged: that there are ways to be smart beyond what standardized intelligence tests measure (e.g., Mayer, Salovey, & Caruso, 2000). Indeed, some have remarked that "the EI construct gives hope for a more utopian, classless society" (Zeidner, Matthews, & Roberts, 2009, p. xii). Goleman's book quickly climbed the *New York Times* best-seller list and catapulted emotional intelligence to prominence on the international stage. It was then that the term "emotional intelligence" came into wide usage among the general public and researchers (for instance, a search on Google Scholar returns 32 results for publications with "emotional intelligence" in the title in the 20 years before Goleman's book was published, and over 10,000 results in the 20 years following). But along with that popularization came many misconceptions about the infant construct. Perhaps most problematic, as others have argued (e.g., Zeidner, Roberts, & Matthews, 2002), Goleman's (1995a) description of the construct encompassed a plethora of valued, nonintellectual human characteristics (e.g., motivation, persistence, willingness to delay gratification, hope; p. 34) that are beyond the scope of emotional intelligence, strictly defined. Thus, in the two decades that have followed, science has had to work to catch up to—and put into perspective—the hype.

In this chapter, we describe the four-branch ability model of emotional intelligence (Mayer & Salovey, 1997; Salovey & Mayer, 1990) and its measurement. We review the correlates of emotional intelligence in several domains of functioning and outline approaches to developing the four emotional intelligence abilities. We consider current limitations and areas of controversy in the field and conclude by proposing promising directions for expanding our understanding of the construct.

The Ability Model of Emotional Intelligence

Emotions are a critical source of information about the environment (e.g., Levenson, 1994; Schwarz, 1990; Schwarz & Clore, 1983) that can organize and direct cognitive activities and behaviors in adaptive ways (e.g., Darwin, 1872; Frijda, 1986; Izard, 1971; Leeper, 1948; Salovey & Mayer, 1990; Schwarz & Clore, 1983). Emotions may signal to us, among other things, that we are in harm's way (fear), have experienced something pleasurable and should strive to repeat it (happiness), our access to something we need or desire is being blocked (anger), or that we have lost something important (sadness). (See Ekman, 1992, 1994, for a discussion of basic emotions and their common antecedent events.) The functional utility of emotions has been established since Darwin's (1872) time, but what was novel about emotional intelligence theory when it was introduced was its assertion that individuals might *vary* in their ability to make advantageous use of the information emotions impart.

In 1997, Mayer and Salovey revised their original (Salovey & Mayer, 1990) definition of emotional intelligence to refine and outline more specifically the abilities the construct encompasses. They wrote:

> Emotional intelligence involves the ability to perceive accurately, appraise, and express emotion; the ability to access and/or generate feelings when they facilitate thought; the ability to understand emotion and emotional knowledge; and the ability to regulate emotions to promote emotional and intellectual growth. (p. 10)

The distinct but related mental aptitudes identified in this definition constitute the four-branch or ability model of emotional intelligence. Other models have emerged as the concept has gained traction (Cherniss, 2010) such as the Bar-On (1997, 2006) model, which includes intrapersonal and interpersonal skills, general mood, adaptability, and stress management; the Boyatzis–Goleman model (Boyatzis & Sala, 2004), concerned mainly with social and emotional competencies considered pertinent to performance in the workplace; and the trait emotional intelligence model (Petrides & Furnham, 2001; Petrides, Pita, & Kokkinaki, 2007), consisting of sociability, emotionality, well-being, and self-control. These models represent "mixed models" of emotional intelligence, so-called because they "mix" some skills from the ability model (e.g., perceiving emotion) with elements of personality and behavioral preferences such as assertiveness and self-esteem (see Mayer, Roberts, & Barsade, 2008; Mayer, Salovey, & Caruso, 2008). Trait emotional intelligence proponents posit that the construct "encompasses . . . empathy, impulsivity, and assertiveness as well as elements of social . . . and personal intelligence" (Petrides & Furnham, 2003, p. 278). Bar-On (1997) proposed that emotional intelligence includes, among other preferences and traits, optimism and the *perceived* ability to manage relationships.

Mayer and Salovey (1993) cautioned against confusing behavioral preferences with intelligence, writing, "Although a trait such as extraversion may depend on social skill, or result in it, a trait is a behavioral preference rather than an ability. Knowing what another person feels, in contrast, is a mental ability" (p. 435). When conceptualized as a set of mental abilities, emotional intelligence is not only a new, distinct psychological variable, it also meets the criteria for a standard intelligence (Carroll, 1993; Fancher, 1985). Specifically, ability emotional intelligence (1) is a set of mental abilities that (2) are distinct from but correlated with one another and with abilities included in other recognized intelligence frameworks, and that (3) increase with age and experience (Mayer, Caruso, & Salovey, 1999; Mayer, Salovey, Caruso, & Sitarenios, 2001; Rivers et al., 2012). In contrast, emotional intelligence conceptualized—as in mixed models—as a combination of personality traits, behavioral preferences, and perceived mental abilities overlaps with other variables. This makes discerning its unique impact on outcomes of interest complicated at best (Brackett & Mayer, 2003; Brackett, Rivers, Shiffman, Lerner, & Salovey, 2006). This is one reason researchers have criticized the use of "emotional intelligence" as a catchall term for valued noncognitive qualities (e.g., Daus & Ashkanasy, 2003; Joseph & Newman, 2010; Zeidner, Roberts, & Matthews, 2004). A construct that is defined too broadly risks becoming meaningless if the aim is to investigate its unique relationship to important life outcomes and to understand how it can be targeted via intervention. Emotional intelligence, understood and assessed as a discrete mental ability, incrementally predicts certain outcomes (e.g., social effectiveness) over and above general intelligence and personality (see Mayer, Salovey, et al., 2008). It is presumably for these reasons that the four-branch model has been called the "gold standard" in emotional intelligence research (Daus & Ashkanasy, 2003, p. 72). The remainder of this chapter focuses on the ability model and its measurement and correlates, beginning with a delineation of the model's four branches.

The Four Branches of the Ability Model

Mayer and Salovey's critical review of the literature on intelligence, emotion, and the relationship between the two resulted in the four-branch model of emotional intelligence, which encompasses perceiving emotion, using emotion to facilitate thought, understanding emotion, and regulating emotion (Mayer & Salovey, 1997; Salovey & Mayer, 1990). Each of these abilities is described here.

Perceiving Emotion

The first branch of emotional intelligence is the ability to accurately perceive and appraise emotions in the self and others. This ability supports humans' innate tendency to be social. As one prominent social psychologist has written, "Social living is only possible because humans possess an elaborate cognitive capacity to perceive and evaluate others, infer their intentions, and respond with sophisticated and highly adaptable interpersonal strategies" (Forgas, 2006, p. 270). Individuals skilled in emotion perception can identify emotions in their own physical states and thoughts as well as in others' facial expressions, vocalizations, postures, and movements. They can also discern emotion in cultural artifacts such as works of art. They are able to express their emotions and the needs related to them. A more advanced skill on this branch is the ability to determine whether or not an emotional expression is genuine. Individuals' ability to perceive emotions in others' faces, voices, and movements begins in infancy (e.g., Flom & Bahrick, 2007; Nelson & Dolgin, 1985; Schwartz, Izard, & Ansul, 1985; Walker-Andrews, 2005; Zieber, Kangas, Hock, & Bhatt, 2014) and forms the foundation for the other emotional skills. Once emotion perception abilities are established, using, understanding, and regulating emotions become possible (Joseph & Newman, 2010; Mayer et al., 1999; Mayer & Salovey, 1997).

Using Emotion to Facilitate Thought

Consistent with a foundational premise of emotional intelligence—that emotions can assist cognitive processing—the second branch of the ability model encompasses individuals' capacity to leverage emotions to facilitate cognitive activities like problem solving. Individuals equipped with this skill can determine which activities may benefit from the emotion they are currently experiencing, and can also generate the emotions most likely to facilitate tasks that need to be done. For instance, research supports a significant link between pleasant, high-arousal emotions (e.g., happiness) and creative, original thinking (Baas, De Dreu, & Nijstad, 2008; Fredrickson, 1998; Jamison, 2005; however, see also Hunsinger, Isbell, & Clore, 2012). In contrast, unpleasant, high-arousal emotions like fear are associated negatively with cognitive flexibility (Baas et al., 2008). However, unpleasant emotions do appear to be better suited than pleasant ones for deductive reasoning tasks (Palfai & Salovey, 1993) and making contingency judgments (Schwarz & Bless, 1991). According to the ability model, someone skilled in using emotions is more likely to take advantage of a pleasant, high-energy emotion to brainstorm or generate new approaches to a problem.

Understanding Emotion

The ability to understand the causes and consequences of emotions falls under the third branch of the framework. A basic skill on this branch is labeling emotions accurately and understanding that different emotion words are related (e.g., "joyful" and "elated" are nuanced experiences of "happy"). Individuals vary in their ability to label qualitatively distinct emotional experiences with different emotion words (Barrett, 1998; Barrett, Gross, Christensen, & Benvenuto, 2001; Feldman, 1995). For example, one person may report feeling "mad" or "bad" after any unpleasant event while another person specifies that one event caused "frustration" while another caused "despair." This phenomenon is referred to as emotion differentiation or emotion granularity (Barrett et al., 2001). Research has linked greater emotion differentiation—especially for unpleasant emotions—to lower levels of depression (Demiralp et al., 2012; Erbas, Ceulemans, Lee Pe, Koval, & Kuppens, 2014) as well as less neuroticism and higher self-esteem (Erbas et al., 2014). Theoretically, these findings can be attributed to high differentiators' greater understanding of the causes and consequences of a variety of emotions, which should allow them to respond to and regulate emotions more adaptively (Erbas et al., 2014; Schwarz, 1990). Individuals who label unpleasant emotions in a granular way tend to regulate unpleasant emotions more frequently, and by employing a larger repertoire of strategies, than those who describe their emotional experiences in broader strokes (Barrett et al., 2001).

Other skills on the third branch include recognizing why certain emotions occur (e.g., accomplishing a goal causes pride), foreseeing the trajectory of an emotion that goes unregulated (e.g., sadness can degrade into hopelessness), surmising what occurred to change one emotion into another (e.g., anger transitions to satisfaction when an injustice is righted), and understanding how multiple emotions can "blend" to form another emotion (e.g., disgust and anger combined become contempt). Although not made explicit in this model, to understand emotions fully one also should take into account the historical and cultural contexts in which they are experienced. For example, individuals displaying acedia (sloth) in the early Christian Church and modern-day sufferers of depression may share feelings of apathy. However, acedia was considered to be a cardinal sin, while depression is increasingly explained in terms of neurochemical imbalances that have no bearing on one's moral standing (Frevert, 2011). Thus,

> Even if there are signs of acedia . . . and depression that resemble each other, the labeling, framing and contextualising of those signs are vastly different. Relating the symptoms to diverse systems of reference (magic, religion, arts and sciences, neurobiology) affects the value attributed to them. This in turn affects the appraisal and experience of those states. (p. 36)

As emotional intelligence matures and is examined more thoroughly in light of cultural distinctions and shifts in societal values over time, the need to consider context when assessing the causes and consequences of emotions will only increase.

Regulating Emotion

Individuals' ability to manage their own and others' emotions is the scope of the fourth branch of emotional intelligence. This branch includes skills such as remaining open to experiencing both pleasant and unpleasant emotions, judging the usefulness of a particular emotion in a specific situation, and using effective emotion regulation strategies with consideration for the situational context and desired outcome. Emotion regulation strategies vary in effectiveness. For example, studies have examined the relative efficacy of cognitive reappraisal and expressive suppression. Individuals who reappraise (i.e., construe in a different way in their minds) an event that could potentially elicit a negative emotional response have been found to experience more pleasant and fewer unpleasant emotions and to function better interpersonally and experience greater well-being (Gross & John, 2003). Individuals who engage in expressive suppression (e.g., disguising how they feel) experience the opposite outcomes: more unpleasant and fewer pleasant emotions, less effective interpersonal functioning, and poorer well-being (Gross & John, 2003). In fact, deficits in emotion regulation ability are a hallmark of many psychological disorders—including but not limited to mood disorders—and addressing these deficits directly may significantly aid in the treatment of such conditions (Werner & Gross, 2010). The ability model of emotional intelligence posits that individuals with more refined emotion regulation skills are more likely to choose effective regulation strategies (i.e., those with fewer cognitive and social costs).

In order to demonstrate that these four abilities—perceiving, using, understanding, and regulating emotion—provide an adaptive advantage, we must be able to assess them validly in diverse samples and examine their relationship to domains that are important for successful, healthy functioning. Next, we consider how emotional intelligence is measured and review some of its established correlates.

Assessing Emotional Intelligence

Accumulating research demonstrates that emotional intelligence can be assessed reliably and validly with performance measures, which ask respondents to demonstrate emotional intelligence by completing carefully designed exercises and tasks. Performance measures contrast with self-report (e.g., Bar-On Emotional Quotient inventory [EQ-i]; Bar-On, 2006) and multirater (e.g., Emotional Competence Inventory [ECI]; Boyatzis & Sala, 2004) measures, which ask respondents to estimate and report on their own or others' capabilities rather than to demonstrate them. Although self-report measures offer practical advantages such as being relatively inexpensive, quick, and easy to administer (e.g., Riggio & Riggio, 2001), in most cases these advantages do not outweigh the limitations of this measurement approach. Self-report measures are problematic because they substantially overlap with existing personality measures (Brackett et al., 2006; Webb et al., 2013), capture perceived—not actual—abilities (Paulhus, Lysy, & Yik, 1998), and are susceptible to social desirability bias and faking (Day & Carroll, 2008; Tett, Freund, Christiansen, Fox, & Coaster, 2012). Multirater measures such as the ECI (Boyatzis & Sala, 2004) attenuate some of the limitations of self-report measures by requiring input from at least two different sources, which increases internal validity (Palmer & Stough, 2005). However, the psychometric properties of multirater measures of emotional intelligence are not well established (Cherniss, 2010). For these reasons, using performance measures of emotional intelligence, when feasible, is preferable to using other measurement approaches.

The Mayer–Salovey–Caruso Emotional Intelligence Test (MSCEIT; Mayer, Salovey, & Caruso, 2002b) is the most commonly used performance measure of emotional intelligence in adults, and its validity has been demonstrated in multiple studies (e.g., Brackett & Mayer, 2003; Mayer, Salovey, & Caruso, 2012; Rossen & Kranzler, 2009). The MSCEIT can be completed in approximately 40 minutes, administered either via a computer or paper version of the test. The test assesses each of the four branches of the ability model via two tasks. For instance, the perceiving emotions branch of the test asks respondents to view photographs of human faces and works of art and to identify how much of each of a particular emotion is represented in each picture. The managing emotions branch of the test presents respondents with a series of emotion-laden scenarios and asks them to rate the effectiveness of various strategies for maintaining, reducing, or otherwise regulating the particular emotions highlighted in the vignettes. Five scores are generated for the MSCEIT: an overall emotional intelligence score and four branch scores. The MSCEIT can be scored in two ways (Mayer, Salovey, & Caruso, 2002a): responses are awarded a certain number of points based on the degree of their overlap with *either* responses provided by a large, normative sample (consensus scoring) or those provided by a panel of emotion experts (expert scoring). Consensus and expert scores are correlated highly (Brackett & Salovey, 2006). The Mayer–Salovey–Caruso Emotional Intelligence Test—Youth Version (MSCEIT-YV; Mayer, Caruso, & Salovey, 2005) is a valid performance measure of emotional intelligence in youth ages 10–17 years (Peters, Kranzler, & Rossen, 2009; Rivers et al., 2012). Its language, pictures, and vignettes have been adapted to the adolescent population (e.g., younger faces).

An important consideration when determining the usefulness of an emotional intelligence measure is its relationship to measures of other constructs that, theoretically, should or should not overlap with it. Emotional intelligence, as a cognitive ability, should overlap to some degree with existing intelligence paradigms while still demonstrating unique variance (Mayer et al., 1999). As a measure of mental ability, emotional intelligence theoretically should not overlap significantly with measures of personality or general well-being. A recent meta-analysis found that, indeed, MSCEIT scores correlate positively with measures of verbal, nonverbal, and overall intelligence (Kong, 2014). Conversely, MSCEIT scores are discriminable from measures of well-being and personality, such as the Big Five, while self-report measures such as the EQ-i are significantly less separable from such constructs (i.e., they overlap to a greater degree with personality measures; Brackett & Mayer, 2003). Furthermore, the MSCEIT and self-report measures of emotional intelligence are only minimally related (Brackett & Mayer, 2003). These associations, or lack thereof, lend support to the utility of the MSCEIT for measuring validly the distinct, mental ability to reason with and about emotions. A more thorough comparison of emotional intelligence measures can be found in Mayer, Roberts, et al. (2008).

The MSCEIT and MSCEIT-YV are not without limitations. The tests do not capture the real-time application of emotion knowledge. For example, when someone experiences a strong emotion, is that person able to regulate it effectively in the moment? The current versions of the MSCEIT cannot evaluate this. Additionally, a number of studies have questioned the four-factor structure of the tests (e.g., Maul, 2011). In particular, there is some evidence to support the potentially superior fit of a three-factor structure that does not include the second branch: using emotions to facilitate thought (e.g., Fan, Jackson, Yang, Tang, & Zhang, 2010; Maul, 2011; Palmer, Gignac, Manocha, & Stough, 2005). Despite these limitations, converging evidence suggests that, of the assessments currently available, the MSCEIT measures emotional intelligence most reliably (Jordan, Dasborough, Daus, & Ashkanasy, 2010). Next, we describe the correlates of emotional intelligence as assessed by the MSCEIT and the MSCEIT-YV.

Correlates of Emotional Intelligence as Measured by the MSCEIT

Due in part to the many disparate definitions of emotional intelligence that emerged after the concept was proposed (e.g., Cherniss, 2010), extraordinary claims have been made about its significance; for instance, that "a highly developed emotional intelligence will make you a candidate for CEO or a brilliant trial lawyer" (Goleman, 1997, p. 76). While being emotionally intelligent is no guarantee of achieving great success in any particular field, evidence accumulated over the last 25 years suggests that emotional intelligence—measured as an ability—is related to important outcomes in many domains: particularly, health, relationships, academic achievement, and work performance (see Brackett, Rivers, & Salovey, 2011; Mayer, Roberts, et al., 2008; Rivers et al., 2012, for reviews). We summarize some key associations with the MSCEIT and MSCEIT-YV here. For most of the associations described, correlations range from .15 to .40. Associations that are not statistically significant are not included in this summary.

Emotional Intelligence and Health

One of the ways emotional intelligence appears to facilitate adaptive living is through its relationship to health outcomes. A recent meta-analysis demonstrated that individuals higher in emotional intelligence experience better physical, mental, and psychosomatic health (Martins, Ramalho, & Morin, 2010). Among adolescents, emotional intelligence appears to predict mental health (i.e., higher scores correlate with less depression and fewer conduct problems) over and above personality and cognitive ability (Davis & Humphrey, 2012) and to protect against suicidal behavior (Cha & Nock, 2009). Additionally, it appears that emotional intelligence protects against engagement in health risk behaviors for both adults and adolescents. Adolescents higher in emotional intelligence are less likely to use alcohol (Trinidad & Johnson, 2002) or smoke cigarettes, and report lower intentions to smoke cigarettes (Duncan et al., 2013; Trinidad & Johnson, 2002; Trinidad, Unger, Chou, & Johnson, 2004). Among college students, higher emotional intelligence has been linked to lower rates of substance abuse, adjustment problems, and aggressive behaviors (Rivers, Brackett, Omori, et al., 2013). Among adult males, lower emotional intelligence has been linked to increased use of illegal drugs and alcohol (Brackett, Mayer, & Warner, 2004). While the relationship between emotional intelligence and broad health categories (i.e., physical, mental, and psychosomatic) is well established (Martins et al., 2010), more research is needed to expand knowledge of the associations between emotional intelligence and specific health difficulties and risky behaviors, as well as the mechanisms underlying the associations.

Emotional Intelligence and Interpersonal Functioning

Emotional intelligence is thought to contribute to successful interpersonal functioning by equipping individuals with the tools needed to assess and understand others' emotions and points of view, and to communicate about and manage their own and others' emotions more effectively. Individuals higher in emotional intelligence are perceived by peers to be more interpersonally sensitive than those with lower scores (Lopes, Salovey, Côté, Beers, & Petty, 2005). Such individuals also tend to report better relationships with friends, parents, members of the opposite sex, and romantic partners (Brackett, Warner, & Bosco, 2005; Lopes et al., 2004; Lopes, Salovey, & Straus, 2003) and to exhibit more secure attachment styles in adulthood (Kafetsios, 2004) as compared to their counterparts with lower MSCEIT scores. Among men, MSCEIT scores have been shown to predict social competence (Brackett et al., 2006). Adolescents who score higher on the MSCEIT-YV are rated both by themselves and by their teachers as being more socially competent than students with lower scores (Rivers et al., 2012). These and similar findings should not be interpreted, however, as indicating that emotionally intelligent individuals are merely more agreeable (although in some samples there is a modest correlation between the two variables; e.g., $r = .24$ in Brackett et al., 2004). For one thing, the results of most of these studies remain significant after controlling for personality variables (see Brackett, Rivers, et al., 2011). Moreover, it appears that individuals higher in emotional intelligence prefer to feel the emotions that are most useful for a given situation, whether those emotions are pleasant or not (Ford & Tamir, 2012). For example, a person high in emotional intelligence who needs to confront someone is more likely to prefer to feel anger than a more pleasant, but potentially less useful, emotion (Ford & Tamir, 2012). Similarly, a recent study indicates that individuals higher in emotional intelligence demonstrate flexibility when choosing interpersonal strategies (i.e., cooperating *or* competing as is beneficial, as opposed to always cooperating) in a way that maximizes their gains over the long term in a laboratory-based, socially interactive game (Fernández-Berrocal, Extremera, Lopes, & Ruiz-Aranda, 2014). It would appear, then, that individuals high in emotional intelligence may be more interpersonally successful because they are more flexible and responsive to their social circumstances—and the resultant emotions—at any given time. Future research could investigate whether this is the case.

Emotional Intelligence and Academic Achievement

Accumulating data suggest that emotional intelligence is related to academic performance through the former's impact on students' attention, self-regulation, and adaptation in school (Lopes & Salovey, 2004). Among a sample of college students, overall MSCEIT scores correlated with verbal SAT scores (Brackett et al., 2004). In one study, the managing emotions scores of high school students were found to be the best predictor of academic success (DiFabio & Palazzeschi, 2009), even more than grit (Ivcevic & Brackett, 2014), a construct that has taken center stage in the popular press on what children need to succeed (e.g., Tough, 2012). Studies show that measuring emotional intelligence as an ability, compared with self-reports, is a more efficacious method for predicting academic success, as measured by grade point average (GPA; DiFabio & Palazzeschi, 2009) and teacher ratings of academic performance (e.g., Mestre, Guil, Lopes, Salovey, & Gil-Olarte, 2006). The latter study was conducted among Spanish adolescents using the Spanish-language version of the MSCEIT (Extremera & Fernández-Berrocal, 2002), and the relationship between ability emotional intelligence remained significant for boys, but not girls, after controlling for personality and cognitive ability (Mestre et al., 2006). Furthermore, understanding and managing emotions scores were higher among academically gifted—as compared with average—Israeli high school students (Zeidner, Shani-Zinovich, Matthews, & Roberts, 2005). Efforts to teach emotional intelligence skills through evidence-based social and emotional learning (SEL) programs have also been linked to improved academic achievement (Durlak, Weissberg, Dymnicki, Taylor, & Schellinger, 2011), including interventions that target the skills associated with the ability model (Brackett, Rivers, Reyes, & Salovey, 2012). These associations are discussed further in the section "Teaching Emotional Intelligence in the Classroom."

Emotional Intelligence and Professional Performance

Emotional intelligence has been a popular topic in organizational settings since its introduction, spurred in part by such claims as "For star performance in all jobs, in every field, emotional competence is twice as important as purely cognitive abilities" (Goleman, 1998, p. 34). Research *has* linked emotional intelligence to important workplace outcomes including performance and leadership ability, although the associations cannot be characterized as "twice as" predictive as those related to cognitive ability. Recent meta-analyses have found that individuals with higher emotional intelligence scores perform better on the job (Joseph & Newman, 2010; O'Boyle, Humphrey, Pollack, Hawver, & Story, 2011), particularly in the context of jobs requiring more emotional labor (e.g., displaying specific emotions, as would be expected of customer service workers; Côté, 2014; Joseph & Newman, 2010). In two studies, emotional intelligence correlated with leadership emergence, which is the extent to which someone not in an official leadership position exerts influence with his or her colleagues (Côté, Lopes, Salovey, & Miners, 2010). These associations remained significant after controlling for cognitive ability and personality (and no correlations were found between self-reported emotional intelligence and leadership emergence). While individual studies (e.g., Leban & Zulauf, 2004) have shown promising associations between emotional intelligence and transformational leadership—the leadership style in which leaders motivate and inspire their subordinates to work toward a common vision (Bass, 1985; Bass & Riggio, 2006)—a recent meta-analysis (Harms & Credé, 2010) found a relationship only when the same rater assessed both emotional intelligence and transformational leadership. When multiple rating sources were used (e.g., the leader assessed emotional intelligence and a peer or subordinate assessed leadership style), there was no significant relationship between the variables (Harms & Credé, 2010). Future investigations in this area might consider the possible role of emotional intelligence in leaders' decision-making styles, as well as observed leadership styles as opposed to self- or informant ratings of leadership styles. (See Brackett and colleagues, 2013, and Côté, 2014, for more detailed reviews of the literature on emotional intelligence in the workplace.)

Summary

Emotional intelligence, measured as an ability, correlates with important outcomes in the domains of health, relationships, academics, and the workplace, but more work should be done to ascertain the mechanisms by which such associations occur. Furthermore, as the MSCEIT-YV was developed more recently than the MSCEIT, additional investigations into the correlates of emotional intelligence among older children and adolescents should be undertaken. Given the link between emotional intelligence and important life outcomes, emotional intelligence appears to be a desirable set of abilities to possess, and individuals may wonder whether—and how—they can increase their emotional intelligence. We now turn to a consideration of how emotional intelligence might be developed.

Developing Emotional Intelligence

Mayer and Salovey (1997) observed early on that since "most skills can be improved through education . . . it is likely this will hold true for at least some of the skills related to emotional intelligence" (p. 19). Perhaps a less cautious endorsement of this concept is this statement from neuroscientists Davidson and McEwen (2012):

> Just as we as a society are learning to take more responsibility for our physical health by engaging in regular physical exercise, we can also take more responsibility for our minds and brains by engaging in certain mental exercises that can induce plastic changes in the brain and that may have enduring beneficial consequences for social and emotional behavior. This also invites the perspective that qualities such as well-being ought to be viewed, at least in part, as a product of trainable skills and that interventions explicitly designed to promote well-being may have beneficial behavioral and biological effects. (p. 690)

We propose that, as a set of mental abilities or skills that underlie adaptive social and emotional functioning and well-being, emotional intelligence and the training of its component skills may be understood from a similar perspective. Although empirical evidence of the potential for emotional intelligence skill growth has been slow to accumulate, that which does exist is promising. In this section, we review the existing evidence as well as overview the state of efforts to improve emotional intelligence in the home and at school. We also consider how burgeoning technological advancements might expand the reach and format of emotional skill-development endeavors across the lifespan.

Theoretical and Empirical Evidence Related to Developing Emotional Intelligence

Just as we would not expect a person's intelligence to change dramatically over time, it is unlikely that individuals experience *dramatic* shifts in their overall emotional intelligence beyond the natural increase that occurs with age and education. However, it is clear that people can and do learn information about emotions and related skills, and can acquire new emotion language and regulation strategies as they age and accumulate a wider range of life experiences. Indeed, neuroscientists have suggested that "social and emotional characteristics can be educated in ways that are not dissimilar from certain forms of cognitive learning" (Davidson & McEwen, 2012, p. 694). A recent review of the literature supports this assertion; emotional intelligence interventions show promise, with preliminary studies demonstrating a moderate effect size (Schutte, Malouff, & Thorsteinsson, 2013). This review, however, identified only two studies that both used a true experimental, random-assignment design and that assessed participants' emotional intelligence with ability assessments. For instance, one well-designed intervention study showed a significant increase in emotional intelligence among young adults in the treatment group and not the control group, with effects still measurable at a 6-month follow-up (Nelis, Quoidbach, Mikolajczak, & Hansenne, 2009). However, this study used measures of trait and not ability emotional intelligence, so results should be interpreted with caution. There is a need for additional, well-designed investigations into the impact of ability emotional intelligence training.

Despite their limitations, the existing studies Schutte and colleagues (2013) identified provide a foundation for further examinations into the development of emotional intelligence. One study found that athletes randomly assigned to participate in 10 three-hour emotional intelligence workshops had significantly higher MSCEIT scores at posttest than at baseline, and had significantly higher MSCEIT scores than their peers in the control group (Crombie, Lombard, & Noakes, 2011). A second study found similar results among business school students (Reuben, Sapienza, & Zingales, 2009). Participants assigned to a 16-hour, not-for-credit course in emotional intelligence showed a significant gain in overall MSCEIT performance upon course completion, while the pre- and posttest MSCEIT scores of their peers in an attention-control (i.e., business etiquette) course showed no significant change. Whether the effects of either intervention were lasting is unclear and future studies should attempt to replicate the findings and track retention of skills over time. As Lindebaum (2009) cautions, there is a significant difference between short-term training and comprehensive education where emotional intelligence is concerned.

Another well-established finding that bears on our consideration of the potential for teaching emotional intelligence is that individuals' *beliefs* about the malleability of intelligence are linked to achievement (e.g., Blackwell, Trzesniewski, & Dweck, 2007; Hong, Chiu, Dweck, Lin, & Wan, 1999; Stipek & Gralinski, 1996). Specifically, individuals who believe skills can be improved through attention and effort tend to perform better than those who believe intelligence is fixed and unchangeable. Furthermore, comprehensive, evidence-based efforts to shape children's social and emotional development early on in life have been shown to provide clear social, emotional, behavioral, and academic advantages (Durlak et al., 2011). It is for the reasons outlined in this section that we encourage individuals—particularly caregivers and educators—to adopt and promulgate an optimistic view of the potential for developing emotional intelligence. Promising avenues for developing these skills in the home, at school, and by leveraging new technologies are where we now turn.

Parents' Socialization of Children's Emotional Skills

Mayer and Salovey (1997) wrote that "emotional skills begin in the home with good parent–child interaction" (p. 19). Of course, children may be socialized by caregivers other than parents, but for ease of language we use the term "parents" for socializers in the home as opposed to those in the education system. Parents teach children (whether consciously or not) how to behave and interact around emotions through (1) their reactions to their children's expressions of emotion, (2) their discussion of emotions, and (3) their own emotional expressiveness (Eisenberg, Cumberland, & Spinrad, 1998). Children's observation of these modeled behaviors is a key component of emotional development (Bandura, 1977; Morris, Silk, Steinberg, Myers, & Robinson, 2007; Parke, 1994). Families' emotional climate—including the marital relationship and parenting styles—also has an impact on children's emotion socialization and, in particular, emotion regulation ability (Morris et al., 2007). The emotion socialization process is bidirectional; families influence the child's socialization process and the child (via gender, temperament, and other factors) influences the family's actions and responses related to emotion socialization (Eisenberg et al., 1998; Morris et al., 2007).

One prominent theoretical framework of emotion socialization in the home posits that parents' philosophies of emotion fall into two categories: emotion dismissing and emotion coaching (Gottman, 2011; Gottman, Katz, & Hooven, 1996; Katz, Maliken, & Stettler, 2012). According to this theory, called parental meta-emotion philosophy, parents with a dismissing philosophy tend to minimize or deny their children's negative emotions. In contrast, parents who coach emotions are more likely to engage in five behaviors: (1) being aware of children's emotions, even at a low intensity; (2) taking the perspective that emotional expression indicates an opportunity to connect and teach; (3) communicating to children that their emotions are acceptable; (4) helping children label their emotions; and (5) setting appropriate boundaries and/or facilitating emotional problem solving. While this theory is not explicitly based in the ability model of emotional intelligence, it does map on to three of the four branches: perceiving, understanding, and managing emotions. Parents' emotion philosophies appear to predict actual parenting behaviors as well as children's physiological ability to regulate emotions (Gottman et al., 1996). A recent review of the literature related to this theory found that parents' emotion socialization style was related to important child outcomes, including peer relationships and psychosocial adjustment (Katz et al., 2012).

Two interventions based in parental meta-emotion philosophy are Tuning in to Kids (Havighurst, Wilson, Harley, & Prior, 2009) and Tuning in to Toddlers (Lauw, Havighurst, Wilson, Harley, & Northam, 2014). Both programs aim to strengthen parent–child emotional connections by teaching the five-step model of emotion coaching described above via videos, group exercises (such as role plays and discussions), and home activities. A randomized control study of Tuning in to Kids found that after six group sessions and two booster sessions, parents in the intervention group showed improved awareness and regulation, more emotion labeling and coaching behavior, and less emotion dismissing behavior. Children of parents in the intervention group showed increased emotion knowledge (Havighurst, Wilson, Harley, Prior, & Kehoe, 2010). A pilot study of Tuning in to Toddlers revealed that after attending six sessions, parents were rated by themselves and by observers as using more emotion coaching behavior, less emotion dismissing behavior, and a higher level of emotion talk (Lauw et al., 2014). Future evaluations of the program designed for toddlers would be improved by the use of a control group.

As interventions with a basis in this model become more fully developed and available, additional research should be done to determine their impact on actual parenting behavior and child outcomes. Parent training programs and interventions more closely based in the four-branch model of emotional intelligence should also be developed, keeping in mind that it is critical to ensure that emotion socializers themselves are proficient in the perception, use, understanding, and managing of emotions before they can successfully cultivate emotional intelligence in children. This is true for parents or other caregivers in the home, and for teachers in the classroom, where we turn next.

Teaching Emotional Intelligence in the Classroom

Over the past couple of decades, it has become increasingly clear that emotions are central to students' academic, personal, and social success both in and outside of the classroom. In 1994 at a conference hosted by the Fetzer Institute, the term "social and emotional learning" (SEL) was introduced to describe efforts to promote skill building among youth that support positive relationships and well-being throughout life (Elbertson, Brackett, & Weissberg, 2010). The Collaborative for Academic, Social, and Emotional Learning (CASEL) was formed soon after with the mission of integrating SEL into existing academic curricula from early childhood through high school. With hundreds of programs now available that claim to teach social and emotional competencies to students, standards for what constitutes effective SEL programming have been adjusted throughout the years (e.g., Durlak et al., 2011; Elias et al., 1997; Payton et al., 2000). CASEL (*www.casel.org*) has begun to identify and endorse school-based SEL programs ("CASEL SELect" programs; see CASEL, 2012) that meet rigorous standards, including offering quality training and implementation support and being well designed, evidence based, and universal (i.e., implemented across the entire student body and not just select groups of at-risk students).

The positive impact of teaching SEL in schools using high-quality programming has been established empirically. A meta-analysis including over 200 studies of school-based SEL programs found that teachers delivered them successfully and that they significantly enhanced students' social and emotional skills, behavior, attitudes toward school, and academic performance (Durlak et al., 2011). The authors of the meta-analysis identified four components that are critical to successful SEL programs: they should be sequenced, active, focused, and explicit (SAFE; Durlak et al., 2011). Two SEL programs that are rooted in emotion science and meet these SAFE standards are RULER (an acronym for the five key skills of emotional intelligence: recognizing, understanding, labeling, expressing, and regulating emotion), and the promoting alternative thinking strategies (PATHS) curriculum. Here, we overview these programs briefly.

RULER is a schoolwide approach to developing children's emotional intelligence from prekindergarten through high school that was developed at the Yale Center for Emotional Intelligence (Brackett, Kremenitzer, et al., 2011). RULER is grounded in the ability model of emotional intelligence and is designed to enhance emotional skills and improve interactions between and among school leaders, teachers, students, and families. RULER supports educators in using new teaching practices to help children learn about emotions and refine their ability to be self-aware, acquire the language of emotions, and practice emotion regulation skills. For instance, using RULER's Mood Meter, teachers and students develop the skills of emotional intelligence by checking in with and labeling their emotions on a regular basis, examining and understanding the likely causes and consequences of those emotions, and expressing and regulating emotions using effective strategies. In addition to tools that foster empathy, emotional awareness, and effective emotion regulation, classrooms use RULER's Feeling Words Curriculum to support students' attainment of a large "emotions vocabulary" that is contextualized and integrated into routine academic instruction via shared personal stories, discussions of world events, and developmentally appropriate storybooks and literature.

Evidence is accumulating for RULER's positive impact. One quasi-experiment showed that students in middle school classrooms integrating RULER for one academic year had higher year-end grades and higher teacher ratings of social and emotional competence compared with students in the control group (Brackett et al., 2012). A randomized control trial in 62 schools found that classrooms randomly assigned to the RULER intervention had higher degrees of warmth and connectedness between teachers and students, more indicators of student autonomy and leadership, less bullying-related behaviors, and a greater focus on students' interests and motivations, as rated by independent observers of the classrooms (Rivers, Brackett, Reyes, Elbertson, & Salovey, 2013). These first-year shifts in the emotional qualities of classrooms were followed by other improvements: compared with classrooms randomized to the control, business-as-usual condition, independent observers rated classrooms in the RULER condition as exhibiting greater emotional support, better classroom organization, and better instructional support at the end of the second year (Hagelskamp, Brackett, Rivers, & Salovey, 2013). Higher emotional intelligence and more advanced social problem-solving skills were associated with greater fidelity of program implementation (Reyes, Brackett, Rivers, Elbertson, & Salovey, 2012).

The PATHS curriculum (Kusche & Greenberg, 1994) was designed to promote social and emotional development among students who are deaf or hearing impaired (Greenberg & Kusché, 1993) but has since expanded to include students in general education from prekindergarten through sixth grade (see *www.pathstraining.com*). PATHS has its theoretical basis in the affective–behavioral–cognitive–dynamic (ABCD) model of development (Greenberg & Kusché, 1993), which recognizes that children's emotional experience precedes their cognitive and linguistic development, and posits that these affective, cognitive, linguistic, and behavioral systems must be integrated strategically as children develop in order to nurture social and emotional competence. PATHS promotes emotional awareness, understanding, and regulation to help children choose adaptive approaches to interpersonal challenges. PATHS teachers deliver developmentally appropriate lessons at least two times per week throughout the school year. The lessons allow children to practice emotion regulation strategies, to label emotions, and to problem solve about their emotional experiences. PATHS has been shown to decrease students' externalizing and internalizing behaviors and depression, as well as to increase students' emotion recognition and understanding skills, teacher ratings of students' prosocial behavior, and students' social problem-solving skills (Domitrovich, Cortes, & Greenberg, 2007; Greenberg & Kusché, 1998; Greenberg, Kusche, Cook, & Quamma, 1995; Kam, Greenberg, & Kusche, 2004).

Because SEL, like emotional intelligence, has been defined in many ways, standardizing SEL efforts could help to illuminate their impact and moderators (Durlak et al., 2011). SEL is not synonymous with emotional intelligence, and so care should be taken in interpreting outcomes of SEL interventions as evidence for the effects of teaching emotional intelligence. Relatedly, there is currently no comprehensive measure of ability emotional intelligence for children 9 years and younger. This presents a major challenge to researchers' ability to evaluate home- and school-based efforts to enhance emotional intelligence in young children, even though individual measures of the specific subskills that make up emotional intelligence exist for this age range (e.g., the emotion perception "box task," which is not reliant on reading or verbal skills; Russell & Widen, 2002). The development of an omnibus measure-of-ability emotional intelligence in young children would constitute a groundbreaking contribution to the field; it would allow for more thorough and even evaluation of intervention attempts, and would inform our understanding of the timing and nature of the developmental milestones of emotional skill acquisition.

Leveraging Technology to Enhance Emotional Intelligence

Across domains (i.e., homes, schools, and even professional organizations), technology may pave new pathways to developing emotional skills, particularly as it becomes increasingly accessible, portable, and sophisticated. Rosalind Picard and colleagues, working in the Affective Computing Research Group at MIT, use biosensors and long-term measurements of autonomic nervous system function to increase self-awareness and improve emotion regulation in everyday life via a wearable device ("iCalm"; Hedman et al., 2009). RULER's Mood Meter, described above, now is available as an "app" that can be downloaded to mobile devices to allow (and remind) users of all ages to label and track their emotions over time to discover their emotional tendencies and triggers. Going a step further, virtual avatars and robots are increasingly employed to assess users' emotions and aid in emotion regulation (Klein, Moon, & Picard, 2002; Picard & Klein, 2002; Ring, Barry, Totzke, & Bickmore, 2013; Wada & Shibata, 2007). For example, one study found that virtual agents (avatars) that actively engaged isolated older adults and assessed their emotional states succeeded in reducing the users' feelings of loneliness (Ring et al., 2013). This type of interaction has the added benefit of modeling to adults that some unpleasant emotions may be reduced by engaging in social contact. In a similar vein, therapeutic robotic seals introduced into geriatric care settings were found to increase socialization and reduce stress among users, as assessed by video observations and the analysis of hormone levels, respectively (Wada & Shibata, 2007).

The technologies described here could theoretically be incorporated into settings such as schools using programs like RULER to bolster skill-building efforts, and may be particularly helpful for reaching individuals who are less comfortable sharing their emotions via traditional conversation and group discussion. Teachers could prompt students to interact with a social robot or avatar placed in the classroom, out of earshot of other students. The agent could prompt students to indicate how pleasant or unpleasant they feel and how high or low their energy is, and then could help students to label their emotions and determine what activities might benefit from them. The agent could also recommend strategies for reducing negative emotions or maintaining positive ones. A similar, adult-centered interface could be used in workplaces in relatively private places to encourage self-awareness and reflection. Data could be shared immediately with individual users or could be collected and considered in the aggregate to determine general emotional states and whether particular days of the week or specific events generally trigger more unpleasant or pleasant emotions. Results could guide shifts in schedules or activities and could inform more individualized emotional intelligence interventions for specific settings and groups.

Limitations and Future Directions for Emotional Intelligence

Even after 25 years of research, much about emotional intelligence remains to be learned and refined. Perhaps most pressing to address, the current approach to measuring the construct is far from perfect. As discussed above, there is some debate regarding the fitness of the four-factor structure of the MSCEIT, and there should be continued attempts to replicate the proposed structure or to present and test alternatives. The challenges of measuring the real-time application of emotional knowledge must also be addressed with innovative approaches—for example, by finding cost- and time-effective ways to induce emotions and assess regulation strategies as they are actually employed. The fact that the majority of ability emotional intelligence research uses the MSCEIT increases the likelihood that test effects have become confounded with construct effects (MacCann & Roberts, 2008). Researchers have developed new measurement approaches in an effort to address this concern (e.g., the Situational Test of Emotional Understanding and the Situational Test of Emotion Management; MacCann & Roberts, 2008), and these merit further exploration. Finally, there is a need for a comprehensive performance assessment of emotional intelligence for children under the age of 10. The success of such a measure will depend on its sensitivity to developmental milestones (cognitive, emotional, and linguistic) across childhood.

Other considerations for future research have to do with the generalizability of conclusions about emotional intelligence across genders and cultures. It has been established meta-analytically that females score significantly higher on performance measures of emotional intelligence than do males (Joseph & Newman, 2010). It would be interesting to examine whether interventions are differentially effective across sexes, and whether skill-development efforts could or should be tailored to gender differences to help close this gap. In terms of cultural context, there is reason to believe that global variance in emotion display rules and other cultural norms around emotions would impact the fit of the construct and related scales across cultural groups. It is only recently that cross-cultural investigations of ability emotional intelligence have been undertaken, but there is limited evidence that the MSCEIT is generalizable across Eastern (Pakistani) and Western (French) student samples (Karim & Weisz, 2010). Thus, the question of cultural generalizability begs further exploration.

Finally, while it is natural to frame emotional intelligence in terms of its adaptive and positive consequences for individuals and society, some researchers have also begun to explore the construct's relationship to social deviance and Machiavellianism—in other words, its "dark side" (Austin, Farrelly, Black, & Moore, 2007; Côté, DeCelles, McCarthy, Van Kleef, & Hideg, 2011; Winkel, Wyland, Shaffer, & Clason, 2011). Are individuals who are better at perceiving and regulating emotions in themselves and others also better able to manipulate others' emotions toward selfish or even immoral ends? While empirical evidence is limited and mixed, there is some indication that higher emotional intelligence may be related to deviant behavior in some contexts (Winkel et al., 2011). Future research could endeavor to identify the conditions that make the "misuse" of emotional intelligence less likely.

Conclusion

Emotions permeate every aspect of our lives. They provide us invaluable information about our environment and the people in it, and they become adaptive when they are attended to and leveraged with skill. For the past quarter-century, emotional intelligence research has helped to illuminate what it means to apply skill to our emotional experience. While multiple perspectives still abound on what emotional intelligence is, what it should be expected to predict, and how it should be measured, a picture of the construct as a set of specific mental abilities best measured via performance assessments is beginning to emerge as the accepted standard. The exact extent to which the enhancement of these abilities in individuals is possible remains to be seen, but it is clear that well-designed efforts to enhance emotional intelligence show promise for improving functioning and well-being in many domains.

CHAPTER 31

New Light on the Affect–Cognition Connection

Gerald L. Clore and Alexander J. Schiller

Human adaptability requires continually anticipating and preparing for what is likely to happen next. As this process unfolds, the relevance, value, and importance of anticipated events are appraised along with accessible responses. If done consciously and deliberately, this process would be costly and slow, leaving the individual depleted and lost in thought. Instead, affective appraisals occur automatically and unconsciously, generating feelings that vary in pleasantness and activation. These two attributes of affective feelings act as information about value and urgency. They can therefore confer value on associated thoughts, plans, people, and possibilities, making some things depressing and awful but others exciting and wonderful. We discuss how this happens from the perspective of the *affect-as-information* approach, which holds that affect confers value on whatever is in mind at the time (Clore, Gasper, & Garvin, 2001; Schwarz & Clore, 1983, 2007).

In recent research extending this model, we have discovered that affect can confer value on one's own thoughts and inclinations as well as on objects in the environment (Huntsinger, Isbell, & Clore, 2014; Schiller & Clore, 2015). In this chapter, we examine several key concepts, review research on how affect influences concepts, and review research on how affect influences judgment and regulates thought. In each case, we focus on how affect can serve as information about the value of one's own opinions, thoughts, and inclinations.

Key Concepts

Evaluation

Evaluating the environment is one of the mind's most important tasks. All living things continually evaluate that which they encounter. In humans, familiarity activates the smiling muscles of the face (Winkielman & Cacioppo, 2001), whereas unfamiliarity almost universally elicits vigilance (Creswell, Quinn, Whittingham, & Butler, 2003; Welp, Rushen, Kramer, Festa-Bianchet & de Passillé, 2004). This occurs even at the level of the immune system, as unfamiliarity leads lymphocytes to attack and kill other cells. Somewhat surprisingly, even plants evaluate stimuli in their environments, reacting to the presence of alien plants by increasing their own root profusion (Casper & Jackson, 1997), and reacting to the vibrations of chewing caterpillars by secreting toxins (Appel & Cocroft, 2014).

Extensive data show that people's everyday verbal descriptions are overwhelmingly evaluative. In their classic work on the connotative meaning of words, Osgood, Suci, and Tannenbaum (1957) concluded that the connotative meaning of all words in all languages is dominated by evaluation. In addition, analyses of almost any interpersonal rating data by factor analysis show that the first and largest factor is invariably one of evaluation.

This evaluative inclination is also evident in human moods and emotions, which are kinds of affective reactions. Rather than the fixed responses of lower animals and plants, affective reactions provide a kind of mental way station between stimuli and responses, which allows humans to respond in a flexible manner to the situations in which they find themselves (Scherer, 1984).

Affect

"Affect" refers to evaluation at any level and in any modality, including affective feelings, thoughts, expressions, and so on. The term "affect" is frequently used in psychology, but seldom defined. Although a noun, it functions as an adjective, because, like light, affect is seen only in reflection, when it illuminates something else. Zajonc (1980) illustrated this adjectival aspect of affect when he wrote:

> perhaps all perceptions contain some affect. We do not just see "a house": we see "a handsome house," "an ugly house," or "a pretentious house." We do not just read an article. . . . We read an "exciting" . . . "important" . . . or a "trivial" article. . . . And the same goes for a sunset, a lightning flash, a flower, a dimple, a hangnail, a cockroach, the taste of quinine, . . . the color of earth in Umbria, the sound of traffic on 42nd Street, and . . . the sight of the letter Q. (p. 154)

In this poetic rendition of his view, Zajonc was saying that affect illuminates our experience and gives meaning to the wide variety of events, actions, and objects that we encounter.

As implied by Zajonc's (1980) treatment, affect provides a common currency for evaluating the variety of otherwise incommensurate objects that people encounter. It confers value on objects of perception and thought, reflecting a versatile hedonic rule, which is that "If it feels good, it is good." Thus, pain feels bad, relief from hunger, thirst, cold, and heat feels good, as does sex, contact with conspecifics, and so on. To prevent excess, the pleasure of continuing to eat, for example, decreases along with the decrease in the biological value of further food intake.

The hypersociality of humans complicates matters, requiring behavior regulation not only for individual survival but for the survival of the groups on which they depend. If one lists the human emotions—including anger, jealousy, pity, gratitude, love, contempt, and so on—most are social emotions. Such emotions mark in memory the recurring problems that arise in human interaction and motivate behavior through the patterns of feeling that are involved. Thus, in shame situations, pain is attached both to one's action and one's motivation, whereas in anger situations, pain is attached to the actions of others, but righteous pleasure to one's own motivation. Each kind of social situation may be marked with a different pattern of valence and arousal attached to different aspects of the situation, including outcomes, actions, and objects (Ortony, Clore, & Collins, 1988).

Information

According to the affect-as-information model (Schwarz & Clore, 1983, 2007), however, the key to affective influence is not the affect or emotion itself, but the compelling information it provides. The approach is summarized in a set of principles (Clore, Wyer, et al., 2001). For example, the *affective information principle* is that *affective feelings are conscious registrations of unconscious appraisals of something as good or bad in some way.* That is, affective feelings provide embodied value information as experiences *of* goodness or badness, rather than as indirect information *about* value. The valence and arousal of "core affect" (Russell, 2003) provide value and urgency information. Surprising or arousing things, for example, attract attention, get priority treatment (Simon, 1967), and tend to be remembered (Cahill & McGaugh, 1998).

Mood Inductions

The research reviewed in this chapter often employs mood inductions and we refer to "mood effects," but moods themselves are of interest really only as a source of affective cues that last long enough to observe how they influence subsequent judgment and performance. Editors often want investigators to rule out mood as a potential explanation for findings, but since most affective influences do not involve full-blown moods or emotions, the utility of such checks is unclear.

Popular methods for inducing affect include having participants write about emotional experiences, see emotional films, hear emotionally evocative music, or pose emotional facial expressions (see Coan & Allen, 2007, for a review; Westermann, Spies, Stahl, & Hesse, 1996, for a meta-analysis). A recent comparison of common methods found them all to be effective, especially in combination (Zhang, Yu, & Barrett, 2014). Although reliance on irrelevant mood inductions as a tool has led some to assume that the affect-as-information model applies only to moods and misattributions, in fact, the same attributional processes apply to all affective reactions, not just to incidental ones.

Success in getting irrelevant moods to affect judgment and thought depends on multiple factors (see Greifeneder, Bless, & Pham, 2011, for a review). These include individual differences (e.g., attending to emotion; Gasper & Clore, 2000) and whether inductions are involving but sufficiently subtle that they can be misattributed to the object of interest. However, even obvious manipulations can be effective if participants are occupied with a secondary task (Martin, Seta, & Crelia, 1990).

A common error made in unsuccessful replications of mood studies comes, paradoxically, from efforts to be especially rigorous. Such efforts often involve the inclusion of premeasures of mood or of manipulation checks that ask about feelings before measures of the dependent variable. These focus participants on their feelings, making them an object of perception, thus losing their ability to modify other entities—for example, some failures to replicate (e.g., Van Damme & Seynaeve, 2013) ask about mood at the beginning and again before the dependent measure. One failure to replicate included seven mood assessments spread throughout the procedure (Bruyneel et al., 2013). Successful studies generally delay assessment until the end of the experiment. Any preliminary mood measurement should be minimal and embedded in other, nonmood questions, since a focus directly on feelings often eliminates mood effects (Hunsinger, Isbell, & Clore, 2011; Schwarz & Clore, 1983).

Affect and Judgment

Two recent discoveries merit special attention; one concerns affect and judgment. Before describing that discovery, however, we review the basic affect and judgment phenomenon to provide some background (see also Isbell & Lair, 2013). The question is "How do affective reactions influence evaluative judgments?"

Feelings as Information

In the spring of 1983, a simple experiment surveyed life satisfaction, varying whether people were interviewed on warm and sunny or cold and rainy spring days (Schwarz & Clore, 1983). The results showed that foul weather dampened people's moods, resulting in less positive judgments of life satisfaction. That effect vanished, however, when experimenters asked the participants questions about the weather *before* asking them about life satisfaction. Nasty weather still lowered mood, but happy or sad feelings were not experienced as information about life satisfaction once linked to the weather—their true source.

According to these results, the impact of affect depends on its object. Thus, affect influences judgment when experienced as a reaction to an object of judgment, but not otherwise. Relevant principles (Clore, Wyer, et al., 2001) include:

1. The *affective judgment principle: When focused on an object of judgment, a person may experience a concurrent affective reaction as an evaluation of that object.*
2. The *affective attribution principle*: *The information value of affect, and hence its consequences, depend on the object to which the affect is attributed.*

Recent research has further tested these affect-as-information principles by presenting pictures of fear faces (or frowns or spiders) outside of awareness. In the continuous flash-suppression paradigm, a flashing image in one eye captures attention, suppressing conscious experience of an emotional image in the other eye (e.g., Anderson, Siegel, White, & Barrett, 2012). In one such study, a fear face was presented out of awareness to participants' nondominant eye (Lapate, Rokers, Li, & Davidson, 2014). In the aware control condition, fear faces appeared in both eyes so that participants were fully conscious of them. Measuring skin conductance indicated that the level of negative affect was the same in the two conditions. However, responses to a neutral face presented immediately afterward were different. As long as participants remained unaware of the source of their negative affect, greater skin conductance was associated with greater dislike. But when they were aware and could correctly attribute their reactions to having seen the fear face, negative affect had no influence on their judgments of the neutral face.

The results conceptually replicate those of Schwarz and Clore's (1983) weather study described earlier. In both, unassigned negative affect (from mood or unconscious fear faces) was experienced as a negative reaction to whatever was in mind at the time (life satisfaction or a neutral face). But negative affect had no influence on ratings of life satisfaction or faces when participants attributed their affect to its true (irrelevant) source.

Generality

The processes described in these experiments are potentially at work in any situation in which new judgments are required. For example, in one study, students were asked to judge the adequacy of a scientific experiment (Munro, Stansbury, & Tsai, 2012). When confronted with findings that challenged their personal views, students experienced negative feelings, which made them think something must be wrong with the research. However, when unpleasant aspects of the experimental room were made the focus, negative affect had no effect on judgments of scientific validity. The same result occurred in a replication when participants were told that they might feel tense because a beverage they had consumed had been caffeinated. Those participants felt just as negatively, but their feelings were not experienced as reactions to the objectionable research findings.

Other research suggests that affect can also influence jury decisions. In a study of a mock trial, accountancy students served as jurors in a suit brought against an accounting firm in a corporate bankruptcy case (Kadous, 2001). Three versions of the testimony that the participants heard differed in the degree of emphasis that was placed on distressing outcomes of the bankruptcy for investors, workers, and the community. Despite the fact that the accounting practices were the same in each version of the case, jurors were increasingly likely to see the firm as negligent the more the version they read mentioned distressing consequences of the bankruptcy. The results were very different, however, for jurors who had earlier been asked to indicate how distressed they felt about serving on the jury. Answering that question first made their negative feelings seem like reactions to jury duty rather than like reactions to wrongdoing. As predicted, those jurors tended to find the accounting firm not guilty. These studies illustrate that affect and its object are separable, and that the meaning of affect is not self-announcing but reflects the context in which it is experienced. Thus, as indicated earlier, the impact of affect depends on its object, and its object depends on what is in mind at the time.

Specific Emotions

The studies reviewed thus far all involve induced moods as sources of affect, but what about specific emotions? Like moods, emotions are affective reactions, but their influence is constrained by their specificity or by the kinds of situations to which they are relevant.

According to appraisal theory (e.g., Ortony et al., 1988), the emotion of sadness concerns certain *undesirable outcomes*, whereas fear is about *the prospect of* undesirable outcomes, and anger is about undesirable outcomes *caused by others' blameworthy actions*. All are negative emotions, but the particulars that differentiate them limit the range of objects about which they are informative.

A test of the idea involved a comparison of anger and sadness (Keltner, Ellsworth, & Edwards, 1993). The results showed that sadness (which concerns negative outcomes) increased the judged likelihood of situationally caused events, whereas anger (which is about blameworthy agency) increased the judged likelihood of human-caused events. Thus, the influences of specific emotions depended on the similarity between their appraisal patterns and the judgments to be made.

Another study involved the "endowment effect," which refers to the fact that merely owning something makes it seem more valuable, hence elevating the price for which one is willing to sell it relative to the price at which one would be willing to buy a comparable article. The negative emotion of disgust, because it concerns the distastefulness of objects, can alter the endowment effect by decreasing the selling price of an owned object (Lerner, Small, & Loewenstein, 2004). But, whereas disgust is about unappealing objects, sadness signals undesirable outcomes (Ortony et al., 1988). By highlighting the possibility of negative outcomes, sadness reversed the endowment effect. Rather than following their inclinations, sadness led participants to decrease their selling price and increase their buying prices. Thus, the two negative emotions influenced the same phenomenon differently: one signaled that the object was unappealing, the other that outcomes might be undesirable.

Disgust can also increase the severity of moral judgments under some conditions (e.g., Wheatley & Haidt, 2005). For example, morally ambiguous actions were judged to be immoral after smelling a disgusting odor, working in a disgusting workspace, remembering disgusting experiences, or seeing a disgusting film. For individuals who scored high in private body consciousness, the negative emotion of disgust was found to affect judgments of morality (Schnall, Haidt, Clore, & Jordan, 2008). The same results did not occur for the negative emotion of sadness. Further, electromyography (EMG) measures of facial muscles indicating disgust have also been found to relate to moral judgments (Cannon, Schnall, & White, 2011) and hand washing to lead to less severe judgments (Schnall, Benton, & Harvey, 2008).

These and many other studies have been stimulated by Haidt's (2001) intuitionist account of moral judgment. The high profile of that work has made related research a target of critics. A paper reporting a meta-analysis of 50 relevant studies (Landy & Goodwin, 2015) found many confirmations of the hypothesis, the strongest resulting from gustatory/olfactory modes of disgust induction. The authors argued, however, that the effect was small if averaged with studies not showing the effect, and proposed a return to the rationalist model of moral judgment. They focused, however, only on whether disgust was induced, but not also on whether conditions favored misattribution of disgust to the objects of moral judgment (Schnall, Haidt, Clore, & Jordan, 2015).

Fear and anxiety involve displeasure about the prospect of undesirable outcomes of events, and accordingly, they can lead to pessimism about future outcomes and to risk-averse decisions (Lerner & Keltner, 2000), as well as to heightened risk judgments (e.g., Constans & Mathews, 1993; Gasper & Clore, 1998). Fear and anxiety have also been found to increase the perceived risk of terrorism (Lerner, Gonzalez, Small, & Fischhoff, 2003) and to an emphasis on the safety of consumer products (Raghunathan, Pham, & Corfman, 2006). When looking down from a tall balcony, fearful individuals have been found to overestimate the height of the balcony (Stefanucci & Storbeck, 2009). Similarly, when research participants estimated the slant of a hill while standing on a skateboard at the top, fear made the hill look steeper (Stefanucci, Proffitt, Clore, & Parekh, 2008). In contrast, when they stood at the bottom, sadness made the hill seem steeper (Riener, Stefanucci, Proffitt, & Clore, 2011). These differences in effects reflect differences in the focus of the different emotions. Presumably, fear exaggerated the risk of steepness when viewed from the top, whereas sadness exaggerated the effort of ascending the hill when viewed from the bottom.

This sample of research on emotion and judgment shows that, whereas negative emotions do lead to some kind of negative judgment, their specific effects are constrained by the particular kinds of negative situations of concern for a given emotion (see Lerner & Keltner, 2001, for an elaboration of this idea).

Affect in the Construction of Reality

These affective influences on judgment are examples of constructive processes in everyday perception. In the domain of sensory perception, the brain integrates inputs from different modalities so that from seeing, hearing, smelling, tasting, and touching, that which is sensed emerges as a multifaceted object. The research on affect suggests that affective reactions play a similarly constructive role, as indicated in the earlier quote from Zajonc (1980), "We do not just see 'a house': we see 'a handsome house,' 'an ugly house,' or 'a pretentious house'" (p. 154).

Although we believe this to be an accurate account, bottom-up processes in constructing perceptions and judgments are costly in terms of attentional and processing resources. Therefore, rather than constantly starting over, the brain acts as a Bayesian prediction device using existing knowledge and prior values to anticipate incoming information. If anticipations are accurate, little accommodation or incorporation of new information is required. Accordingly, when making judgments about something familiar, one may simply retrieve a prior judgment, rather than start from scratch to form a new one. As a consequence, affect may confer its value not on the nominal object of judgment, but on the person's own provisional opinion of that object. This is the insight driving the research reviewed next.

Affect and Judgment: A New View

Interesting results have come from recent research examining how affect influences judgments of things that are disliked. One experiment concerned reactions to cycling champion Lance Armstrong (Schiller & Clore, 2015). Armstrong had become a symbol of courage by overcoming cancer to win seven Tour de France cycling titles. Just before the study, however, a scandal emerged, leading him to confess that his victories had been aided by performance-enhancing drugs, ensuring that most research participants would see him in a negative light. They were then asked how much they would like to have one of what had been highly popular "Livestrong" bracelets, sold by Armstrong's foundation for cancer research. The results were interesting because rather than the usual "rose-colored glasses" effect (positive mood leading to positive judgments), positive mood led participants to judge the bracelets more negatively than did negative moods.

To determine the reliability of this result, a second study conducted a year later (Schiller & Clore, 2015) focused on another disgraced athlete. It produced an even stronger version of the same effect. Participants rated how much they would like a poster picturing Alex Rodriguez (“A-Rod”), the New York Yankees third baseman who at the time was said by some to be the greatest athlete ever to play baseball. Just before the study, rumors that illicit drugs had enhanced his exceptional performance were confirmed. Again, rather than a rose-colored-glasses effect, happy moods led participants to rate a poster of A-Rod more negatively than did sad moods.

In these experiments, people in positive moods did not give the benefit of the doubt to Armstrong or Rodriguez, as one might have expected. Rather, they were more confident in the negative judgments they already held. In contrast, negative moods made participants more tentative about their negative judgments. Apparently, affect served, not as information about the target athletes, but as information about the participant’s own provisional opinions of them.

What are we to make of these seemingly anomalous findings? Why has this pattern not appeared in prior research? The reason is that the phenomenon can be detected only when provisional opinions are negative, as in these experiments. In the negative case, if positive affect leads to greater confidence in one’s opinion, it should lead to a more extreme negative judgment, as we observed. But if the initial opinion had been positive, a positive judgment in positive mood would have been indistinguishable from the usual prediction in which positive affect simply enhances the value of any associated object.

As a further test of this idea, an experiment examining mood effects on ratings of subjective well-being was conducted (Schiller & Clore, 2015). The usual rose-colored-glasses effect was found to be significant (i.e., positive moods leading to more positive judgments). However, when we analyzed rating extremity rather than the rating means, it was apparent that positive mood had also made ratings significantly more extreme. The mean and variance effects were comparable in size, with the extremity effect being slightly larger. The data do not allow us to determine if both processes or only the confidence effect was operating.

We believe that the most plausible general account of mood and judgment, including these recent results, involves the *affective immediacy principle*, which is that *affect is always experienced as being about whatever is in mind at the time* (Clore, Wyer, et al., 2001). If so, would directing judges’ attention to the object of judgment in the world create rose-colored-glasses effects and directing attention to participants themselves create extremity effects? That research remains to be conducted.

For the present, we conclude simply that affective reactions are *sometimes* self-reflective, providing information about one’s own inclinations. A set of results with similar implications comes from five experiments on judgments of trustworthiness done by Lount (2010). He found that positive affect served as feedback about the judge’s own potential responses, rather than as information about the object of judgment (the other person)—that is, rather than simply increasing trust, positive mood led to increased trust only when the faces to be judged did in fact look trustworthy. In contrast, positive mood decreased trust judgments when the faces looked untrustworthy. The results thus further support the idea that positive affect empowers whatever responses and inclinations are currently most accessible.

In summary, in our review of studies examining affect and judgment, we focused on recent findings showing that the evaluative information conveyed by affective reactions can be self-referential. The conditions under which this is likely are not yet fully clear, including whether this is always or only sometimes the case. But in those studies in which self-referential effects were found, initial opinions were made salient. If self-referential effects require a focus on initial inclinations, then such self-relevancy effects are special cases of the affective immediacy principle that the object of affect is always whatever is perceptually salient or cognitively accessible at the time.

Affect and Thinking

We turn next to the question of how affect regulates cognitive processing or thinking (as opposed to judgment). There is now considerable evidence that affect is routinely self-directed (Huntsinger et al., 2014). We review this research and the elaboration of the affect-as-information model that it suggests.

Early studies of mood and persuasion showed that moods influence not only judgments but also modes of cognitive processing (Schwarz, 1990; Worth & Mackie, 1987). One might have expected on the basis of judgment research that positive affect would simply increase the evaluation and persuasiveness of attitude messages. However, the results showed that was not the case. Happy moods led to moderate persuasion regardless of argument quality, whereas sad moods led participants to reject weak arguments and to be persuaded only by strong ones. Being sad apparently made people think systematically, whereas being happy led people to rely on judgment heuristics. Results across studies were consistent with such a dual-process account in which happy moods elicit peripheral, heuristic, or "system-one" processing, whereas sad moods lead to central, systematic, or "system-two" processing (see Schwarz, Bless, & Bohner, 1991; Schwarz & Clore, 2007, for reviews).

The hypothesis that happy and sad affect are linked to particular styles of cognitive processing has been a very productive one, leading to strong predictions about the emotion–cognition connection. For example, compared with negative affect, positive affect leads to a global focus (Gasper & Clore, 2002), creativity (Isen, 1984), broadened attention (Rowe, Hirsch, & Anderson, 2007), semantic and affective priming (Storbeck & Clore, 2008b), stereotyping (Bodenhausen, 1993), false memories (Forgas, Laham, & Vargas, 2005; Storbeck & Clore, 2005), schema-guided memory (Bless et al., 1996), part-list cueing effects (Bäuml & Kuhbandner, 2007), fundamental attribution errors (Forgas, 1998), judgment heuristics (Gasper, 1999), ease-of-retrieval effects (Ruder & Bless, 2003), and implicit–explicit attitude correspondence (Huntsinger & Smith, 2009).

Extensive research thus leads to the strong expectation that positive affect promotes global (relational, category-level, substantive, top-down) processing, and that negative affect promotes greater local (referential, item-level, bottom-up) processing. Such effects have been found in many different labs using various affect inductions and a variety of cognitive tasks. There is some variation, of course, but overall, the data present a very consistent picture (see Greifeneder et al., 2011; Schwarz & Clore, 2007, for reviews).

A variety of explanations for these consistent patterns have been offered, including mood-congruent priming (Forgas, 1995; Isen, 1984), resource depletion (Mackie & Worth, 1989), affect infusion (Forgas, 1995), assimilation–contrast (Fiedler, 2001), broaden-and-build processes (Fredrickson, 2001), dopamine (Ashby, Isen, & Turken, 1999), motivation (Gable & Harmon-Jones, 2010), and affect regulation (Tice, Bratslavsky, & Baumeister, 2001). These differ from one another in various ways, but they are similar in one way: they all assume that positive and negative affect do activate particular styles of thought.

In contrast, an affect-as-information approach has assumed only that affect provides information about situations, which allows cognitive processing to be regulated adaptively (Schwarz & Clore, 2007). Recent research from this perspective suggests ways in which it might be usefully elaborated, as we see next.

Affect as Feedback

We now turn to review recent work on seven phenomena concerning affective influences on thinking. This research casts new light on the consistent patterns uncovered over the past 25 years or so. These phenomena have generally been understood as direct and more or less fixed consequences of affect. But the most recent research provides a simpler interpretation (Clore & Huntsinger, 2007; Huntsinger, 2013; Huntsinger et al., 2014; Isbell, Lair, & Rovenpor, 2013), as shown by research on mood and global–local focus.

Global–Local Focus

In 1959, Easterbrook published an often-cited paper indicating that emotional arousal narrows attention. The hypothesis came from his memory of what had happened to him years earlier during an awkward parachute landing. After hitting his head, he was distressed, and noted that his spatial and temporal focus seemed to shrink (Easterbrook, 1982). In time, it became an accepted principle that stress and emotion lead to restricted attention.

The hypothesis that emotion narrows attention turned out to apply primarily to negative emotions, such as sadness and anxiety, rather than to emotion generally. Many studies show that fear and anxiety are associated with vigilance and restricted attention (see Bar-Haim, Lamy, Pergamin, Bakermans-Kranenburg, & van IJzendoorn, 2007, for a meta-analysis). However, mood studies find that happy feelings broaden attention (e.g., Basso, Shefft, Ris, & Dember, 1996; Derryberry & Reed, 1998; Fredrickson & Branigan, 2005; Gasper & Clore, 2002).

Various explanations for the association between affect and global–local focus have been offered. Some accounts stress neural connections (Anderson, 2009) and the role of dopamine in the brain (Ashby et al., 1999). Other accounts have stressed psychological processes. For example, the broadened attentional focus of positive affect is adaptive because it results in "undoing" the narrow focus engendered by threats and other stressors (Fredrickson, 2001). Similarly, to the extent that positive affect signals a benign situation, it allows one to think expansively, resulting in a global focus, heuristic thinking, and creativity (Schwarz & Clore, 2007). All of these processes seem likely to be involved, but recent research indicates that an additional process is also important. It is summarized in the *affective processing principle* (Clore, Wyer, et al., 2001; Clore, Gasper, et al., 2001), which says that *when one is task oriented, affective reactions may be experienced as confidence or doubt about cognitively accessible information, so that positive and negative affect lead to greater and lesser reliance on one's beliefs, expectations, and inclinations.* In this affect-as-feedback approach, positive and negative affective reactions are viewed as "go" and "stop" signals, respectively, for engaging in or inhibiting whatever response is currently most accessible (Clore & Huntsinger, 2007; Huntsinger et al., 2014). It explains the effect of mood on global–local focus, for example, by noting that people generally adopt a moderately global focus anyway—the global superiority effect (Navon, 1977; Wegner & Vallacher, 1986). Positive affect may therefore be associated with broad attention simply because it says "Go" to that existing inclination. If so, what would happen if a local focus were made more accessible?

To answer that question, experiments varied mood and the accessibility of global versus local orientations (Huntsinger, Clore, & Bar-Anan, 2010). To alter response accessibility, global or local responses were primed using the Navon task (Experiment 1) and global or local *concepts* were primed in a lexical decision task (Experiment 2). Participants then wrote either about happy or sad events or listened to happy or sad music. Global–local focus was assessed on a separate task (Kimchi, 1992). The results showed that the effect of mood on global–local focus depended on which focus had been made most accessible through priming. Positive mood promoted a global focus when a global orientation had been made most accessible, but a local focus when a local orientation had been made most accessible. By contrast, sad mood inhibited (and tended to reverse) adoption of the orientation that had been primed, which is consistent with its hypothesized role of stopping dominant responses.

These results suggest that positive affect promoted whatever focus was most accessible. When a local focus was accessible, happy moods led to a local orientation and sad moods to a focus on the big picture. The results, therefore, are consistent with the affective processing principle that, in task situations, affect serves as self-directed or response-focused feedback, rather than as information about the world.

Stereotyping

Many studies have reported a tendency for individuals in positive as opposed to negative moods to rely on stereotypes when forming impressions of others (see Bless, Schwarz, & Kemmelmeier, 1996; Schwarz & Clore, 2007, for reviews). For example, when judging a defendant's guilt, people in happy moods rely more on stereotypes than those in sad or neutral moods (Bodenhausen, 1993). This relationship has been interpreted as a by-product of the tendency of positive moods to promote global or category-level processing. Indeed, in studies of consumer behavior, happy moods are associated with a focus on brand names, whereas sad moods are associated with a focus on the specific attributes of products (Adaval, 2001).

This relationship between positive affect and stereotyping provided a second opportunity to test the "go and stop" interpretation of mood effects on processing. If positive affect says "Go" to the most accessible response, then for "chronic egalitarians" (Moskowitz, Gollwitzer, Wasel, & Schaal, 1999) positive affect should not increase stereotyping. Indeed, the results of a relevant study showed that among those individuals with a chronically accessible goal to be egalitarian, being in a positive mood reduced rather than increased their tendency to use gender stereotypes (Huntsinger, Sinclair, Dunn, & Clore, 2010; see also Hunsinger et al., 2011). In addition, across four experiments that used multiple methods, multiple stereotypes, and measured stereotyping with both explicit and implicit measures, positive affect showed no fixed tendency to increase the use of stereotypes, but rather enhanced whatever set of cognitions had been made most salient—sometimes a stereotype and sometimes a counterstereotype (Huntsinger, Sinclair, et al., 2010).

Broadened Attention

Rowe et al. (2007) reported that positive mood broadened attentional scope on a flanker task, and from functional magnetic resonance imaging (fMRI) data, Anderson (2009) concluded that happy mood influences basic visual–cortical encoding processes that underlie perception. In contrast, the alternative affect-as-feedback interpretation is that happy mood leads to broadened attention only because adoption of a relatively broad attentional scope is already the dominant response.

To test this hypothesis, Huntsinger (2012) repeated the experiment by Rowe et al. (2007) but first varied the relative accessibility of a global or a local focus. That manipulation consisted of varying the letters to be detected on the Navon (1977) task to require a global focus, a local focus, or half and half. The results showed that the impact of positive mood varied with the focus that had been primed. Priming a global focus led positive affect to elicit larger flanker effects, whereas priming a local focus led to the opposite: smaller flanker effects. Especially interesting were the results of the 50–50 priming group. When global and local perceptual orientations were equally accessible, no mood effects appeared, because there was no dominant response for positive and negative affect to empower or inhibit.

Persuasion

The most prominent paradigm for studying persuasion involves presenting participants with strong or weak persuasive messages for a position of personal relevance to participants (Petty & Cacioppo, 1986). As indicated earlier, the standard mood and persuasion finding is that people in sad moods differentiate strong and weak persuasive arguments (suggesting systematic processing), whereas those in happy moods tend not to distinguish strong and weak arguments, being moderately persuaded by both. That pattern was seen when affect was introduced *before* exposure to persuasive arguments. However, the pattern reversed when affect was introduced *after* exposure to the persuasive arguments (Bless, Mackie, & Schwarz, 1992).

This change of order had such dramatic effects, we believe, because it changed the object of affect from the persuasive arguments to the participants' thoughts about the arguments. When positive affect was induced after arguments had been presented, it led them to be more convinced by strong than weak arguments. Positive affect presumably validated the positive thoughts participants had about strong arguments, as well as the negative thoughts they had about weak arguments. In contrast, negative affect invalidated both, leading sad participants not to distinguish strong from weak arguments and hence to be moderately convinced by either. This "self-validation" explanation (Briñol & Petty, 2003) has proven to be powerful and has stimulated extensive research (see Briñol & Petty, 2009, for a review).

The results and the self-validation account are consistent with the affect-as-information approach. Recall that according to the affective immediacy principle (Clore, Wyer, et al., 2001), *the object of affect is experienced as whatever is in mind at the time*. In the method used in the self-validation studies, participants' thoughts were made especially accessible by having them write down their thoughts in response to strong or weak persuasive arguments immediately after reading them. The "yes" or "no" information conveyed by affect was therefore directed at these *thoughts* rather than at the arguments, so that people in happy moods felt more confident and people in sad moods less confident in their thoughts about the arguments.

Support for this new perspective on affect and persuasion came from an experiment by Briñol, Petty, and Barden (2007) employing a measure of need for cognition (Cacioppo & Petty, 1982). Individuals high in need for cognition generally report more thoughts than do those low in need for cognition. This greater accessibility of thoughts should make the thoughts likely objects of affect. Positive affect should then be experienced as confidence and negative affect as lack of confidence in them. As expected, the results showed that happy moods did indeed lead high-need-for-cognition individuals to distinguish strong from weak arguments. But among low-need-for-cognition participants, for whom thoughts are believed to be less accessible, the persuasive arguments rather than their thoughts became the object of affect. As a result, happy moods simply led participants to like the arguments more and to be more persuaded by them than sad moods did. The results thus suggest that, contrary to widespread assumptions of a fixed relationship between affect and processing style, affect operates on whatever cognition or inclination is most accessible at the time.

Creativity

As reviewed earlier, the idea that feeling happy stimulates creativity is well known and well supported (see Baas, De Dreu, & Nijstad, 2008; Davis, 2009, for meta-analyses). Such findings have led to assumptions of a direct connection between positive affect and creativity (e.g., Isen, 2008). Recent research, however, indicates that the connection is not fixed but malleable (Huntsinger & Ray, 2014). In two experiments, either a global or a local thinking style was primed by giving numerous global or local practice trials on the Navon letter task. Then mood was induced and creativity was assessed. The results showed that creativity was greater in happy than in sad moods only when the usually dominant global focus was most accessible. In contrast, when a local focus had been primed, sad mood enhanced creativity. These reversals were apparent on several measures of creativity, including the Unusual Uses Test, the Remote Associates Test, and other insight problems, and they appeared on both quantitative and qualitative indices of creativity (Mednick & Mednick, 1967).

The most surprising result was that sad participants primed with a local focus showed enhanced creativity. However, that result is consistent with the model in that whereas a local focus usually limits creativity, the stop signal of negative affect resulted in a more global focus, which in turn enhanced creativity. Conversely, the "go" signal of positive affect resulted in reliance on the primed local focus, which inhibits creativity. Hunstinger and Ray (2014) thus discovered that even the time-honored relationship between positive affect and creativity is variable rather than fixed. The key, again, is that the influence of affect on cognition depends—not on the affect, mood, or emotion itself—but on the information conveyed, which in turn depends on its object.

Note that such findings do not invalidate the wealth of data showing an association between positive affect and creativity, but they do undermine the inferences usually drawn from such results. Positive affect does tend to enhance creativity, but only because, independently of affect, a global focus is dominant for most people most of the time (Navon, 1977; Wegner & Vallacher, 1986). What these experiments suggest is that heightened creativity came from the enhanced global focus, not from happiness, because the same positive affect reduced creativity when a local focus was made dominant. Thus, it appears that nothing about positive affect itself leads to creativity; its role is simply to say "Yes" or "No" to whatever is the dominant focus.

Judgment Heuristics

Positive affect leads to the use of some judgment heuristics and negative affect leads to the use of others. For example, positive affect was found to lead people to commit the conjunction fallacy on Tversky and Kahneman's (1974) Linda problem (Gasper, 1999), and negative affect led to increased use of anchoring and adjustment on other judgment tasks (Bodenhausen, Gabriel, & Lineberger, 2000). Recent results, however, indicate that whether someone commits the conjunction fallacy or relies on anchors to make quantitative judgments depends not only on mood, but on what thinking style was already most accessible before the mood induction (Huntsinger & Ray, 2014). To vary that accessibility, the experimenters primed either heuristic or systematic thought styles by having participants supply a missing letter for each of a series of words, including either heuristic primes (e.g., intuitive, spontaneous, impulsive) or systematic primes (e.g., analytical, reasoned, methodical).

In studies using this priming methodology, when heuristic processing was made especially accessible, more individuals in the happy mood condition committed the conjunction fallacy, as in prior studies. But when systematic processing was primed, that effect disappeared. Again, rather than having fixed effects on thought, the influence of affect depended on what thinking style was most accessible at the time.

In a study of anchoring effects in judgment (Huntsinger & Ray, 2014), the same priming procedure was used, and greater anchoring effects were found in sad than happy moods, as in prior research. This result, however, held only as long as heuristic processing was the more accessible style. When systematic processing was primed, the results were reversed, with anchoring occurring more in happy than in sad moods. Again, rather than activating a particular style of thinking, the role of affect was to say "Go" or "Stop" to whatever response inclination was most accessible at the time. These data again indicate that the impact of affect depends on its object (Clore & Huntsinger, 2009).

Implicit–Explicit Attitude Correspondence

Research indicates that two of the factors that influence implicit–explicit attitude correspondence are mood (Huntsinger & Smith, 2009) and trust in one's intuitions (Jordan, Whitfield, & Zeigler-Hill, 2007). Happy moods presumably increase correspondence by promoting the inclusion of contextual information, including internal contextual information in the form of expectations, primes, and intuitions.

However, if positive affect serves as feedback about the value of the most accessible processing orientation, then varying which orientation is most accessible should change whether positive or negative affect promotes attitude correspondence. As a test of this idea, Huntsinger (2011) measured trust in intuition in one experiment and primed high or low levels of trust in other experiments. He found that when trust in intuitions was high, positive affect maintained that trust and led to higher implicit–explicit attitude correspondence, as in previous research. But when people's trust in intuition was low, positive affect empowered that lack of trust, which led to lower implicit–explicit correspondence. Comparable results occurred in four studies with multiple attitudes, modes of priming, and mood inductions. These results again indicate that affective reactions regulate thinking styles by saying "Yes" or "No" to current cognitions and inclinations, consistent with the affective processing principle (Clore, Wyer, et al., 2001).

Summary and Conclusions

Although affect may provide information about one's external situation (Frijda, 1988), the research we have reviewed indicates that it often serves as information about one's own current cognitions and inclinations—that is, as feedback. From this feedback perspective, positive and negative affect is seen to influence thinking by conferring positive or negative value on current mental content. That conclusion is consistent with the affective processing principle (Clore, Wyer, et al., 2001), the self-validation model of affect in persuasion (Briñol & Petty, 2003), the performance feedback model (Wyer, Clore, & Isbell, 1999), and the mood-as-input model (Martin, Ward, Achee, & Wyer, 1993). It is also consistent with the cognitive tuning hypothesis (Schwarz, 1990; Schwarz & Clore, 2007), which is that affect regulates processing to fit task demands. To varying degrees, there is also much in common with other proposals for explaining the influences of affect on styles of information processing, including Forgas's (1995) substantive processing formulation, Fiedler's (2001) assimilation–accommodation model, and Bless's (2001) emphasis on general knowledge structures.

The proposed view is also consistent with the current emphasis in the field on prospection. Friston (2010) has proposed that a primary job of the brain is to anticipate the next moment in order to waste as little effort as possible. It is useful, then, to see the information provided by affect as anticipatory and as providing feedback, not so much about what one has already done but about what one is prepared to do. The information it provides is directed toward cognitions, inclinations, and anticipated actions (Baumeister, Vohs, DeWall, & Zhang, 2007).

A number of other feelings have effects on processing similar to those of affective valence, including the experience of power, arousal, and certainty. For example, feelings of power should act very much like positive affect in that they should empower individuals to rely on their own cognitions and inclinations (Overbeck & Droutman, 2013). Similarly, a long line of research shows that elevated arousal increases dominant responses, so that arousal should also promote reliance on currently accessible inclinations (Corson & Verrier, 2007). In addition, some research shows that the degree to which a given emotion involves feelings of certainty can increase the processing effects typical of positive affect (Tiedens & Linton, 2001). Indeed, a role for feelings of certainty is quite compatible with the role for feelings of confidence that we have emphasized in the current approach. The effectiveness of all of these factors in regulating cognitive processing is compatible with the affect-as-information model and with its central proposition that the various phenomena we have reviewed result, not from affect per se but from the compelling information that affect and other feelings provide when processed with information from the context.

The key to the current view, however, is the observation that the various affective influences on information processing or thinking are malleable rather than fixed. Instead of having direct effects on cognitive processes, affective reactions serve as embodied evaluations of current thoughts and inclinations. The influences of affect, then, can be as varied as the thoughts and inclinations on which affective reactions confer positive or negative value.

CHAPTER 32

A Fundamental Role for Conceptual Processing in Emotion

Christine D. Wilson-Mendenhall and Lawrence W. Barsalou

The idea that there are consistent and discriminable patterns for a small number of "basic" emotions (e.g., fear, anger, sad, happy, disgust) motivates a great deal of emotion research (see Tracy & Randles, 2011, for a recent review of these models). This view is also pervasive outside of the scientific arena, in education, government policy, industry, and entertainment. The logic is clear: If we could discover these emotion-specific patterns, we would unlock the mystery of human emotions, because these basic emotions are also the foundation of more complex emotions. As science has a tendency to do, however, the empirical evidence is forcing us to pause. A more complicated picture is emerging, one in which there is tremendous variability in the physiological, neural, behavioral, and subjective changes that occur during emotions like fear, anger, happiness, sadness, and disgust (Barrett, 2006; Barrett et al., 2007; Lindquist, Siegel, Quigley, & Barrett, 2013; Lindquist, Wager, Kober, Bliss-Moreau, & Barrett, 2012; Ortony & Turner, 1990; Quigley & Barrett, 2014). Moreover, there are a great number of emotional experiences that do not fall into these categories. Perhaps, although elusive, some set of basic emotions is still the answer—the key to understanding this variability—and we should keep searching for them. But what if we could explain this variability without appealing to basic emotions? We suggest that conceptual processing offers a natural explanation of the variability in emotional life. Furthermore, conceptual processing offers a very different perspective on the functions of emotions than has traditionally been discussed in theories of emotion, and motivates a very different approach to studying them.

In this chapter, we explore possible roles that conceptual processing plays in emotion, drawing on both the cognitive and affective science literatures. In short, we suggest that concepts develop in memory for emotional experiences as they do for many other forms of experiences, shaped in large part by attention and learning and by the "niche" in which an individual operates, including internal bodily, external sensory, and sociocultural environments (Barrett, Wilson-Mendenhall, & Barsalou, 2015; Barsalou, 2009; Wilson-Mendenhall, Barrett, Simmons, & Barsalou, 2011). The emotion literature often emphasizes the role of conceptual processing and language in explicitly remembering and communicating emotional experiences. We propose that conceptual processing also plays a role in the implicit generation of emotional experiences. Concepts develop so that previous experiences can be used to guide responding in the present situation (via prediction and inference; Barsalou, 2003b, 2009; Barsalou, Niedenthal, Barbey, & Ruppert, 2003). Our goal for this chapter is to illustrate how conceptual processing could play a fundamental role in emotion.

Concepts Develop for Prediction and Inference

Concepts work so seamlessly most of the time that we are not aware that they are functioning. Consider a typical start to a weekday morning: you hear your alarm clock sound. This may seem like a simple event, but let us break it down. In more simple terms, you hear a sound that arouses your nervous system somewhat automatically due to its acoustical properties.[1] Now, what do you do? If you did not know anything about alarm clocks, you might begin by orienting toward the sound and trying to find its source. You do not do this, however. Instead, prior experiences with alarm clocks that exist in memory, which are organized in your concept of alarm clock, shape how you respond to this sound. Information not only about the alarm clock object itself (e.g., its visual features, sounds it produces, how you act on it, co-occurring changes in your internal state), but also information contained in other related concepts that underlie the situations that involve alarm clocks (concepts like morning, bed, sleep, refreshed, exhausted, etc.) guide how you respond to this sound. You know that you can control the sound (stop or delay it) and that it is a signal to wake up. Unlike a rigid conditioned response, you can act flexibly based on the situational context, because concepts underlying the larger situation are also available in memory and are integrated with your concept of an alarm clock. If exhausted upon hearing the alarm, you press the snooze button; if well rested upon hearing the alarm, you press the off button. Perhaps you set the alarm extra early the night before, so you hit the snooze button twice. Perhaps you forgot to set the alarm, and wake up on your own instead of hearing an alarm, so you do not hit any button, and instead search for the time display. Thus, a concept like alarm clock refers to a set of patterns in memory that share various similarities and can flexibly be used to guide action. It refers to the aggregation of information about category instances into some kind of integrated representation (Barsalou, 2003a, 2005, 2012; Barsalou & Hale, 1993; Murphy, 2002). Concepts underlie our ability to interpret and engage in the situations that characterize everyday life.

The purpose of concepts, in other words, is prediction—going beyond the information that is present to *infer* what will happen next and to shift the biological system in ways appropriate to the situation (in the form of motor actions, perceptual sampling, attention shifts, visceromotor regulation, metabolic changes, etc.; Barsalou, 2009). In this way, concepts actively *interpret and construe* experience, dynamically shaping moment-to-moment "responding" in the form of perceiving, coordinating action, regulating the body, and organizing thoughts. Many theorists emphasize the value of prediction (and inference) in terms of filtering sensory information from the external environment, which allows us to act quickly and efficiently, and to allocate appropriate resources to novel stimuli (e.g., Clark, 2013). Prediction is also valuable in terms of filtering sensory information from the body and initiating efficient visceromotor responding (e.g., Barrett & Bar, 2009; Barrett & Simmons, 2015; Seth & Critchley, 2013). Prediction also plays central roles in internally oriented thought and reasoning, filtering and allocating attention to organize or redirect thoughts, plan for the future, generate new ideas, and so on (Barsalou, 2009).

Concepts develop to interpret virtually every aspect of the situations we experience—externally oriented experiences of objects and scenes in the world (e.g., violin, banana, mountain, statue), internally oriented experiences of our bodies (e.g., hunger, pain, itch, sweet), complex mental experiences that often involve how our internal and external worlds meet (e.g., anger, doubt, belief, analyze), and social experiences and institutions that involve many minds and bodies (e.g., government, protest, religion, concert). Simple and concrete concepts typically emerge earlier in the lifespan,[2] with more complex and abstract concepts, including many emotion concepts, developing later (Bretherton & Beeghly, 1982; Bretherton, Fritz, Zahn-Waxler, & Ridgeway, 1986; Gilhooly & Gilhooly, 1980; Kuperman, Stadthagen-Gonzalez, & Brysbaert, 2012; Ridgeway, Waters, & Kuczaj, 1985; Wellman, Harris, Banerjee, & Sinclair, 1995). As we will see, many different situational patterns accrue for each concept so prediction occurs as efficiently as possible at any given moment, in any given situation—guiding perception, action, regulation, and decision making. Furthermore, concepts are dynamic and flexible. Attention and learning support accruing many different patterns for a concept, and continually updating and expanding these patterns. Sometimes the changes in the patterns that underlie a concept are dramatic, as we see for emotion concepts later.

In the sections that follow, we focus on the characteristics of conceptual processing that are most relevant for understanding how concepts underlie emotional experiences. We propose that concepts develop to efficiently mobilize changes that characterize affective and emotional experiences.[3] Learning situated conceptualizations can explain the tremendous variability in emotional experiences within an individual and across different individuals.

Attention Is Integral to Establishing Concepts

A concept reflects a coherent aspect of experience that is represented by a set of patterns in memory. Attention is central to acquiring (and using) concepts because the brain's attention systems select specific aspects of the current experience, which often become integrated with similar schematic experiences in memory (Barsalou, 1999). In contrast to a "snapshot" or "recording" of experience like what a camera would produce, specific concepts develop from extracting aspects of experience than can be used to interpret similar experiences in the future (e.g., red, apple, hungry; Barsalou, 1999; Schyns, Goldstone, & Thibaut, 1998). Parsing experience into concepts is productive because, later, this enables constructing an infinite number of possible situated experiences from a finite number of concepts. Because no two situations are exactly the same, it is critical for the brain to organize information in memory so it is readily available for interpreting the situation at hand, which often involves the dynamic assembly of concepts. In this section, we discuss how attention operates in ways that are integral to establishing and using concepts to navigate situations.

Selecting Meaningful Units

Selection is a core function of attention and reflects efficient processing of what is most relevant to ongoing goals and behaviors (Chun, Golomb, & Turk-Browne, 2011; Johnson & Dark, 1986; Peelen & Kastner, 2014; Treisman, 1969). Selection can operate on properties of one modality (e.g., visual, auditory, gustatory) and on dimensions of space, time, or intensity that typically occur across modalities (Bahrick, Lickliter, & Flom, 2004). We assume that selective attention operates on interoceptive sensorimotor activity grounded in the body in a parallel way to how it operates on externally oriented sensorimotor activity.[4]

Selective attention establishes the meaningful units upon which concepts are built. For example, the spread of attention across multiple sensory modalities while allocated to a specific location in space serves to bind local sensory information into a multisensory object concept (Busse, Roberts, Crist, Weissman, & Woldorff, 2005; Treisman, 1998). Initially, intersensory redundancy appears to drive selective attention (e.g., temporal synchrony, rhythm, tempo, and changing intensity that a person's face and voice often express; Bahrick et al., 2004). As attentional skills develop, coordinated attention across modalities guided by time, space, and intensity dimensions is central to learning the relations (e.g., above, after, cause, intend) that are critical components of many concepts (e.g., Cohen & Amsel, 1998; Cohen, Chaput, & Cashon, 2002; Logan, 1994). Although people are sometimes aware of attending to a specific aspect of experience (e.g., when studying, when meditating), selection processes operate continually outside of awareness, which underlies accruing and integrating the many patterns underlying concepts in memory.[5]

Top-Down Processing Becomes Routine

As concepts develop in memory, top-down conceptual patterns and bottom-up sensory input often interact to direct selection processes (Chun et al., 2011; Corbetta, Patel, & Shulman, 2008) that include orienting, filtering, searching, and expecting (Plude, Enns, & Brodeur, 1994). This interaction supports the transition from the rigid stimulus–response responding present in early life to more adaptive, situated responding. The mechanisms underlying stimulus-driven attention are important because they bias attention toward novel features of experience (e.g., Klein, 2000) and disrupt top-down cognitive control to reorient attention. These kinds of disruptions tend to occur, for example, with a temporally abrupt onset, change in intensity, appearance of new objects, and moving or looming stimuli (especially as an interaction becomes more probable) (Chun et al., 2011). Evidence increasingly suggests, however, that bottom-up, sensory-driven processing occurs relatively infrequently, reflecting an interruption in routine top-down processing when it does occur (Clark, 2013; Vetter & Newen, 2014). Whether a stimulus is sufficiently novel to reorient attention is dependent on the concepts accessible in memory.

Top-Down Processing Interprets and Construes

Through attention operations, top-down conceptual processing dynamically shapes moment-to-moment perception, action, regulation, and decision making (Barrett & Bar, 2009; Barsalou, 2009). Extensive evidence in perception, for example, demonstrates that top-down conceptual predictions change and distort sensory information based on what is predicted to occur, shaping attention and perception through expectation (Barsalou, 2009; Vetter & Newen, 2014). The brain coordinates mental activity through internally driven interpretation and prediction, not through reflexive, externally driven responding (e.g., Raichle, 2010). Computationally, in predictive coding neuroscience models, information from memory does not merely modulate incoming sensory activity, it drives it, which means it can change how sensory information is being sampled (Bastos et al., 2012). It is more efficient to change perceptions of the environment to be consistent with patterns in memory (i.e., what a person already implicitly knows).[6]

Because it is unclear whether veridical perception even exists, recent proposals suggest that discussing levels of conceptual "penetration" or "construal" may be more productive (Vetter & Newen, 2014). The predictions driving construal penetrate very early perceptual processing (McCauley & Henrich, 2006). Top-down color knowledge, for example, can be decoded from patterns in primary visual cortex (V1) when participants view achromatic objects (Bannert & Bartels, 2013). The top-down penetration of early sensory processing is not specific to vision, occurring in other sensory modalities and during multisensory integration (Barsalou, 2009; Vetter & Newen, 2014). Initial evidence suggests that top-down processing of interoceptive activity also occurs (Barrett & Bar, 2009; Barrett & Simmons, 2015; Petersen, Schroijen, Molders, Zenker, & Van den Bergh, 2014; Seth & Critchley, 2013). In our view, then, attention and other systems are typically operating via conceptual processing, with predictions that distort perception, facilitate motor actions, regulate the viscera (and so on) continually occurring, and with updating occurring in novel situations. As we see next, top-down conceptual processing is what underlies efficiently engaging in situations, including the situations in which emotions emerge.

Learning Establishes Flexible, Situated Concepts

Learning grounded in attention establishes concepts that support interpreting and navigating experience in increasingly complex ways. Learning a concept involves accruing instances—patterns in memory—for an aspect of an experience (Allen & Brooks, 1991; Barsalou, 1987; Medin & Schaffer, 1978; Murphy, 2002). As we will see, the patterns that become organized in memory for a concept, the different instances, reflect the situations in which they occur (Barsalou, 2003b, 2008b; Barsalou, Breazeal, & Smith, 2007; Yeh & Barsalou, 2006). We refer to representing a concept in a situation, a situated instance, as a *situated conceptualization* (Barsalou, 2003b, 2009; Barsalou et al., 2003; Wilson-Mendenhall et al., 2011). Developing situated conceptualizations supports prediction and inference through efficiently assembling concepts to dynamically interpret and construe what is occurring based on prior experiences (Barsalou, 2009). More simple, concrete concepts that reflect *local* components of situations (e.g., apple conceptualizes part of an event in which a family bakes an apple pie together during a holiday) tend to develop as focal aspects of situated conceptualizations (Barsalou, 2003b, 2008b). As learning occurs in situations and attention operations become increasingly driven by top-down assemblies of concepts during situated conceptualization, more complex, abstract concepts emerge. These concepts, which typically integrate local components into *configural relational* structures (e.g., tradition integrates various parts of the event, including apples, baking, family, and holiday), tend to develop as entire situated conceptualizations (Barsalou, 1999; Barsalou & Weimer-Hastings, 2005; Wilson-Mendenhall, Simmons, Martin, & Barsalou, 2013). In this section, we build on our discussion of attention to examine how increasingly complex concepts, including the concepts underlying emotional experiences, are learned. We demonstrate how language underlies very different patterns, situated conceptualizations, becoming organized as instances of concepts. We first discuss our general theoretical approach and then apply it to emotional experiences.

Implicit Statistical Learning Is Occurring Early

Because aspects of situations tend to occur repeatedly, the brain organizes these regularities together as concepts in memory to facilitate interpreting similar situations in the future. Simple concepts can develop very early via implicit mechanisms in the brain that extract the organizational structural or "statistical regularity" across instances in the stream of situated activity filtered through attention (Aslin & Newport, 2012; Turk-Browne, 2012). Statistical learning is a powerful learning mechanism that is operating well before an infant is a year old (Kirkham, Slemmer, & Johnson, 2002; Saffran, Aslin, & Newport, 1996). Initially, the system easily extracts physical regularities that tend to be stable in the external environment (e.g., the boundary between earth and sky is consistently horizontal, not vertical), perhaps due to evolved biological scaffolding that needs minimal tuning (Turk-Browne, 2012). As selective attention becomes more sophisticated, statistical learning also operates on aspects of situations that tend to co-occur together and exhibit stable relations to one another (e.g., sky is above the horizon and ground is below it; Turk-Browne, 2012). The patterns underlying concepts at this point may be relatively rigid, with more flexibility introduced as language develops.

Words Support Flexible Learning in Different Situations

A word can further facilitate statistical learning through its redundancy with repeated sensorimotor patterns that are never exactly the same, strengthening the association (e.g., the word "apple" co-occurring with similar taste sensations and actions during eating; Smith, Suanda, & Yu, 2014; Smith & Yu, 2008; Yoshida & Smith, 2005). The redundancy provided by the word facilitates situated conceptualization. When the word "apple" is used in future, similar situations, for example, the brain mobilizes patterns in memory, generating top-down predictions that shape taste perception and guide actions (Barsalou, 2009). A word also provides a redundancy that can guide increasingly dissimilar experiential regularities—extracted via attention—to become established for a concept. Experiences of apple during a grocery shopping situation, for example, differ from experiences of apple during an afternoon snacking situation (e.g., involving searching for apples in produce bins, placing them in a cart, paying for them, and so forth in the shopping situation vs. involving grasping apple slices, inserting them in the mouth, tasting and chewing them, and so forth in the snacking situation). Whereas the patterns that accrue upon using the word "apple" when eating a snack support interpreting and engaging in future snacking situations, the patterns that accrue upon using the word "apple" when grocery shopping support interpreting and engaging in future shopping situations. Different perceptions, actions, regulation, and so on emerge in the two situations (Barsalou, 2003b, 2008b). As we return to later, regularities that are established across various instances of a concept using language and attention, and that are most useful for top-down prediction, are often driven by goal-oriented action in situations (e.g., eating apples as a healthy snack, selecting apples in the grocery store, picking apples as a leisure activity), which become richer and more varied with increasing cognitive capacities and novel experiences (Barsalou, 1991, 2003b). Throughout life and especially during childhood, implicit acquisition of these regularities is often structured through interactions with others (e.g., parents, siblings, caregivers, teachers; Akhtar & Tomasello, 2000; Tomasello, 1992).

Initially, words are important for establishing the patterns that underlie local aspects of situations—the more simple, concrete concepts upon which complex, abstract concepts are built. Because learning operates as continuous situated activity cascades across the brain,[7] the patterns that become organized in memory for a concept, the different instances, are each integrated within a situation (Barsalou, 2003b, 2008b; Barsalou et al., 2007; Yeh & Barsalou, 2006). Some instances of apple, for example, might become integrated within a situated conceptualization involving the concepts cutting board, kitchen, and knife; whereas other instances of apple might become integrated within a situated conceptualization involving the concepts tree, orchard, and autumn; and still other instances within a situated conceptualization involving the concepts pie, oven, and grandma. Many empirical studies demonstrate the extensive presence of situational information as people develop and use concepts (e.g., Bar, 2004; Barsalou & Weimer-Hastings, 2005; Chaigneau, Barsalou, & Zamani, 2009; Wu & Barsalou, 2009; see Yeh & Barsalou, 2006, for a review). Rather than the concept functioning in a rigid manner across situations, it is functioning flexibly in widely varying sets of concepts that contextualize it in each situation.

Language Supports Learning More Complex Concepts

As concepts develop in situations, words transition from operating as a co-occurring redundancy for establishing patterns to operating as top-down mobilizers that efficiently construct increasingly elaborate situated conceptualizations (Barsalou, Santos, Simmons, & Wilson, 2008; Vigliocco, Meteyard, Andrews, & Kousta, 2009). Words become especially important for coordinating concepts such that they are integrated into the configural, relational patterns in situated conceptualizations that underlie many abstract and emotion concepts. When this type of learning is occurring, language—typically in the form of sentences, not single words—guides attention to various aspects of a situation (Zwaan & Madden, 2004; Zwaan & Radvansky, 1998). Language supports productively assembling and combining concepts to establish more complex concepts, often through syntax that facilitates recursive embedding, mental time travel, and other configural, relational operations (Barsalou, 1999, 2008a; Clark, 2006; Schmid, 2000). Because language draws on internally oriented attention processes associated with working memory to assemble more elaborate situated conceptualizations, abstract concepts typically emerge later in development.

Consider, for example, a situation in which an individual tells her grandchildren that baking apple pie at this time every year is a holiday tradition as she places the pie in the oven. Language that situates the word "tradition" guides the top-down coordination and integration of concepts into a situated conceptualization underlying the concept of tradition. Assembling concepts into a situated conceptualization, linked to a specific word (e.g., the word "tradition"), supports efficient interpretation and engagement in future, similar situations. As we will see, it coordinates trajectories of moment-to-moment prediction and inference that guide perceiving, coordinating action, regulating the body, and organizing thought. It also supports efficient communication and interaction with others (Barrett, 2012). Learning concepts in this way often remains implicit in the sense that individuals are not aware of having learned a concept—they did not intend to learn a concept or remember how they learned it.

As the word "tradition" and supporting language is used in different situations, different situated conceptualizations develop that underlie the concept (e.g., for holiday traditions involving annual activities, for religious traditions involving weekly rituals, for vacation traditions involving travel with friends; Barsalou, 2003b, 2008b). Because the situated conceptualizations reflecting different instances of an abstract concept can vary dramatically, goals often represent what is regular and co-occurring across subsets of them (e.g., goals like sharing an enjoyable activity with family, teaching an important skill to others, and performing a valued duty in the community, for the abstract concept of tradition).[8] Importantly, though, goal-driven regularities are not particularly useful for interpreting and engaging in the situation without the situation-specific assembly of concepts embedded in the situated conceptualization (Wilson-Mendenhall et al., 2011).

Learning Concepts for Emotional Experiences

We assume that many emotion concepts develop like abstract concepts do (see also Vigliocco et al., 2009), with situated conceptualizations that assemble concepts developing as an emotion word and supporting language is used in different situations. These situated conceptualizations emerge out of the more simple concepts that develop for aspects of affective experiences, including internal states. Through a discussion that parallels that above, we highlight empirical examples from across the lifespan to illustrate how situated conceptualizations underlying emotions could be learned.

Learning Statistical Regularities Early

We assume statistical regularities in the body's internal environment (e.g., underlying hunger, arousal) could be learned in an analogous manner to those in the external environment. We further assume that regular situational co-occurences involving interoceptive activity could be learned in this manner. The simple reflexes that newborns display in response to the distress of overwhelming arousal (e.g., eye closing, head aversion, non-nutritive sucking) disappear quickly as more adaptive learned patterns become established in memory from experience (Kopp, 1989).[9] Infants learn situational co-occurrences among their internal states, their caregivers' actions, and their own actions as caregivers play an increasingly central role in regulating infants' arousal states (Kopp, 1989), which support interpreting and actively engaging in future, similar situations. Different cries, for example, can be used to signal hunger, pain, or boredom to a caregiver. The parent–infant synchrony that presumably supports statistical learning during the first year predicts conceptually driven capacities for symbolic play and internal state talk at 2–3 years of age (Feldman, 2007; Feldman & Greenbaum, 1997).

By 8 months of age, infants are establishing conceptual patterns that allow them to anticipate the affective changes that result from others' actions (e.g., cringing in anticipation of the physical discomfort involved in a vaccination, becoming distressed when an attachment figure prepares to leave; Bretherton et al., 1986).[10] The concepts infants are using, although rudimentary, appear to be increasingly flexible and situated (i.e., flexibly drawing on different instances of a concept). For example, 11-month-old infants express distress and increase attention when mom disappears into a closet, relative to when mom disappears through a doorway, suggesting that they are sensitive to the situation in which separation occurs (Littenberg, Tulkin, & Kagan, 1971).

Learning in Situations Using Words

We assume that initial word learning facilitates accruing patterns that underlie internal state concepts and other concepts in affective situations—an important precursor to developing more complex emotion concepts. Infants understand and begin to refer to the basic physiological and affective internal states that are central to daily routines and situations (e.g., sleepy, hungry, good, happy, tired, hot) as they learn words throughout the second year (Benedict, 1979; Bretherton & Beeghly, 1982; Ridgeway et al., 1985). We assume that different instances of these concepts accrue as they are named in different situations, and that they are increasingly integrated with other concepts as situated conceptualizations develop. We further assume that the concepts that are developing in affective situations during this time tend to be those that are useful for interpreting and engaging in the situations (and are heavily dependent on interactions with caregivers). When infants express distress or delight, for example, caregiver language tends to center around the eliciting situation and how to concretely resolve/maintain the affective state instead of labeling the entire situation using an emotion word (like “fear,” “anger,” “sadness,” “joy”; Bloom, 1993).

Only later, into their third year of life, do children begin to use words to name and understand discrete emotional experiences (e.g., “sad,” “afraid,” “scared,” “angry,” “mad”; Bretherton & Beeghly, 1982; Bretherton et al., 1986; Ridgeway et al., 1985; Wellman et al., 1995). Interestingly, the concepts that are developing in association with these words appear to initially be anchored on patterns of internal states underlying distress, paralleling the development of concrete, simpler concepts. Children often confuse emotions that feel unpleasant during this time (like anger and sadness), and it is not until later in the preschool years that children’s emotion concepts differentiate emotions of the same valence effectively (Widen & Russell, 2008, 2010). We assume that as language (i.e., phrases and sentences) and working memory operations develop, situated conceptualizations are constructed that support differentiating affective experiences using concepts like fear, anger, sadness, and so on.

Learning Integrated Situated Conceptualizations

As language and attention skills develop in a communicative context that supports learning, we assume that integrated situated conceptualizations underlying emotion concepts are learned (Barrett, 2009, 2013; Lindquist, Satpute, & Gendron, 2015). Assembling a configuration of concepts into a situated conceptualization through language, and linking the situated conceptualization to a specific emotion word (e.g., “fear,” “anger,” “sad”), supports efficiently interpreting and engaging in future, similar situations. The developmental literature provides many examples of parent–child interactions that involve discussing an emotion in the context of specific situations, including the events that preceded an affective state, the expressive actions that accompany an affective state, and subsequent coping actions (Bretherton & Beeghly, 1982; Bretherton et al., 1986). Discussing a child’s experience during a vaccination situation as involving fear (being scared, afraid), for example, might include talking about the restlessness and discomfort of anticipating the shot, the interactions with the doctor, the comforting presence of the parent (holding the child’s hand, etc.), the needle instrument and the actions involved in the injection, the pain experienced and expressive crying, and so on. Integrating concepts underlying these aspects of the experience into a situated conceptualization underlying fear supports later mobilizing them to efficiently generate series of implicit, top-down predictions during future vaccination situations (which drive changes in perception, action, and regulation that we explore in the section “Mobilizing Coordinated Concepts in Situations”). The constructive nature of this process suggests that the situated conceptualizations underlying emotions like fear, anger, sadness, and so on may change quite dramatically in the early years, becoming increasingly elaborate to the extent that such language-based interactions occur.

Across the lifespan, we assume that many different situated conceptualizations are developing for a given emotion concept. Situated conceptualizations underlying fear, for example, might develop in situations that involve undergoing a painful medical procedure, interacting with an intimidating stranger, disappointing a love one, riding a rollercoaster, being rejected by one's peers, injuring oneself in a car crash, starting a challenging new job, damaging one's reputation, and so on.[11] Empirical work increasingly demonstrates that by adulthood, varied situated conceptualizations—instances—underlie any given emotion concept (Barrett, 2009; Lebois, Wilson-Mendenhall, Simmons, Barrett, & Barsalou, 2016; Oosterwijk, Mackey, Wilson-Mendenhall, Winkielman, & Paulus, 2015; Wilson-Mendenhall et al., 2011). Adults can describe different instances of emotions like anger from their own life (Russell & Fehr, 1994). Moreover, they indicate that some of these instances are more typical than others, when instances are presented as specific words (e.g., "fury" is a more typical example of anger than "impatience" or "discontent"; Fehr & Russell, 1984, 1991; Russell, 1991; Russell & Fehr, 1994) or as different situational scenarios (Condon, Wilson-Mendenhall, & Barrett, 2014; Wilson-Mendenhall, Barrett, & Barsalou, 2015). Behavioral and neuroscience evidence suggest that these within-concept typicality ratings are meaningful, with atypical category instances of emotion concepts like fear, anger, and sadness processed less efficiently than typical instances (Russell & Fehr, 1994; Wilson-Mendenhall et al., 2015). Several recent studies provide further evidence that instances of emotion concepts vary, demonstrating that different forms of the same emotion produce different neutral patterns (e.g., oral, bodily, and moral disgust; Harrison, Gray, Gianaros, & Critchley, 2010; Moll et al., 2005; von dem Hagen et al., 2009), context shapes the experience of an emotion (e.g., fear during physical danger differs from fear during social evaluation; Wilson-Mendenhall et al., 2011), and individuals experience the same emotional situation differently (e.g., experiences of anger are dependent on a person's interpretation of an unpleasant situation; Kuppens, Van Mechelen, Smits, De Boeck, & Ceulemans, 2007).

We assume that the various situated conceptualizations underlying an emotion concept may tend to cluster around typical goals or motivations (e.g., avoiding anticipated harm/distress for fear) or emergent feelings (e.g., feeling unpleasant for fear), but that it is unlikely that these regularities are always present. The fear involved in riding a rollercoaster, for example, likely involves different goals (e.g., experiencing a thrill) and may even involve pleasant feelings. Moreover, as described above, goal-driven regularities are not particularly useful for interpreting and engaging in a situation without the situation-specific assembly of concepts embedded in the situated conceptualization (Wilson-Mendenhall et al., 2011).

Mobilizing Coordinated Concepts in Situations

Accruing situated conceptualizations supports the top-down coordination of concepts to efficiently navigate and learn in the situation at hand. Patterns of situated activity are continually interpreted through trajectories of situated conceptualization as a situation is experienced (either because it is presently occurring, or because it is occurring through reconstructing the past or planning/imagining the future; Barsalou, 2003b, 2008b; Barsalou et al., 2007; Yeh & Barsalou, 2006). As this occurs, the brain goes beyond the information present to infer what will happen next and to shift the biological system in ways appropriate to the situation (in the form of motor actions, perceptual sampling, attention shifts, visceromotor regulation, metabolic changes, etc.; Barsalou, 2009). Building on the empirical evidence presented in previous sections, we now address how dynamic situated conceptualization occurs for increasingly complex concepts, concluding with emotion concepts. We approach this theoretical discussion from the perspective of a typically functioning adult mind that developed the capacity for increasingly complex attention and learning as described above. At this point, we assume top-down prediction and inference is routine because concepts accumulated to interpret repeated situations (Barsalou, 2009; Vetter & Newen, 2014) and that the brain's neural architecture is, at many levels, organized for prediction (Barrett & Simmons, 2015; Bastos et al., 2012; Friston, 2012; Friston & Kiebel, 2009; Kroes & Fernandez, 2012; Shipp, Adams, & Friston, 2013). Because no two situations are exactly the same, we further assume that situated conceptualization is a dynamic process that reflects probabilistic activity and tuning, and when we refer to situated conceptualizations *mobilizing*, we are referring to this active, probabilistic processing (Barsalou, 2011).

Mobilizing Local (Often Concrete) Concepts in Situations

In familiar situations, situated conceptualizations can mobilize quickly and fluidly without explicit direction from language (although word forms are likely activated implicitly via pattern completion as an associated part of the situated conceptualization). Consider a situation in which an individual is searching for a healthy snack in the kitchen, and sees an apple. In this situation, with goal-directed conceptual processing of kitchen, healthy, snack, and hungry already occurring, visual processing of the apple provides the critical constituent of the pattern needed to mobilize a situated conceptualization that involves eating the apple. The brain quickly goes beyond the visual experience of the apple to initiate changes in the brain and body. Pattern completion inferences provide educated guesses about what is likely to occur next—inferring actions to execute (e.g., grasping, biting, chewing), external and internal sensations that will occur (e.g., sweet taste sensations, crunchy sound sensations, satiating body sensations), internal regulation to initiate (e.g., metabolic activities), affective feelings that will emerge (e.g., the pleasant satisfaction of choosing a healthy snack), and so forth. The rapid unfolding of top-down predictions prepares and *engages* the body and mind by initiating action and regulation involved in eating the apple (Barrett & Bar, 2009; Papies & Barsalou, 2015). Top-down predictions drive attention and perceptual sampling in the situation, changing the way it is experienced. Because this particular situated conceptualization is driving perception, for example, the apple may appear a more appetizing shade of red than it would otherwise (e.g., if the situated conceptualization did not involve eating the apple).

In contrast, consider a situation in which an individual is searching for apples in the produce section of the grocery store. The situated conceptualization mobilizing in this situation generates a very different set of top-down predictions as the situation unfolds—predictions that drive perception and attention to visual features that distinguish apples from other fruits, initiate executing actions involved in selecting apples and placing them in a cart, and so on. Different situated conceptualizations involving a given concept are constructed to tailor prediction and inference to the situation at hand. The regularities imposed by situations are critical for using concepts to shift the brain and body into states that are consistent with an individual's goals and needs, which can vary dramatically from situation to situation (Barsalou, 2009).

For situations that are highly familiar, situated conceptualization reflects an assembly of concepts that mobilize as a trajectory of top-down predictions, which may continue for as long as patterns continue to loosely match perceptual input and reafferent signals, coordinating attention, perception, action, interoception, and so forth. When there is a considerable discrepancy between experience and the pattern mobilized in the situated conceptualization (i.e., what could be considered novelty), attention operations will interrupt the top-down flow of inferences that are occurring. At this point, situated conceptualization may change dramatically, reassembling concepts to reflect the multimodal change in experience or, alternatively, conceptual processing could become more fragmented as learning and updating occurs in specific modalities. Although the complexity and coordination of conceptual processing may change dynamically in this manner, the brain is always producing predictions at some level to interpret experience. Consider a situation in which an apple that an individual intended to eat feels mushy and smells odd. In this situation, the conceptual processing will begin to produce different predictions related to foods with unusual textures and smells, which might prepare the individual to dispose of the apple. Furthermore, because the salient sensations involved reorienting attention, further encoding and retrieval will likely follow, establishing a situated conceptualization involving rotting apples.

Mobilizing Configural (Often Abstract) Concepts in Situations

Situated conceptualization occurring at any given point in time constrains the situated conceptualization that follows. Consider a situation in which an individual's goal is to prepare for a large meal the morning of a holiday (e.g., American Thanksgiving). Visual processing of an apple mobilizes a situated conceptualization that involves preparing an apple pie. At this moment in time, predictions tailored to apple occur (e.g., motor actions like slicing, taste sensations like sweet) and coordinated concepts mobilize (e.g., knife, sugar, oven), guiding shifts in attention that accompany changes in perceiving, coordinating action, regulating the body, and organizing thoughts. Situated conceptualization dynamically changes as this occurs, generating new predictions from moment to moment to infer what to do next (e.g., to locate and grasp the knife, search the cabinet for sugar).

Through such trajectories, constraints accrue as goal-directed situated conceptualization guides prediction and inference involving local concepts in a situation, and as configural relations among these concepts are integrated in working memory. With specific situational constraints in place, a shift in the assembly of concepts underlying an individual's goals often appears to provide the critical constituent for mobilizing a situated conceptualization underlying a more complex, abstract concept. In the situation described above, for example, the individual's goal might shift from preparing for the meal to sharing an enjoyable activity with family when the kids wander into the kitchen. At this point, the concepts underlying the goal of sharing an enjoyable activity—configuring with concepts underlying family, apples, pie, baking, and holiday—provide the critical constituents for mobilizing a situated conceptualization underlying tradition.

Because a concept like tradition is more complex, the underlying situated conceptualization assembles concepts configured in time and space that generate a series of predictions (inferring what is going to occur). Situated conceptualization, as we refer to it here, really refers to extended trajectories of situated conceptualization that coordinate series of predictions. Linked local concepts not yet perceived mobilize via pattern completion, producing predictions that dynamically shape moment-to-moment experience in the form of perceiving, coordinating action, regulating the body, and so on as described above. Because this particular situated conceptualization is driving perception, for example, the individual might perceive family members' smiles as broader and more intensely positive than they would otherwise, consistent with the goal of sharing an enjoyable activity. Goals often shape the local concepts that are assembling in such situated conceptualizations. If an individual's goal is to share an enjoyable experience, for example, assemblies of local concepts will organize around actions shaping interactions between family members. On the other hand, if an individual's goal is to teach his or her children to execute a family recipe, the assemblies of local concepts will organize around actions shaping precise pie baking.

Similar to other concepts, we assume many different situated conceptualizations, grounded in goals, are constructed for complex, abstract concepts to tailor prediction and inference to the situation at hand. Situated conceptualizations underlying the concept of tradition could include holiday traditions involving annual activities, religious traditions involving weekly rituals, vacation traditions involving travel when friends are available, and so on. We further assume that the situated conceptualizations underlying abstract concepts are largely assembled based on prior learning, with learning and updating occurring in novel situations as described above. Because language is often involved in these more complex experiences, and because abstract concepts involve assemblies of concepts, "ad hoc" variations of situated conceptualizations underlying an abstract concept may occur relatively frequently.

Mobilizing Emotion Concepts in Situations

Initiating shifts in the brain and body quickly is often especially important during emotional experiences. Situated conceptualizations serve this function by coordinating concepts to prepare and engage the body as the situation unfolds. Because the concepts underlying emotional experience often develop as abstract concepts (i.e., that integrate local concepts into configural relational structures), trajectories of situated conceptualization can be initiated when they mobilize. Pattern completion inferences across space and time generate predictions and initiate changes quickly and fluidly.

Consider a situation in which an individual is driving home late in the evening, after indulging in a delicious holiday meal and drinking several glasses of wine. Resting her eyes for just a moment, the car starts to drift off the road. When her hands slip from the steering wheel, she jerks awake. Through a rapid trajectory of situated conceptualizations, key constraints of the situation then emerge (i.e., actions involved in awaking, perceptions of the car drifting off the road) that shift her goal to avoiding the potential harm involved in a car crash. The assembly of these concepts mobilizes a situated conceptualization underlying fear. Linked local concepts not yet perceived mobilize via pattern completion to initiate specific changes in the brain and body (in the form of perceiving, coordinating action, regulating the body, organizing thoughts). For this situation, in which linked local concepts underlying driving are central, visceromotor changes might occur that underlie scanning the road for other cars and activating muscle tension to grip the steering wheel. Shifts in attention and perceptual changes occur such that surrounding cars appear closer and sound louder than they would otherwise. Motor actions occur that support turning the steering wheel and decelerating such that the car stays on the road. Thus, the situation is experienced as "threatening" because the brain is constructing situated conceptualizations to interpret and engage in the situation.

If the concepts assembled in the situated conceptualization were not available in memory (including the concepts underlying car, steering wheel, driving, crashing, etc.), the situation would not be so readily perceived as threatening. Furthermore, the changes that occur during a situation like this one will differ across individuals because situated conceptualization reflects prior learning (i.e., instead of changes reflecting stereotyped patterns of responding that are consistent across individuals).

The changes that occur during situated conceptualizations underlying an emotion concept vary greatly from situation to situation. Consider a very different situation, in which an individual is unprepared for an impromptu work presentation. As he stumbles through the presentation, and his goals shifts to minimizing damage to his professional reputation, the brain mobilizes a different situated conceptualization underlying fear. Predictions generated by the situated conceptualization initiate changes in the brain and body that are specific to the situation. In this situation, for example, visceromotor changes might inhibit the motor system from performing further actions unless absolutely necessary. Shifts in attention occur to organize thoughts involved in a compensatory strategy and to monitor the supervisor's reactions. Perceptual changes occur such that the supervisor's facial actions are interpreted as a frown instead of a neutral expression. As this example illustrates, different situated conceptualizations develop for an emotion concept like fear to initiate changes via prediction and inference as efficiently as possible in the situation.

Similar to other abstract concepts, we assume that goals are central to the situated conceptualizations that underlie emotion concepts. It might be tempting to also assume a one-to-one relationship between goals and emotion concepts (e.g., the goal of avoiding harm and suffering involved in all situated conceptualizations underlying fear). As discussed earlier, however, it appears that goals often vary across the various situated conceptualizations that underlie an emotion concept (e.g., when fear is experienced during thrill seeking), and that goals like avoiding potential harm/distress often operate very differently when grounded in specific situations.

Finally, we assume that the situated conceptualizations underlying emotion concepts are largely assembled based on prior learning, with new learning and updating occurring routinely as novelty is encountered and/or as language is involved in assembling concepts. We further assume that situated conceptualization underlies explicit and implicit forms of emotion regulation, with language often playing a central role in shaping trajectories of situated conceptualization (an extended discussion is beyond the scope of this chapter but see Barrett, Wilson-Mendenhall, & Barsalou, 2014).

Concepts Underlie How Emotions Function

In closing, we would like to briefly address how a situated conceptualization approach built on prediction and inference impacts how we view the functions of emotions, and by doing so, situate our theoretical approach with other theoretical approaches to emotion. Theories of emotions routinely assume that specific emotions or appraisal mechanisms evolved to serve a specific function that is adaptive. Basic emotion models typically assume that each discrete emotion system for fear, anger, disgust, sadness, and so forth evolved to deal with an important kind of problem related to survival, such as escaping predators (Tracy & Randles, 2011). Another major class of theories—appraisal theories—typically suggest that emotions reflect appraisals of the changing environment that function to detect situations relevant to an organism's well-being (Moors, Ellsworth, Scherer, & Frijda, 2013).

A situated conceptualization approach suggests that function is grounded in *learning and mobilizing* situated patterns to guide responding, and this functioning is not specific to emotional experiences. In general, situated approaches to the mind typically view the brain as a coordinated system designed to use information captured during prior situations (and available in memory) to flexibly infer what is currently happening and what to do about it—dynamically shaping moment-to-moment responding in the form of perceiving, coordinating action, regulating the body, and organizing thoughts (Aydede & Robbins, 2009; Barrett, 2013; Barsalou, 2003b, 2009; Glenberg, 1997; Mesquita, Barrett, & Smith, 2010; Wilson-Mendenhall, Barrett, et al., 2013). From a biological systems perspective, it is generally adaptive to use prior experience to predict what will happen in the present or future. This approach is largely consistent with an emerging family of psychological construction theories of emotion (Barrett, 2012; Clore & Ortony, 2013; Cunningham, Dunfield, & Stillman, 2014; Russell, 2003). Situated conceptualizations are especially central in the conceptual act theory

(Barrett, 2006, 2012, 2013), and much of what we have proposed and developed here is inspired by this theoretical approach.

Because a situated conceptualization approach offers a very different perspective on the functions of emotions than has traditionally been discussed, it motivates new research questions. From our perspective, it is critical to understand how situated conceptualizations develop and change. Instead of assuming that specific emotions or appraisals are inherently adaptive, a situated conceptualization approach suggests starting with the basic processes that scaffold attention and learning to establish the conceptual patterns that drive prediction. A possible starting point is that initial goals and motivations are grounded in ensuring immediate and prospective integrity of internal physiology (Critchley & Harrison, 2013), with the increasingly complex conceptual patterns underlying emotions emerging through attention and learning. If we assume that the patterns underlying affect and emotion are learned to a large degree, developmental and lifespan perspectives become increasingly important. Caregivers and close others play a large role in shaping emotional experiences throughout life, with crucial emotional development occurring early in life (Lindquist, MacCormack, & Shablack, 2015).

From our perspective, it is not surprising that emotional experiences vary dramatically within an individual (from situation to situation) and across individuals. Our approach suggests that it is important to understand this variability, and that understanding how situated conceptualizations create this variability could inform how we approach mental health and well-being. Some adults, for example, do not appear to distinguish among discrete emotions like fear, sadness, and anger that are typically unpleasant (Lindquist & Barrett, 2008)—similar to what has been characterized as the initial stages of learning discrete emotions during childhood (Widen & Russell, 2010). Initial evidence suggests that this lack of "granularity" impacts mental health (Demiralp et al., 2012; Suvak et al., 2011; Tugade, Fredrickson, & Barrett, 2004). Restructuring situated conceptualizations and learning new situated conceptualizations (often guided by others) arguably underlies the flexibility to cope with life's challenges. Many of the positive changes that occur in psychotherapy and in supportive relationships could be understood in terms of situated conceptualization (Barrett et al., 2014).

A situated conceptualization approach to emotion differs from many traditional approaches to emotion. From this perspective, the emphasis is on learning, variability, and change, which is how function is understood. Perhaps most importantly, assuming conceptual processing is fundamental to emotion, and thereby changing how we understand the functions of emotion, holds promise for illuminating important individual differences in emotional experiences and vulnerabilities for poor mental health.

Notes

1. Even this may not be that automatic—people learn to sleep through morning alarms, which may become too predictable to be arousing.
2. The neural patterns that underlie initial concepts are developing early in the first year of life (Bergelson & Swingley, 2012; Murphy, 2002; Tincoff & Jusczyk, 1999, 2012) and perhaps before then in the prenatal environment (e.g., patterns that underlie recognizing and responding to a mother's voice; DeCasper & Spence, 1986; Voegtline, Costigan, Pater, & DiPietro, 2013). Because concepts develop to predict what will occur in situations, concepts for experiences that are salient to infants (and that are made salient by parents) will develop first. What is salient to an infant initially may reflect the biological organization that scaffolds learning.
3. In our framework, no strict definitions distinguish affect from emotion. We primarily discuss the categories of emotional experiences that are a focus in the literature (e.g., fear, anger, sadness, happiness), but we assume that many different concepts develop for affective and emotional experiences.
4. Interoceptive activity (involving visceromotor changes) is not typically considered in models of attention, which instead focus on the sense modalities that interface with the external world.
5. For this reason, it is important to distinguish selection of interoceptive activity from "interoceptive awareness," which involves conscious, focal attention to bodily states (Kleckner & Quigley, 2014).
6. Efficiency is not synonymous with well-being. It is generally adaptive to use prior experience to guide responding in the present. Because prediction is experience dependent, however, learned conceptual structures could become entrenched and drive responding in a way that is unhealthy.
7. The term "situated" takes on a broad meaning in our view, referring to the distributed neural activity involved in constructing situations, which reflects the dynamic actions that individuals engage in, and the events, internal bodily sensations, and mentalizing that they experience, as well as the perceptions of the environmental setting and the physical entities

and individuals it contains (Wilson-Mendenhall, Barrett, & Barsalou, 2013; Wilson-Mendenhall et al., 2011).

8. The situated conceptualizations that underlie a concept often exist without any conceptual “core.” Instead, situated conceptualizations tend to vary in their similarity to one another, with regularities clustering in various ways, and with no regularities that are common to all situated conceptualizations (e.g., Lakoff, 1987; Rosch & Mervis, 1975; see also Lebois, Wilson-Mendenhall, & Barsalou, 2015). Furthermore, a representation that is separate from individual instances is not required to represent a concept—“prototypes” can be constructed dynamically (Barsalou, 1987; Murphy, 2002).
9. Kopp (1989) discusses the transition from “preadapted programs” to “elemental cognitive” processes. The elemental cognitive mechanism “implicates perceptual discrimination of an event, memory of past experiences in similar situations and learned associations of contingencies, and current self-needs and goal states” (p. 364).
10. These situated, preverbal patterns may underlie infant behaviors that adults would describe as fear (e.g., when abruptly scolded, when meeting “strange” novel people) or anger (e.g., when a caregiver departs, when unable to manipulate a toy). It is possible that these patterns are the starting points for more complex concepts that later become associated with the words “fear” and “anger.” It is also possible, however, that these patterns change substantially before children begin to organize them in memory around discrete emotion words (as situated conceptualizations develop through language-based learning).
11. Situated conceptualizations can develop as concepts mobilize to interpret a situation that is presently occurring or to interpret a situation that is occurring as a reconstruction of past experience or a projection of future possibilities. Situated conceptualizations underlying fear, for example, can develop when simulating potential pain or discomfort (e.g., during a car crash) via concepts in memory.

CHAPTER 33

MEMORY AND EMOTION

Elizabeth A. Kensinger and Daniel L. Schacter

Although the concept of memory has existed for thousands of years, its systematic study was launched in the 1880s by the seminal experiments of the German philosopher Hermann Ebbinghaus (1885/1962). Through careful assessments of his own memory, Ebbinghaus forged the way for the field of memory research by demonstrating that humans' ability to retain information over time could be studied scientifically. It is telling that Ebbinghaus's studies involved the intentional memorization of nonsense syllables: He believed that to understand memory processes, one should study retention of information void of meaning or personal importance. Although memory researchers seemed to embrace Ebbinghaus's views on this issue for nearly a century, recent decades have seen increased emphasis on examining memory for personally important experiences and for events that evoke emotional reactions.

Throughout this chapter, we use terms like "emotional stimuli" as a shorthand to denote information in the environment that elicits a rapid change in the internal, affective state of the organism. The focus of this chapter is on how these internal changes influence memory. Affective responses are often described within a two-dimensional space consisting of arousal (the subjective feeling of excitation or the physiological response evoked) and valence (the pleasure or displeasure experienced; see Feldman Barrett & Russell, 1999; Russell, 1980). In this chapter, we focus on episodic memory, or consciously accessible memories of past events. We first describe how the arousal of a response can affect memory, and we then describe how the valence of an affective response can affect the way the event is remembered.

We consider how each of these aspects of an affective response can influence the likelihood of remembering an event, the vividness with which the event is remembered, and the details retained about the event. In each section, we present the behavioral data and cognitive theories of emotional memory, and we also discuss the relevant neuroimaging and neuropsychological research that has been influential in examining the extent to which memory for emotional experiences is supported by processes distinct from those that support memory for nonemotional events. The neuroimaging studies also have helped to pinpoint the effects of an affective response on the initial creation of a mnemonic representation and on the eventual retrieval of that information. We highlight the general conclusions that have emerged from the research, and note some of the ongoing debates and open questions that remain.

The Influence of Emotional Arousal on Episodic Memory

Not all memories come to mind with equal ease. Moments that elicit arousal often are remembered disproportionately well, with higher recall rates for positive arousing or negative arousing stimuli than for neutral stimuli (reviewed by Buchanan & Adolphs, 2002; Hamann, 2001). This finding was anticipated by William James (1890) when he stated, "An experience may be so exciting emotionally as almost to leave a scar upon the cerebral tissues" (p. 670), and the propensity to remember arousing experiences has been documented across a variety of experiments, using words, sentences, pictures, narrated slide shows, and autobiographical memories (reviewed by Berntsen & Rubin, 2002; Buchanan, 2007). These benefits can be particularly pronounced when examining a person's ability to remember information over long delays (Quevedo, Sant'Anna, & Madruga, 2003; Revelle & Loftus, 1992), likely because of the cumulative effects of emotion on both the encoding and also the consolidation phases of memory.

Although the enhancement of memory by arousal is not always seen in the quantity of information retrieved (see Bennion, Ford, Murray, & Kensinger, 2013, for a discussion), in many of these instances there are still other signatures of memory enhancement present, such as an increased feeling of reexperience or memory vividness. In this section, we examine the processes that give rise to memories for arousing experiences, first presenting behavioral evidence that high-arousal information is more likely to be remembered with subjective vividness and with select details, and then describing the encoding and retrieval processes that may convey those benefits.

Emotional Arousal Enhances Memory Vividness

People claim to remember where they were and what they were doing when they learned of the assassination of President Kennedy (Brown & Kulik, 1977; Christianson, 1989; Winograd & Killinger, 1983), the September 11th terrorist attacks (Budson et al., 2004; Hirst et al., 2009; Paradis, Solomon, Florer, & Thompson, 2004; Pezdek, 2003; Smith, Bibi, & Sheard, 2003), or the explosion of the space shuttle *Challenger* or *Columbia* (Bohannon, 1988; Kensinger, Krendl, & Corkin, 2006; Neisser & Harsch, 1992). These details are not always accurate (as we expand upon later in this section), but what remains noteworthy about the memories is that individuals reexperience them with tremendous vividness. Memory for these arousing events is more likely to be associated with the autonoetic consciousness that defines an episodic memory (Tulving, 1985).

Extremely vivid memories—coined "flashbulb memories" by Brown and Kulik (1977)—form only rarely, yet many studies have confirmed that individuals often remember emotionally arousing stimuli in a more vivid manner than nonarousing stimuli (e.g., Conway, 1990; Kensinger & Corkin, 2003; Rubin & Kozin, 1984; Schaefer & Philippot, 2005). Even for "micro-events" or stimuli presented relatively briefly within a laboratory setting, when individuals are asked not only whether they recognize having seen those micro-events before, but also whether they vividly "remember" their prior occurrence, rates of "remembering" tend to be much higher for arousing pictures or words than for nonemotional ones (Dewhurst & Parry, 2000; Kensinger & Corkin, 2003; Ochsner, 2000; Sharot, Delgado, & Phelps, 2004). This boost in the ability to vividly remember emotional information often occurs even when overall recognition rates are equivalent for emotional and neutral information (e.g., Ochsner, 2000; Sharot et al., 2004).

Emotional Arousal Leads to Selective Memory Benefits

It is important to emphasize that arousal leads to *selective* memory benefits. Although arousing events are typically remembered more vividly than nonarousing events, they are not remembered with complete detail (e.g., Levine & Edelstein, 2009; Mather & Sutherland, 2011; Phelps & Sharot, 2008). Some details are likely "lost" during the initial processing of the event, never becoming part of a memory representation. Even Brown and Kulik (1977) realized that arousal does not lead to a memory that is truly picture-perfect, because some aspects of the event might never be recorded. They stated, "An actual photograph, taken by flashbulb, preserves everything within its scope; it is altogether indiscriminate . . . a flashbulb memory is only somewhat indiscriminate and is very far from complete. In these respects, it is unlike a photograph" (p. 75). Other details appear to be encoded at the time of an event's occurrence and then later forgotten or distorted. While Brown and Kulik (1977) believed that recollections of surprising and consequential events would be immune to memory distortion or disruption, such that all the information that was encoded would be maintained in memory, numerous studies since have demonstrated that emotional memories are prone to significant forgetting and distortions over time. Individuals often report high confidence in so-called flashbulb memories despite low consistency in their reports over time, and there often is little or no correlation between how confident individuals are about their memories and how accurate or consistent their memories are (Neisser & Harsch, 1992; Schmidt, 2004; Schmolck, Buffalo, & Squire, 2000; Talarico & Rubin, 2003). Clearly, emotional events do not leave indelible traces.

Some have argued that arousal provides no benefit to memory for detail, enhancing the *feeling* of vividness without elevating the *amount of content* included in the memory trace (e.g., Sharot et al., 2004). As evidence has accumulated, however, a more likely proposal seems to be that arousal provides *selective* memory benefits. It does not enable the formation of a memory that includes all event details; rather, it increases the likelihood that select components of an experience are remembered. Debates still continue about how best to characterize the event features that are most likely to be incorporated into a memory for an arousing event (e.g., Kensinger, 2009; Mather & Sutherland, 2011). As reviewed by Levine and Edelstein (2009), these details have been described as those that capture attention; are perceptually, temporally, or conceptually integral to the emotional event; or are goal relevant (see Levine & Edelstein, 2009, table 1, p. 13). What is generally agreed upon, however, is that arousal leads to enhanced memory for some select details from the event and not others.

If arousal leads only to selective memory benefits, then the disconnection between an individual's reported confidence or vividness in a memory and the objective assessments of his or her retrieval of detail may stem from two primary factors. First, individuals may ascribe vividness or confidence not only by the number of details remembered but also by the richness or ease with which some details come to mind (see Phelps & Sharot, 2008, for a discussion). Thus, if some details come to mind easily or vividly, an individual may give a high vividness rating to the memory as a whole, or may even give an inflated rating for other event details, assuming that all event details have been retained well. Second, for many events, arousal may play a larger role in the maintenance of internal details, such as the affect experienced at the time of the event, and a lesser role in the maintenance of details that can be objectively measured, such as where, when, and how an event unfolded. Participants may report a vivid memory based on their retention of internal details, yet these internal details may provide little aid in answering questions about the objective details of the event.

The Neural Mechanisms through Which Emotional Arousal Enhances Memory

When Brown and Kulik (1977) first described "flashbulb memory," they linked these memories to Robert Livingston's (1967) "now print" theory, proposing that there was a special memory mechanism that was induced for these events, permanently "printing" them into an accessible memory trace. Perhaps because of this history, researchers have focused intensively on whether arousal enhances memory via the engagement of special mechanisms, or whether arousal simply intensifies the same processes that allow vivid remembering of nonarousing information. Although parsimony favors the hypothesis that the same processes are recruited to remember arousing and nonarousing information, there is evidence that arousal may trigger a cascade of processes not typically engaged for nonarousing information. Behavioral evidence for such a distinction comes from studies that have asked participants to encode arousing and nonarousing information while performing a secondary task. For example, Kensinger and Corkin (2004) asked participants to study words either with full attention devoted toward the encoding task or with attention divided between the encoding task and a secondary, sound-discrimination task. The addition of the secondary task impaired the likelihood of recognizing nonarousing words and reduced the vividness with which the nonarousing words were remembered, whereas it did not have a large effect on the recognition rates or vividness of memories for the arousing words (see also Bush & Geer, 2001). This finding is consistent with proposals that emotional information is privy to prioritized or relatively automatic processing (reviewed by Dolan & Vuilleumier, 2003) and suggests that arousal can modulate memory even in the absence of the elaborative processes that typically enhance memory.

Lesion studies suggest that many of the effects of arousal are critically tied to the engagement of the amygdala, an almond-shaped region of the medial temporal lobe. Patients with damage to the amygdala do not show a memory boost for arousing information: Although they are not amnesic, they are no more likely to remember arousing events than they are to remember neutral ones. The absence of the memory enhancement for arousing information has been reported in patients with focal amygdala damage (e.g., Adolphs, Cahill, Schul, & Babinsky, 1997; Brierley, Medford, Shaw, & David, 2004; Cahill, Babinsky, Markowitsch, &

McGaugh, 1995; Markowitsch et al., 1994) and in individuals with amygdala atrophy caused by Alzheimer's disease (e.g., Abrisqueta-Gomez, Bueno, Oliveira, & Bertolucci, 2002; Kensinger, Brierley, Medford, Growdon, & Corkin, 2002; Kensinger, Anderson, Growdon, & Corkin, 2004).

The amygdala-mediated effects of emotion on memory seem to be tied to noradrenaline release. Adrenergic agonists enhance memory (Soetens, Casaer, D'Hooge, & Hueting, 1995), adrenergic blockade reduces memory (Cahill, Prins, Weber & McGaugh, 1994; Strange & Dolan, 2004), and individuals with a genetic variant that is thought to increase the availability of noradrenaline show a greater enhancement of emotional memory (de Quervain et al., 2007). The effects of adrenergic modulation on memory are particularly pronounced for emotional information (e.g., Segal & Cahill, 2009)—and in fact, are often absent for neutral information—possibly because amygdala activity in the absence of noradrenaline is insufficient to modulate hippocampal activity (Anderson, Yamaguchi, Grabski, & Laeka, 2006; Onoda, Okamoto, & Yamawaki, 2009; Segal, Stark, Kattan, Stark, & Yassa, 2012).

While these studies have demonstrated the necessary contribution of the combination of adrenergic responses and amygdala engagement to arousal-mediated memory enhancements, neuroimaging methods have provided further clarity with regard to the stages of memory at which arousal yields its effects. Researchers can examine the neural processes engaged at the moment that a subsequently remembered stimulus is processed, or can assess the processes engaged at the moment of retrieval. Neuroimaging studies can also elucidate the extent of overlap between the processes that give rise to memories for arousing stimuli and those that support memories for nonarousing information.

Encoding Processes Contributing to Memory for Arousing Events

Neuroimaging studies using a subsequent-memory design, sorting neural engagement during encoding on a post hoc basis into subsequently remembered and subsequently forgotten stimuli (e.g., Wagner et al., 1998), have demonstrated that the amygdala plays a fundamental role during the encoding of high-arousal information. Amygdala activity is stronger for arousing items that are subsequently remembered than for items that are subsequently forgotten (reviewed by Hamann, 2001; Phelps, 2004; Kensinger, 2009). Moreover, the individuals who show the greatest amygdala activity during the viewing of arousing items are those who show the greatest emotional memory enhancement (Cahill et al., 1996) and remember arousing stimuli vividly (Kensinger & Corkin, 2004). For nonarousing stimuli, amygdala activity at encoding typically does not relate to memory (e.g., Kensinger & Corkin, 2004), suggesting that the amygdala guides memory only in the presence of an arousal response.

It is important to note that activation of the amygdala leads to *selective* memory benefits. Amygdala activation during encoding does not enable the formation of a memory that includes all event details; rather, it increases the likelihood that select components of an experience are remembered (reviewed by Kensinger, 2009). Amygdala activity tracks with the likelihood of remembering the emotional content from a scene (e.g., a snake) but not with the ability to remember the nonemotional context within that scene (e.g., the forest in which the snake was located; Waring & Kensinger, 2011) or with other contextual details such as the encoding task participants performed while viewing a scene (Dougal, Phelps, & Davachi, 2007; Kensinger & Schacter, 2006a; Kensinger, Addis, & Atapattu, 2011).

Although the amygdala only enhances memory for select event details, its activity at encoding does tend to correlate with a vivid memory upon subsequent retrieval. Amygdala activity during encoding corresponds with the likelihood that people will claim to vividly "remember" an event (Dolcos, LaBar, & Cabeza, 2004; Kensinger & Corkin, 2004; Mickley & Kensinger, 2008), and the greater the amygdala activity during encoding, the greater the vividness that people will later ascribe to an emotional memory (Kensinger et al., 2011).

Arousal does, then, lead to some "special" memory mechanisms, insofar as the relation between the amygdala and memory performance is specific to arousing stimuli. The amygdala, however, does not act in isolation and does not appear to store the memories for arousing information, as evidenced by the fact that amygdala damage does not lead to amnesia (Zola-Morgan, Squire, Alvarez-Royo, & Clower, 1991). Instead, the amygdala appears to exert its influence largely through its modulation of other regions, most of which are implicated in the processing and retention of nonarousing stimuli as well. It has long been proposed that the amygdala interacts with regions of the cortex to modulate memory (Gerard, 1961). The amygdala is one of the most extensively connected subcortical regions of the brain, with links to numerous cortical and subcortical regions (Amaral, Price, Pitkanen, & Carmichael, 1992; Amaral, 2003). It is, therefore, in an excellent position to modulate functioning throughout many networks. A meta-analysis of emotional memory encoding (Murty, Ritchey, Adcock, & LaBar, 2010) emphasized the role of not only the amygdala, but also other medial temporal lobe regions typically implicated in successful encoding, including the hippocampus and parahippocampal gyrus, as well as the visual, prefrontal, and parietal cortices.

Lesion and neuroimaging evidence have confirmed that the amygdala can modulate the functioning of the sensory cortices. In one study investigating the links between amygdala activity and visual attention, patients with varying amounts of amygdala damage were scanned while they performed a task in which they had to attend to fearful or neutral faces (Vuilleumier, Richardson, Armony, Driver, & Dolan, 2004). Individuals with intact amygdala showed enhanced activity in the fusiform gyrus (a visual processing region) when they attended to fearful faces as compared with neutral faces. Patients with extensive amygdala damage did not show this pattern: They showed equivalent fusiform activity for neutral and fearful faces. Moreover, the amount of amygdala preservation corresponded with the amount of fusiform modulation based on the emotional content of the attended faces. These results suggest that the amygdala can modulate visual processing in humans, increasing the likelihood that an emotional item in the environment is detected and attended.

In addition to these influences on sensory processes, a number of neuroimaging studies have provided evidence for amygdalar modulation of mnemonic processes, suggesting that interactions between the amygdala and the hippocampus serve a critical role in modulating the memory enhancement for emotional information in humans (reviewed by McGaugh, 2013). In healthy individuals, there are strong correlations between the amount of activity in the amygdala and in the hippocampus during the encoding of emotional information (e.g., Dolcos et al., 2004; Hamann, Ely, Grafton, & Kilts, 1999; Kensinger & Corkin, 2004; Kensinger & Schacter, 2005a). Although these correlations cannot speak to the direction of modulation, a neuroimaging study examining encoding-related neural activity in patients with varying amounts of amygdala and hippocampal damage provided evidence for the importance of reciprocal connections. While in the scanner, patients were asked to encode a series of emotionally aversive and neutral words. Outside of the scanner they performed a recognition task and the encoding trials were sorted on a post hoc basis into those words that were later remembered and those that were later forgotten. The critical finding from the study was that the extent of amygdala atrophy correlated negatively with the magnitude of activity in the hippocampus during the encoding of emotional information, and the amount of hippocampal atrophy also was inversely related to amygdala activity (Richardson, Strange, & Dolan, 2004). Thus, bidirectional connections between the amygdala and the hippocampal system may be important for modulating the encoding of emotional information (see also Kilpatrick & Cahill, 2003).

Ongoing research continues to distinguish the effects triggered by each component of an arousal response, including effects on visual attention and sensory modulation by the amygdala (Dolan & Vuilleumier, 2003; Talmi, Anderson, Riggs, Caplan, & Moscovitch, 2008), and interactions between the amygdala and the hippocampus (reviewed by McGaugh, 2004; Phelps, 2004). The relative contribution of each may also depend on the delay after which memory is being assessed. A long-lasting memory results from a cascade of processes, begun during the initial encoding of the event, and continued as the event is consolidated in memory (Mueller & Pilzecker, 1900). The ultimate effects of arousal on memory, therefore, reflect a culmination of the processes engaged both as the event is initially experienced and in the time that intervenes until retrieval. An active topic of current research is to understand how the effects of arousal on memory unfold over this time course. For instance, Talmi and colleagues (2008) reported that interactions between the amygdala and fusiform gyrus during encoding may explain why emotional information is remembered well after shorter delays, whereas interactions between the amygdala and regions of the hippocampal system may become more important for explaining the enhancement in memory for emotional information after longer delays.

Retrieval Processes Contributing to Memory for Arousing Events

Arousal continues to affect memory through its influences at the moment of retrieval. Just a decade ago, it was unclear whether the amygdala was activated during the retrieval of arousing events (see Damasio et al., 2000; Reiman et al., 1997), but since then, evidence has accumulated to implicate the amygdala in the retrieval of arousing experiences (Daselaar et al., 2008; Dolcos, LaBar, & Cabeza, 2005; Fink, Markowitsch, & Reinkemeier, 1996; Kensinger & Schacter, 2005b; Markowitsch et al., 2000; Greenberg et al., 2005). Just as during encoding, enhanced connectivity between the amygdala and the hippocampus may aide in the retrieval of arousing events (Dolcos et al., 2005; Greenberg et al., 2005; Sharot et al., 2004; see also Addis, Moscovitch, Crawley, & McAndrews, 2004).

In an attempt to better pinpoint the nature of the contribution of amygdala engagement to retrieval, some neuroimaging research has used a protracted retrieval trial to distinguish the *search* phase, as a person attempts to retrieve content related to an internal or external cue and to monitor the success of the attempts, from the *elaboration* phase, as a person expands upon the content retrieved. Enhanced amygdala activity appears to aid the recovery of information during the search phase (Daselaar et al., 2008; see also Markowitsch et al., 2000), with amygdala activity occurring early on, even before people retrieve a memory in full. The hippocampus is also more strongly engaged during the search for an emotional event compared with a neutral event (Daselaar et al., 2008; Ford, Morris, & Kensinger, in press); this difference arises even when the retrieval cue is always neutral (Ford et al., in press), suggesting that hippocampal activity is modulated by the emotional content of the information that is associated with a cue, even before that information has been fully recovered.

The role of the amygdala may extend beyond that initial search phase, to enhance the feeling of reexperience (Sharot et al., 2004). Amygdala activity is greater when people are asked to remember the emotional content of an event as compared with other event details (Smith, Stephan, Rugg, & Dolan, 2006). Amygdala activity is also greater in individuals who have stronger emotion associated with a retrieval cue (Sharot et al., 2004), and the amygdala activity correlates with the degree of reported reexperience of the event (Denkova, Dolcos, & Dolcos, 2013). Just as remembering a sound can reactivate auditory cortex (e.g., Buckner & Wheeler, 2001), so might remembering an emotion reactivate the amygdala.

A study that investigated emotional memory in patients with amygdala damage supports the conclusion that the amygdala is involved in both memory search and also in the reexperience of emotion (Buchanan, Tranel, & Adolphs, 2005). Patients with and without amygdala damage were asked to recall events that occurred prior to their brain damage. Because the medial temporal lobes had been intact at the time of the event and for some period of time thereafter, atypical features of their memory were likely to be connected to the retrieval phase rather than to the encoding or initial consolidation phases (although contributions of long-lasting consolidation processes cannot be ruled out). The patients with amygdala damage were less likely to retrieve memories of unpleasant events, and when they did retrieve those unpleasant events, they rated them as less intense. These findings are consistent with the neuroimaging evidence that the amygdala helps with the search and recovery of arousing memories (such that amygdala damage reduces the likelihood that arousing events will be remembered) and also participates in the reexperience of emotion during retrieval (such that the intensity of reexperienced affect is reduced with amygdala damage).

As during encoding, the amygdala engagement during retrieval is likely to modulate many processes, not only those within the medial temporal lobe. Arousing events are often associated with more retrieval activity within visual cortices (Piefke, Weiss, Zilles, Markowitsch, & Fink, 2003; Van Strien, Langeslag, Strekalova, Gootjes, & Franken, 2009), perhaps reflecting the recovery of sensory information, and within frontal regions, perhaps reflecting the thematic elaboration or online maintenance and reliving of the event (see Daselaar et al., 2008; Greenberg et al., 2005, for more discussion).

Summary of Effects of Arousal on Memory

Arousal often enhances the likelihood of remembering an event and, even when it does not affect this quantitative assessment of memory, it still tends to alter the subjective quality of memory. Memories of high-arousal experiences tend to be more vivid than memories of low-arousal events. These effects of arousal seem critically tied to the combined activation of the adrenergic system and engagement of the amygdala during the initial encoding of an event. This combination enables the modulation of the hippocampal memory system as well as prefrontal and sensory cortices, enhancing the likelihood that a memory is created and that the trace includes some types of details that will enable the recovery of a rich memory trace. The amygdala participates in retrieval as well, and it appears that the amygdala may again modulate these same systems to aid in the search and recovery of information from memory.

The Influence of Emotional Valence on Episodic Memory

Although some of the research examining the effects of arousal on memory has focused only on negative high-arousal stimuli and has excluded positive information, the general pattern of results discussed in the previous section has been found to hold for all high-arousal stimuli, regardless of their valence. A topic of ongoing investigation is the extent to which the valence of an event (whether it elicits positive or negative affect) influences the memory for that event. To assess the effects of valence, researchers often have contrasted memory for positive and negative stimuli, rated to be equally high in arousal. If different memory patterns are associated with the positive and the negative events, then these differences have been attributed to the valence of the events. In the sections below, we outline what this research has revealed about the effects of valence on the likelihood of remembering an event and on the quality of the memory. We also describe the neural mechanisms that may relate to these effects of valence.

Effects of Valence on the Quantity and Quality of Information Remembered

When examining the effects of valence on the likelihood of remembering information, virtually every conceivable outcome has been observed. Often, the boost in recall or recognition is comparable for positive and negative stimuli (e.g., Adelman & Estes, 2013; Bradley, Greenwald, Petry, & Lang, 1992; Kensinger et al., 2002). In some studies, particularly those assessing memory for verbal or pictorial stimuli presented within a laboratory setting, negative items are more likely to be recalled than positive ones (e.g., Keightley, Chiew, Anderson, & Grady, 2011). Yet other studies, generally those assessing memory for autobiographical experiences or information encoded in reference to the self, have revealed the opposite pattern: a greater tendency to recall positive events than negative ones (e.g., D'Argembeau, Comblain, & van der Linden, 2005; Linton, 1975; Matt, Vazquez, & Campbell, 1992; White, 2002), sometimes referred to as the *Pollyanna effect* (Matlin & Stang, 1978).

Some of these conflicting findings may be explained by the proposal that memory mechanisms have evolved to facilitate the encoding and retrieval of the affective information that is most relevant to one's goals (Lazarus, 1991; LeDoux, 1996). Remembering a negative experience often may be relevant to survival (see Nairne, Pandeirada, & Thompson, 2008, for evidence that memory is better for survival-relevant information) or well-being, because reexperiencing the event will help a person plan for (or avoid) its future reoccurrence (LeDoux, 1996). In these instances, more attention may be paid to the negative item, thereby enhancing memory for this negative information. However, there likely are instances in which positive events are just as relevant, or more relevant, to one's goals as negative events. Indeed, when positive and negative stimuli are equally related to one's current concerns, they show similar capture of attention (Riemann & McNally, 1995). Furthermore, there is some evidence that individuals (e.g., older adults) who seek positive goal states show enhanced attention toward positive as compared with negative stimuli and also enhanced memory for positive events (reviewed by Mather & Carstensen, 2005).

For autobiographical memories, a related possibility is that there is a memory benefit for the valence of information most likely to be processed in a self-referential fashion. Positive experiences may be more likely to be integrated into a person's conception of themselves (see Matlin & Stang, 1978) and, thus, to be remembered. Negative experiences may be better remembered when individuals are focused instead on other-perception rather than on self-referential processing (e.g., Dreben, Fiske, & Hastie, 1979; Skowronski & Carlston, 1987), or when individuals are depressed and, therefore, have a more negative self-concept (Dalgleish & Watts, 1990).

The findings discussed so far suggest that the differential effects of valence may be mediated by effects separate from the affective response. These findings emphasize the need to consider more than just arousal when examining the influence of positive and negative affect on memory. If positive and negative experiences differ in their self-relevance or in their relation to an individual's motivational state or goals, then these differences could underlie effects that would otherwise be attributable to valence. Indeed, recent debates center on whether valence—or other factors often connected to valence—best explain the effects on memory (see

Sakaki, Niki, & Mather, 2012; Levine & Edelstein, 2009).

There is evidence, however, to suggest that the valence of a response may directly influence the way in which an event is processed and remembered. According to the "affect-as-information" framework (e.g., Schwarz & Clore, 1983, 1988, 1996; Clore et al., 2001), the way we feel can alter the way that we process information. Positive affect may promote the reliance on heuristic schemas (see Mandler, 1984; Rumelhart, 1980, for discussion of schemas), on gist-based information, and on broadly activated associative networks (see Fredrickson, 2004, for a related "broaden-and-build" theory of positive affect; and Shenhav, Barret, & Bar, 2013, for a proposal that this relation between positivity and associativity may relate to the role of the medial orbitofrontal cortex in both of these abilities). Thus, when in a good mood, we may notice the global characteristics or "big picture" of an event (e.g., Clore et al., 2001; Fiedler, 2001). Negative affect, by contrast, may elicit a greater focus on the details around us; it may narrow our attention onto those details, at times causing us to lose sight of the "big picture" (Schwarz, 1990; Storbeck, 2013; Wegner & Vallacher, 1986).

These different ways we process information can have downstream impacts on how we remember events that elicited positive or negative affect. While they may not affect the likelihood that we remember the event's occurrence, they are likely to influence the types of details we retain about the events. Thus, effects of valence may become more apparent when we switch from assessments of the likelihood of remembering an event to assessments of the subjective vividness of an event or the details that are remembered.

A number of studies have suggested that the valence of the response elicited by the event does influence the subjective vividness of the memory. Negative events often are remembered with a greater sense of vividness than positive events (e.g., Ochsner, 2000; Dewhurst & Parry, 2000). Positive stimuli, in contrast, often are remembered with only a feeling of familiarity (e.g., Ochsner, 2000; Bless & Schwarz, 1999). Valence can also influence the likelihood that details are accurately remembered. Although the exact nature of these findings remains debated (see Kensinger, 2009), negative information may be more likely to be remembered with some types of details than positive information, perhaps because attention is focused on some details of the negative experiences.

It has been unclear to what extent these laboratory findings extend to autobiographical events infused with emotional importance. Research on autobiographical memory often has supported the opposite conclusion from laboratory research: that positive memories are more vivid than negative ones (e.g., D'Argembeau, Comblain, & van der Linden, 2003; Schaefer & Philippot, 2005). For example, Schaefer and Philippot (2005) asked participants to recall positive, negative, and neutral events and, for each, to rate the number of sensory, semantic, temporal, and contextual associations retrieved about the memory (using the Memory Characteristics Questionnaire; Johnson, Foley, Suengas, & Raye, 1988). They found that participants' ratings were higher for positive than for negative memories, indicating greater retrieval of contextual detail for positive events. However, some studies suggest little effect of valence on memory vividness, and instead have found intensity to be the primary predictor of autobiographical memory characteristics (e.g., Talarico, LaBar, & Rubin, 2004).

A difficulty in these studies is finding positive and negative events that are comparable across a range of event dimensions (e.g., duration of event, public or private nature of event, amount of media coverage or rehearsal). Four studies have attempted to circumvent many of these difficulties by examining whether a person's response to an event outcome (finding it positive or negative) influences what he or she remembers about the event. Levine and Bluck (2004) asked participants to indicate whether particular events had occurred during the verdict decision in the O. J. Simpson trial. Kensinger and Schacter (2006b) examined what Red Sox fans and Yankees fans remembered about the final game of the 2004 playoff series, in which the Red Sox overcame a surprising 0–3 setback in the series to win the championship. Bohn and Berntsen (2007) asked individuals to retrospectively rate their emotions and recall details regarding the fall of the Berlin Wall. Holland and Kensinger (2012) asked participants to remember details about the 2008 presidental election. All four studies found that valence affected some memory characteristics, with negative affect being more likely to enhance memory accuracy or memory for detail. Levine and Bluck (2004) found that individuals who were happy about the verdict were more liberal in accepting that something had occurred and made more memory errors than individuals who were unhappy with the verdict. Similarly, Kensinger and Schacter (2006b) found that Red Sox fans, who found the outcome of the game to be positive, showed more memory inconsistencies over a 6-month period and were more likely to be overconfident in their memories than were Yankees fans, who found the outcome to be negative. In line with the suggestion that negative emotion might be linked to enhanced memory for details, Bohn and Berntsen (2007) found that those individuals who reported feeling negative about the fall of the Berlin Wall had higher memory accuracy than indivdiuals who felt positive about the event. Holland and Kensinger (2012) similarly found that participants who were displeased with the outcome of the 2008 election remembered more details of the election night consistently over the next 6 months than those who were pleased with the outcome.

Studies that have induced participants into positive or negative moods within a laboratory setting generally have corroborated these findings. Participants are more liberal in endorsing items as ones that they have studied when they are in a good mood, and they are more susceptible to false memories when in that pleasant state (Bless et al., 1996; Park & Banaji, 2000; Storbeck & Clore, 2005). Negative mood, by contrast, makes individuals more conservative in endorsing items and reduces the propensity to inaccurately endorse items that are related (but not identical) to studied items (Storbeck & Clore, 2005; Storbeck, 2013).

The effects of valence on memory, however, may depend on the delay after which memory is assessed. Breslin and Safer (2011) tested the memories of Yankees and Red Sox fans for the 2003 and 2004 American League Championship Series, which the Yankees and Red Sox won, respectively. They tested the memories 4–5 years later and found that fans showed the most accuracy for the game that their team had won. Although the requisite longitudinal study has not yet been conducted, the contrast of the results of Breslin and Safer (2011) with those of Kensinger and Schacter (2006b), who assessed fans' memories after an approximately 6-month delay, suggests that the effects of valence on memory may change over time. Breslin and Safer (2011) attribute the different effects of valence to the rehearsal that may occur in the time between an event's occurrence and the moment of retrieval. This finding may also reflect the tendency for negative affect to fade more rapidly than positive affect (see Walker & Skowronski, 2009, for a review). Over long enough time frames, preferential retention of positive information may also relate to age-related changes in affective focus, with an increased prioritization of positive affect (Mather & Carstensen, 2005).

The tendency for negative affect to fade more rapidly over time than positive affect is also relevant to the results of a recent study by Szpunar, Addis, and Shacter. (2012) that examined memory for simulations of future events. Participants were initially instructed to imagine positive, neutral, or negative future scenarios, each comprising a familiar person, object, and location. After delays of either 20 minutes or 24 hours, participants completed a cued recall test that provided two elements of the simulated event (e.g., person, object), and participants tried to recall the third element (e.g., location). At the short delay, participants recalled more positive and negative than neutral simulations, and there were no memory differences between the positive and negative simulations. By contrast, at the long delay, participants recalled more positive and neutral than negative simulations. In other words, there was a significant delay × valence interaction, such that negative simulations were forgotten more quickly over time than either positive or neutral simulations. In line with research on the fading affect bias (Walker & Skowronski, 2009), Szpunar et al. (2012) suggested that the affect that serves to bind together the elements of a simulated event may dissipate more quickly for negative than positive events. Consistent with this idea, Gallo, Korthauer, McDonough, Teshale, and Johnson (2011) reported evidence for a positivity bias in memory for simulated future scenarios following a 24-hour retention interval. In light of other evidence that future simulations exhibit a general positivity bias (see Schacter, 2012; Schacter et al., 2012; Sharot, 2011, for a review and discussion) it remains to be determined whether reduced retention of negative simulations after long delays is specifically characteristic of imagined *future* events or whether it occurs more broadly for imagined events in general.

Neural Mechanisms Underlying the Effects of Valence on Memory

Neuroimaging evidence has corroborated the "affect-as-information" perspective, finding evidence that the effects of valence on memory may be connected to differences in how the information is processed initially. It was noted in the section "The Influence of Emotional Arousal on Episodic

Memory" that emotion seems to increase activity in a large number of regions: not only the amygdala and other medial temporal lobe regions, but also regions in the prefrontal, parietal, and sensory cortices as well. The particular modulation of these regions may vary depending on the valence of an event. Across a few studies, the frontal and parietal regions have been more active during the encoding of positive events, while the sensory regions have been more active during the encoding of negative events (Mickley & Kensinger, 2008; Mickley Steinmetz & Kensinger, 2009). These findings are consistent with the proposal that positive affect is associated with distributed attention and a focus on the conceptual aspects of an event, while negative affect heightens the processing of sensory details.

There is some evidence that this distinction may continue during the retrieval phase, with more prefrontal engagement during the retrieval of positive autobiographical memories and more posterior, sensory activation during retrieval of negative events (Piefke et al., 2003; Markowitsch, Vandekerckhove, Lanfermann, & Russ, 2003). Recent research also suggests that regions within the hippocampal system may be differently recruited during the retrieval of positive and negative events (Denkova et al., 2013; Ford et al., 2014). A difficulty with the interpretation of many of the retrieval studies is that differences between positive and negative memories could stem from a multitude of factors, including differences in the types of content retrieved or in the effort elicited to retrieve them, in the details that become elaborated, or in the reencoding of the event. Parsing apart these effects will be a worthwhile focus of future research.

Summary of Effects of Valence on Memory

There is no clear answer to whether valence affects the likelihood of retrieving an event. The answer likely depends on a number of other factors, including the relevance of the information to the person or the person's goals. There is a clearer effect of valence on the ability to remember information vividly and with at least some detail, with negative information generally being remembered with more vividness and with at least some additional detail. These differences may relate to the different types of processing engaged while experiencing negative and positive affect, with negative affect leading to a greater processing of sensory details and positive affect encouraging a broader scope of attention. The effects of valence on memory may also change over time, emphasizing that processes that unfold over time are likely to interact with those implemented during the initial occurrence of an event.

Conclusions

In this chapter, we have reviewed the effects of arousal and valence on memory. We have described how these features of an affective response can influence the likelihood that an event is remembered, the subjective vividness with which it is remembered, and the likelihood that particular types of details are retrieved. We have emphasized the importance of considering the selective enhancements conveyed by these responses. Arousal leads to good memory for some details but not others, and valence shifts the focus from a detail-oriented processing of negative information to a more general processing of positive information. Thus, the effect of the affective response on memory will depend on the way memory is assessed and the types of information people are asked to retrieve.

We have reviewed neuroimaging and neuropsychological studies, demonstrating that the effects of arousal are connected to engagement of the amygdala and to its modulatory influence on other medial temporal lobe regions and on distributed cortical networks, including the prefrontal, parietal, and sensory regions. The effects of valence may be related to the divergent recruitment of these networks, with positive affect disproportionately recruiting the prefrontal and parietal regions, and negative affect recruiting the sensory cortices. Thus, at least in part, emotional information is remembered better than nonemotional information not because of the engagement of processes unique to memory for emotional information, but rather because of limbic modulation of the same processes that are typically recruited to remember nonemotional information.

Acknowledgments

Preparation of this chapter was supported by Grant Nos. MH080833 (to Elizabeth A. Kensinger), MH060941 (to Daniel L. Schacter) and AG08441 (to Daniel L. Schacter) from the National Institutes of Health.

CHAPTER 34

Language and Emotion

Putting Words into Feelings and Feelings into Words

Kristen A. Lindquist, Maria Gendron, and Ajay B. Satpute

In his 1981 essay "Feeling into Words," the poet Seamus Heaney suggests that putting feelings into words is "a search for images and symbols adequate to our predicament." Of course, a poet would know better than anyone why it is important to understand the link between emotion and language. Humans have the unique capacity to experience complex, nuanced emotions. Humans also have the unique challenge of communicating those experiences to one another with language. To date, much research has investigated how our emotional experiences get translated into language; this research is important for domains ranging from the arts to therapy to cross-cultural communication. Yet what Heaney did not acknowledge is that the symbols we know might also shape how we experience our "predicament" in the first place. That is, language might not just translate feelings into words, but might help shape the nature of those feelings to begin with.

Throughout this chapter, we review the various traditions that have investigated relationships between language and emotion. These traditions stem from different areas of research (e.g., psychology, neuroscience, linguistics, anthropology) and often make different assumptions about the nature of the relationship between language and emotion. We begin our chapter by first offering a few definitions of what we mean by "language" and "emotion," in the first place. We next discuss accounts of the relationship between language and emotion. We first introduce an account that explicitly hypothesizes that language helps to constitute emotions—the *psychological constructionist* model of emotion. Next, we review evidence from the emotion regulation literature that assumes that language can modulate emotions after the fact (e.g., by virtue of "reappraisal" or "affect labeling," as described below). Finally, we discuss a literature on the *emotion lexicon*, which typically (with some exceptions from linguistics) focuses on how emotional experiences get translated into words for the sole means of communication. We close the chapter by suggesting that a psychological constructionist approach can unite findings from across these seemingly diverse domains: it describes how words help shape the emotions that people experience and perceive, proposes the ultimate mechanism by which words help regulate emotions, and explains cultural variation in how emotions get put into words.

Definitions

Before we begin, it bears mention what we mean by the terms "language" and "emotion" throughout this chapter. Herein we use "language" to refer exclusively to the words that people use to describe emotional states (such as anger, disgust, fear, joy, contentment, pride, *schadenfreude*, *amae*, etc.). More specifically, we are referring to what linguists call the "semantic" aspects of language. It is beyond the scope of this chapter to discuss the role of syntax or metaphor in emotion, or how the affective meaning of words impacts their understanding or use (although these are interesting areas of study in their own right). Nor do we discuss words that name other categories (e.g., "mother," "murder") that might themselves have emotional connotations (see Lindquist, MacCormack, & Shablack, 2015, for a brief comment on the implications of these types of words in emotion).

We also have a very particular meaning in mind when we use the term "emotion" throughout this chapter. As it turns out, there is no single agreed-upon scientific definition of the term "emotion." In keeping with the psychological constructionist approach we take in our own research, we thus use the term "emotion" to refer to what are sometimes called "discrete emotions" in the psychology literature—psychological states that are *experienced as* coordinated patterns of physiology, behavior, and thoughts that occur within certain types of situations, and which are described with certain emotion category words (e.g., in English, "anger," "disgust," "fear," "happiness," "sadness"). We differentiate emotions from affect, which consists of basic feelings from the core of the body (for this reason, it is sometimes called "core affect"; Barrett, 2006b; Barrett & Bliss-Moreau, 2009; Russell, 2003). Affect is the representation of the body's ever-changing internal state (from the smooth muscles, skeletal muscles, peripheral nervous system, and neurochemical/hormonal system) and is often described as a homeostatic barometer that allows an organism to understand whether objects in the world are good for it, bad for it, approachable, or avoidable (Barrett & Bliss-Moreau, 2009).

Throughout, we also differentiate between *experiences* of emotion (or affect), which we identify as feelings in one's own body (e.g., a feeling of anger, a feeling of unpleasantness) and *perceptions* of emotion (or affect), which we define as inferring emotional feelings in another based on his or her face, voice, body, behavior, and so on (e.g., seeing someone else as angry, seeing someone else as feeling unpleasant). We turn now tvo the psychological constructionist approach to emotion, which explicitly hypothesizes that the words someone knows for emotion shapes how he or she makes meaning of affect, turning those affective states into emotion experiences and perceptions.

Putting Words into Feelings: Language and the Psychological Construction of Emotion

Psychological constructionist views are a family of psychological and neuroscience models that predict a constitutive role of language in emotions. According to *psychological constructionist* views, emotions are experienced when affective states are made meaningful as specific instances of the emotion categories that exist in a given culture. Emotions are thus considered the resulting products, or constructions, of more basic psychological "elements" (Barrett, 2006a, 2006b; Clore & Ortony, 2013; Cunningham, Dunfield, & Stillman, 2013; Lindquist, 2013; Russell, 2003). According to our particular psychological constructionist approach, called the conceptual act theory (CAT; cf. Barrett, 2006b, 2009, 2012, 2014), these more basic elements are representations of sensations from inside the body (affect), representations of sensations from outside the body (e.g., vision, audition), conceptual knowledge about the emotion categories experienced in one's culture, and executive attention (see Barrett & Bar, 2009; Barrett & Bliss-Moreau, 2009; Barrett & Satpute, 2013; Lindquist & Barrett, 2012; Lindquist, Wager, Kober, Bliss-Moreau, & Barrett, 2012, for reviews). A person experiences an emotion when conceptual knowledge is used to make meaning of his or her core affect (in experiences of emotion), or another person's affective facial movements (in perceptions of emotion), tailoring them to the context at hand. Importantly, rather than viewing emotions as physical types of categories that all individuals are born with, psychological constructionist views conceive of the emotions that are constructed out of more basic elements as nominal kind categories that exist only by nature of fact that a group of people agrees about their features (e.g., a culture agrees that "anger" is an emotion that occurs in contexts when norms are violated, when people scowl, and when vasodilation and an increased heart rate occurs, whereas "fear" is an emotion that occurs in contexts when uncertain events occur, when people gasp, and when vasoconstriction and an increased heart rate occurs; see Barrett, 2012; Lindquist, Gendron, Oosterwijk, & Barrett, 2013, for discussions).

Although all psychological constructionist views agree that emotions are nominal kind categories constructed out of more basic elements, not all views see a role for language in this process.

The CAT is unique in that it explicitly describes a role for language in the construction of emotion, insofar as language supports the acquisition and use of concept knowledge about emotion categories (cf. Lindquist, MacCormack, et al., 2015; Lindquist, Satpute, & Gendron, 2015). The CAT predicts that language plays an especial role in emotion because emotion categories (e.g., anger, fear, disgust) are abstract concepts with highly variable instances (e.g., Barrett, 2006a; Cacioppo, Berntson, Larsen, Poehlmann, & Ito, 2000; Mauss & Robinson, 2009; Wilson-Mendenhall, Barrett, & Barsalou, 2013; Wilson-Mendenhall, Barrett, Simmons, & Barsalou, 2011; see Lindquist, MacCormack, et al., 2015, for a discussion). Language helps humans represent all category knowledge (see Lupyan, 2012), but may be especially important to representing abstract categories that do not have strong perceptual regularities in the world (see Barsalou & Wiemer-Hastings, 2005; Lindquist, MacCormack, et al., 2015; Lupyan, 2012). In the case of abstract categories, words are a form of "glue" that holds the concept together (see Barrett & Lindquist, 2008; Lindquist, MacCormack, et al., 2015, for a discussion). The word "anger" is thus thought to be in part constitutive of an angry feeling because it supports the category knowledge that is brought online to make meaning of a rapidly beating heart, high blood pressure, and unpleasantness when a person's trust is violated, or to make meaning of a calmly beating heart, decreased blood pressure, and pleasantness when a person enacts revenge. This does not mean that a person needs to speak the word "anger," or even think it when making meaning of an affective state. Instead, the idea is that anger groups a population of instances in a person's conceptual knowledge (involving representations of sensations from the body, behaviors, and the context) that are all conceived of as members of the same category despite what otherwise might be large differences among them. For instance, within the behavioral domain, punching, running away, kicking, smiling, crying, and scowling can all occur in an instance of anger. Without the word to bind them, and based on their perceptual similarities alone (what it looks like or feels like to punch, run, kick, smile, etc.), these instances might otherwise belong to different categories and be experienced as such (see Lindquist, MacCormack, et al., 2015, for a discussion). During experiences or perceptions of affect, labels connected to concepts shape the conceptual information that is brought to bear when making meaning of sensations in the environment (a "label feedback hypothesis"; cf. Lupyan, 2012; see Lindquist, MacCormack, et al., 2015, for a discussion of how the label feedback hypothesis applies to emotion).

Mounting evidence from social cognitive, neuropsychological, cross-cultural, and neuroimaging studies is consistent with the psychological constructionist view that language helps constitute emotion. It is beyond the scope of this chapter to discuss all of this evidence since we have done so extensively elsewhere (Barrett, 2009; Barrett, Lindquist, & Gendron, 2007; Barrett, Mesquita, Ochsner, & Gross, 2007; Lindquist, 2013; Lindquist & Gendron, 2013; Lindquist, MacCormack, et al., 2015; Lindquist, Satpute, et al., 2015). However, we discuss several illustrative examples of how emotion words help to create the types of discrete emotional experiences and perceptions that people feel in their own bodies or see in the bodies of others.

Perhaps most notably, evidence shows that impairing participants' access to the meaning of words impairs their ability to perceive emotion on faces, even in tasks that do not require language. This finding suggests that language reaches relatively "deep" into visual perception to help construct a perception that someone else is "angry" or "sad." For instance, temporarily impairing access to an emotion concept by having participants repeat a word (e.g., "anger") out loud 30 times (a procedure called semantic satiation) makes participants slower and less accurate to perceptually match two facial expressions (e.g., judge that two faces are both angry; Lindquist, Barrett, Bliss-Moreau, & Russell, 2006).

Similarly, when language is permanently impaired due to a neurodegenerative disease called semantic dementia, so too is emotion perception. Semantic dementia occurs following neurodegeneration in the left anterior temporal lobe (ATL) of the brain, an important hub in a network supporting the representation of concept knowledge (Patterson, Nestor, & Rogers, 2007). Patients were asked to freely sort pictures of facial expressions (associated with the categories "anger," "disgust," "fear," "sadness," "happiness," and "neutral") into meaningful piles—a task that did not require linguistic responses. Whereas healthy control participants sorted the facial expressions into six or more distinct piles for the six emotion categories represented in the set, patients instead sorted faces into three to four piles representing positive, negative, and neutral feelings (Lindquist, Gendron, Barrett, & Dickerson, 2014). These findings converge with earlier evidence from a patient, LEW, who could no longer access and use words following a stroke (Roberson, Davidoff, & Braisby, 1999). LEW had difficulty sorting facial expressions of emotion into consistent piles and created several different configurations of piles across multiple testing instances.

Just as impairing access to emotion words impairs emotion perception, there is evidence that making emotion words more accessible alters how emotional facial portrayals of emotion, and even one's own body feelings, are made meaningful as discrete emotional perceptions and experiences. For instance, we (Nook, Lindquist, & Zaki, 2015), assessed whether the presence of words in a repetition-priming paradigm task made participants faster and more sensitive to perceive emotions on faces than did the mere presence of other faces. On each trial, participants viewed a rapidly presented facial emotion expression (the *cue* stimulus) followed by a second emotional stimulus (the *target* stimulus) and indicated whether or not the emotion categories reflected in the cue and target stimuli matched or not. On some trials, the target was a second facial expression (*face–face trials*), and on other trials, it was an emotion category word (*face–word trials*). Consistent with the hypothesis that increased accessibility to emotion words facilitates discrete emotion perceptions, we found that pairing emotional faces (e.g., a pouting face) with emotion labels (e.g., "sad") increased individuals' speed and sensitivity in perceiving emotions on faces. By contrast, participants' less sensitive judgments on face–face trials were driven by the similarity of facial features between cue and target (e.g., the presence of a furrowed brow), which did not necessarily differ between different emotion categories. In fact, the findings on face–face trials suggest that participants were not likely to spontaneously perceive faces in terms of discrete emotion because they were focusing on more basic perceptual similarities between faces. Participants did not tend to perceive a face in terms of a discrete emotion category unless a discrete emotion category word was present to facilitate this judgment.

There is also growing, yet still preliminary, evidence that increasing accessibility to emotion words while someone experiences a state of unpleasant affect alters the particular discrete emotion that he or she experiences. To test this hypothesis in a behavioral experiment (Lindquist & Barrett, 2008a), we first increased participants' access to the concepts of "fear" versus "anger" (i.e., "primed" those concepts) by asking participants to write a story about a fearful or angry character. In a control condition that did not prime any emotion concepts, participants wrote a neutral story about characters discussing a neutral event. We next separately manipulated whether participants felt unpleasant and highly activated versus neutral by asking them to listen to unpleasant versus neutral music and relive past experiences in which they felt unpleasant versus neutral. We hypothesized that making the concept of "fear" more accessible prior to making participants feel unpleasant would cause them to make meaning of their unpleasant state as an instance of fear. To test this hypothesis, we assessed participants' degree of risk aversion (i.e., the perception that the world is full of danger), which is consistent with how people view the world when they are in a fearful state. As predicted, those participants primed with the word "fear," who listened to unpleasant music subsequently, behaved in a fearful manner (i.e., saw the world as full of danger).

Another recent study demonstrated that the accessibility of emotion concepts influences how feelings manifest as physiological responses during emotion. Participants who were asked to report on their emotions (thereby activating emotion concepts), and who were then berated by an experimenter while completing a challenging mental arithmetic task, showed relative increases in total peripheral resistance (Kassam & Mendes, 2013), consistent with physiological responses to perceived threats. On the other hand, participants who did not have emotion concepts activated experienced less total peripheral resistance. Labeling states actually reduced heart rate and cardiac output (Kassam & Mendes, 2013), which are more generally related to feelings of arousal. These findings are consistent with other growing evidence that categorizing a stress response with an emotion word associated with adaptive responding (e.g., "excitement") versus an emotion word associated with nonadaptive responding (e.g., "fear") alters the resulting emotional experience, physiology, and behavior (see Jamieson, Mendes, & Nock, 2013, for a review).

Another area of research consistent with the psychological constructionist view that language helps constitute emotion comes from research investigating the role of language in the acquisition of new emotion categories. This research is both correlational, tracking the development of language and its relation to emotion perception across early development, and experimental, demonstrating that pairing affective exemplars with words helps adults acquire novel emotion categories over and above mere experience with category exemplars. The correlational evidence suggests that prior to the development of language, infants are unable to perceive discrete emotions on faces, although they can differentiate pleasant, unpleasant, and neutral expressions relatively well (e.g., after habituating to happy faces, 5-month-olds look longer at any unpleasant face, whether fearful, angry, or sad; Bornstein & Arterberry, 2003). Like infants, 2-year-olds, who only know the very simple emotion words "sad" and "happy," can only reliably differentiate between unpleasant and pleasant facial expressions (e.g., they mistakenly perceive all unpleasant faces as "sad," even in a task that does not require language). Yet as we mentioned in the later section "Putting Feelings into Words: The Emotion Lexicon" as 3- and 4-year-olds begin to learn the words "anger" and "fear," they can correspondingly differentiate between sad, angry, and fearful facial expressions (see Widen, 2013, for a review).

Presumably, words help adults learn the meaning of novel facial expressions in much the same way as they help infants and children over the course of development, and experimental research is consistent with this hypothesis. For instance, in the absence of words to label distinct faces, adults were unable to perceive novel chimpanzee facial expressions (e.g., "play," "scream," "bared teeth," and "hoot" faces) as distinct from one another. In the first phase of the experiment, adults viewed pictures of unfamiliar chimpanzee facial muscle movements (e.g., a bared teeth or screaming face) or viewed the faces while also learning to associate them with nonsense words. Participants were later shown images taken from a continuous morphed array of two facial expressions (e.g., ranging from bared teeth to a scream) and were asked to indicate when two faces from the array were similar to each other, and when they were different. Participants who had learned to associate faces with a label displayed "categorical perception"—they were able to perceive a categorical boundary at the midpoint in the morphed array of bared teeth and scream faces—but participants who did not learn to associate faces with a label did not perceive such a categorical distinction (Fugate, Gouzoules, & Barrett, 2010).

Critically, if language helps constitute emotion, then people who speak languages with different emotion concepts should not just communicate emotion differently, but should also perceive and experience it differently. Consistent with this idea, a recent study found that participants who speak different languages see facial expressions differently. The authors used a computer graphics program to measure and then reconstruct East Asian and Western Caucasian participants' visual representations of facial expressions associated with the categories "happy," "surprised," "fearful," "disgusted," "angry," and "sad." Whereas Western Caucasian participants represented each of the six categories with a distinct set of facial movements, East Asian participants did not (Jack, Garrod, Yu, Caldara, & Schyns, 2012).

Our own recent work finds that emotion words guide emotion perception, but only when the words match the concepts that a culture regularly uses to make meaning of emotional faces. Individuals from a remote culture, the Himba of Namibia, and the United States were asked to complete an emotional face-sorting task like that completed in the study of semantic dementia patients. Participants completed the task either with or without emotion words as cues (e.g., a cue that a pile should contain "anger"/"okupindika" faces). Without emotion word cues, even U.S. participants did not sort in line with an assumed "universal" model of emotion based on the English emotion concepts of "anger," "disgust," "fear," "sadness," "happiness," and "neutral" (e.g., Sauter et al., 2010; see Ekman & Cordaro, 2011, for a discussion). Yet with emotion word cues, U.S. participants sorted more in line with this "universal" model. Importantly, Himba individuals did not sort in line with the "universal" model, even when translated versions of English categories were provided to them (Gendron, Roberson, van der Vyver, & Barrett, 2014). These findings suggest that English-language categories may not reflect the categories that are most relevant for Himba participants during facial emotion perception.

Finally, if language helps constitute emotion, then activity in brain regions correlated with language representation, retrieval, and use should also have increased activity when individuals experience or perceive emotions. Consistent with this hypothesis, meta-analyses of brain activity show considerable overlap in the brain regions with increased activity during language use (e.g., semantics; Binder, Desai, Graves, & Conant, 2009) and those with increased activity during emotional experiences and perceptions (Kober et al., 2008; Lindquist et al., 2012) (see Lindquist, Satpute, et al., 2015, figure 2). Shared areas include the dorsomedial prefrontal, ventrolateral prefrontal, and temporal cortical areas. Dovetailing with meta-analytic observations, we (Satpute, Shu, Weber, Roy, & Ochsner, 2013) recently manipulated components of emotional experience and observed that areas related to semantics played functionally dissociable roles during emotional experiences. Medial prefrontal regions and temporoparietal areas had increased activity when individuals retrieved mental state categories relevant for making meaning of their body states (i.e., making "I feel" judgments). By contrast, lateral prefrontal regions had increased activity when individuals retrieved specific semantic categories to make meaning of their feelings (e.g., affective labels such as "neutral," "bad," and "good"). Finally, consistent with the psychological constructionist account that language helps make affect meaningful, we found that limbic/paralimbic regions correlated with the intensity of experienced negative affect.

Together, these findings suggest that words may in fact be constitutive of emotion, suggesting that feelings don't just get "put into words," but that words get "put into feelings" too. However, not all models of emotion conceive of language as constitutive of emotion. We turn now to a perspective that views language and emotion as separate systems, but which hypothesizes that language can modulate emotions after they are formed.

Putting Feelings into Words: Language and the Regulation of Emotion

According to research on *emotion regulation* in psychology and neuroscience, language can serve as a means of altering an emotion after it is formed. Broadly, emotion regulation refers to a family of strategies in which people voluntarily increase or decrease the intensity, meaning, and/or expression of their emotional experiences (e.g., Beauregard, Levesque, & Bourgouin, 2001; Gross, 1998; Ochsner, Bunge, Gross, & Gabrieli, 2002). Models of emotion regulation often take a dual-systems approach, assuming that the processes involved in emotion regulation are distinct from the processes involved in emotion generation (cf. Gross & Barrett, 2011). The bodily, "bottom-up" processes involved in producing the emotion are thus considered distinct from the cognitive, "top-down" processes involved in regulating the emotion (e.g., Gross, 1998; Ochsner et al., 2002). If language is involved in regulating emotion, then it might be one of the so-called "top-down" mechanisms mediated by cognitive systems of the brain.

One of the most commonly studied cognitive mechanisms of emotion regulation is reappraisal, a method by which people up- or down-regulate their affective response to a stimulus by thinking about or reappraising the stimulus or their reaction to it in another way. The extent to which reappraisal involves language is unclear, but it stands to reason that people may be relying on emotion language when they engage in reappraisal. Imagine, for instance, reappraising the feeling experienced when standing atop a skyscraper as "exciting" as opposed to "frightening." In theory, a person is drawing on knowledge about excitement to do so, and may even be implicitly or explicitly labeling the state anew in his or her own mind.

Many studies reveal that participants can successfully decrease or increase self-reported affective experiences using reappraisal (see Gross, 1998; Ochsner et al., 2004), and are suggestive that language could be involved in this process. For instance, neuroimaging studies find that the act of reappraising a stimulus correlates with activity in the ventrolateral prefrontal cortex and dorsomedial prefrontal cortex, areas that are implicated in the representation of semantic knowledge (Binder et al., 2009) and semantic retrieval (Badre & Wagner, 2007; Satpute, Badre, & Ochsner, 2014; Wagner, Pare-Blagoev, Clark, & Poldrack, 2001).[1] Reappraisal also correlates with decreases in amygdala activity while viewing unpleasant images (see Buhle et al., 2013, for a meta-analysis). Since the amygdala is a brain region that responds to the presence of salient or uncertain stimuli and produces autonomic responding (see Cunningham & Brosch, 2012; Whalen, 2007), a reduction in amygdala activity is taken as convergent evidence of successful emotion regulation. These findings imply that language might be involved in reappraisal, but a clear test of the hypothesis that reappraisal depends on language has yet to be conducted.

By contrast, another area of the emotion regulation literature explicitly hypothesizes that language plays a role in emotion regulation. It has been long known that putting feelings into words after the fact can serve as a form of emotion regulation (Pennebaker & Beall, 1986). Pennebaker and colleagues found that writing or talking about one's emotions can reduce long-term distress associated with traumatic events (Pennebaker, 1997). More recent studies have explored the role of labeling emotions in the moment, or "affect labeling" (cf. Lieberman et al., 2007). Unlike reappraisal, which asks participants to actively reconstruct the meaning of a stimulus, affect labeling involves simply relating a single word with a stimulus (e.g., relating the word "anger" with a picture of a scowling face or feelings in the body). This task does not instruct participants to change the intensity of their emotional state, but nevertheless, labeling one's state has the unintended or incidental impact of reducing the intensity of emotional experiences (e.g., Lieberman, Inagaki, Tabibnia, & Crockett, 2011).

In one experimental paradigm, participants are asked to match a photograph of a person making an affective facial expression (e.g., a face with wide eyes) with one of two verbal labels presented below it (e.g., "fear" or "happiness"). Lieberman and colleagues (see Liberman et al., 2011; Lieberman, 2011) propose that accessing words to describe perceptions causes participants to engage in "reflective consciousness," the kind of consciousness that involves thought and symbolic language use. Engaging in reflective consciousness is thought to simultaneously cause detachment or disruption from "reflexive consciousness," the type of consciousness that involves focusing on "qualia" from perceptions in the world or feelings in one's body (cf. Lieberman, 2011). Their hypothesis is that the very act of using language to describe perceptions detaches individuals from the impact of those perceptions. Consistent with this hypothesis, activity in the amygdala was reduced when participants were asked to match an emotional facial expression (e.g., a scowling face) with one of two words (e.g., "anger" vs. "disgust"; Lieberman et al., 2007). The impact of affect labeling has also been observed behaviorally. Spider phobics took more steps toward a caged spider after using emotion words to describe their situation than when using neutral words (Kircanski, Lieberman, & Craske, 2012).

A current question of interest, particularly for this chapter, is the degree to which affect labeling also has an impact on emotional experience. Most studies of affect labeling present participants with facial expressions (Lieberman, 2011). In these contexts, participants may be labeling the meaning of someone else's facial expression rather than their own affective experience. Only a handful of studies have examined affect labeling in contexts that are more oriented toward eliciting and measuring emotional experience in the participant. Some of these studies show reduced affective experience when labeling emotional experience (Lieberman et al., 2011), but others do not (Kircanski et al., 2012; McRae, Taitano, & Lane, 2010). Nevertheless, findings from affect labeling are all the more impressive when considering that these studies—relative to reappraisal studies—do not involve the voluntary intention to change emotional states. Rather, the instructions to participants are minimal; they are merely asked to match a single word with a stimulus. Lieberman thus suggests that affect labeling is a form of incidental affect regulation; that when children are told "Use your words!," the mere act of doing so reduces unpleasant affective states.

Affect labeling resembles mindfulness-based meditation approaches, which have also been shown to reduce unpleasant feelings. In most forms of mindfulness, practitioners are instructed to label their psychological state using a word (e.g., "anger") with nonjudgmental awareness (Brown, Ryan, & Creswell, 2007): The mind is trained to observe sensations dispassionately, without exerting motivation to maintain or remove them. Mindfulness has been associated with a variety of health benefits and stress reduction (Grossman, Niemann, Schmidt, & Walach, 2004), but of more relevance here is the resemblance of mindfulness-based techniques to affect labeling. For instance, dispositional mindfulness appears to have an interactive effect with affect labeling: activity in the prefrontal cortical regions is greater and activity in the amygdala is less when individuals high in trait mindfulness perform an affect labeling task (Creswell, Way, Eisenberger, & Lieberman, 2007). These findings suggest that individuals high in trait mindfulness may in essence be habitual affect labelers.

In stark contrast to the idea that habitual affect labeling reduces the intensity of one's emotion is a body of literature from anthropology, linguistics, and psychology, which sees language and emotion as fundamentally distinct systems that interact only for the sake of communication. We now turn to this literature, which focuses how emotional experiences and perception get translated (often imperfectly) into the "emotion lexicon."

Putting Feelings into Words: The Emotion Lexicon

Research on the "emotion lexicon" systematically describes the terms that speakers of different languages use for emotions (see Clore & Ortony, 1988, for an excellent example of English emotion categories).[2] This approach (with a few notable exceptions, e.g., in linguistics; Pavlenko, 2006;

Wierzbicka, 1999) tends to see language as epiphenomenal to emotion. Indeed, the dominant view within this literature is that the capacity to experience and perceive certain emotions is innate and universal; these universal experiences then "sediment" out in language for the sole purpose of communication (cf. Fontaine, Scherer, & Soriano, 2013). This view thus assumes that emotions are "natural kind" categories that consist of a class of universal experiences that are united by a deep causal mechanism and shared surface features (e.g., all instances of anger are similar because they have the same biological mechanism and produce similar observable feelings, physiological changes, and behaviors across instances; see Barrett, 2006a; Lindquist et al., 2013 for a discussion).

The language sedimentation idea is most likely the dominant perspective in research on the emotion lexicon because it is most consistent with common sense—people essentialize emotion categories (e.g., Lindquist et al., 2013), assuming that emotion words map on to natural kind categories with universal metaphysical essences that make them what they are. People also believe that language is exclusively for communication, despite growing evidence that language feeds back to intrinsically shape mental states ranging from emotions (see Lindquist & Gendron, 2013; Lindquist, Satpute, et al., 2015, for reviews) to basic visual perception (e.g., Lupyan & Ward, 2013). This said, there are alternate viewpoints, largely in linguistics (Pavlenko, 2006; Wierzbicka, 1999) and in approaches that trace the history of the emotion lexicon (Frevert et al., 2014), that assume, like a psychological constructionist view, that emotion categories are social constructions that vary across culture and over time.

Since it is frequently assumed that emotion categories each share a universal "essence," research on the emotion lexicon likewise assumes that language is a mere "representation" of the emotion categories that already exist, albeit a sometimes imperfect representation of those categories. The translation of emotional experiences and perceptions into words is thus thought to occur in a largely consistent manner across languages. From this perspective, some languages might have an emotion lexicon that is relatively "accurate" and others a relatively "inaccurate" representation of the emotional states that humans are biologically prepared to experience and perceive. Much ethnography on the emotion lexicon has implicitly anchored on this assumption. For instance, Russell (1991) concluded that across 114 ethnographies of emotion surveyed "the ethnographer assumed that the way in which emotion is described in English suited that society and . . . that native words could be accurately translated into English" (p. 433).

In cases where a translational equivalent for an English emotion word does not exist, it is typically assumed that the emotion still exists in nature, but that the society did not develop a need to communicate about that particular state. For instance, Levy (1984) referred to states that exist but are not marked with language as "hypocognized," with the assumption that there are universal patterns of expression/behavior/physiology that mark these states even if they are not represented in language. In this view, individuals may experience and perceive states (e.g., "sadness" in Tahitians) that they have no language to communicate. For example, this assumption was tested in speakers of Yucatec Maya, a language that does not have a word for "disgust" (Sauter et al., 2010). The researchers examined whether Yucatec Maya speakers would still be able to differentiate among scowling (angry), wrinkle-nosed (disgusted), and frowning (sad) caricatures of facial expressions (i.e., show categorical perception, or perceptual distortions of a linear continuum of facial actions) despite not having a word for "disgust" in their language. Yucatec Maya participants could reliably differentiate caricatured facial expressions with wrinkled noses from caricatures with frowns or scowls. However, these findings are open to alternate interpretations because participants saw prototypes of each caricature prior to completing the categorization task, during which they received feedback on the accuracy of their judgments. This experience could have allowed them to form perceptual representations for the three different categories even if they did not previously possess separate representations of each of the three categories. At the very least, these findings are inconsistent with other studies in which individuals fail to show categorical perception for emotional faces when they do not know a corresponding emotional word (e.g., Fugate et al., 2010) or cannot access the relevant emotional word due to verbal load (e.g., Roberson & Davidoff, 2000).

Still other research focuses on documenting diversity in emotion language across cultures, focusing on unique categories that do not have a clear translational equivalent across cultures. For example, emotions such as "liget" and "amae" are concepts for which there is no translational equivalent in English. It is clearly difficult to grasp the meaning of a word that does not have an English translational equivalent, but researchers have attempted to unpack the meaning of such terms by describing the contexts in which they are typically used or combining English-language concepts together. For example, "liget" is an emotion that compels members of the Ilongot tribe to kill others by beheading (Rosaldo, 1980). Based on this context alone, an obvious English translation of liget might be "anger." Yet, Rosaldo (1980) also indicates that the "Ilongots see liget in the perspiration of a person hard at work" and invoke "imagery of focused liget in magical spells before they harvest rice" (p. 24). As a result it can be argued that no single word, or even simple combination of emotion terms from the English-language lexicon will capture the meaning of "liget." Similarly, "amae" is a term from the Japanese language and is the emotion experienced when you "depend and presume upon another's love" (Doi, 1973, p. 180)—it occurs in the context of being lovingly cared for. This emotion word has no exact translation in English, although research (Niiya, Ellsworth, & Yamaguchi, 2006) shows that English-language speakers can understand aspects of the concept of "amae" when associated with Western situations (e.g., a friend asks you for help with the computer in the middle of the night). This finding underscores a caveat about the literature on non-English-language emotion categories, more generally: It is possible that there is a bias toward unearthing and publishing about the concepts that are most easily imported into English, simply because they are understandable (even when that understanding comes from combining several English concepts or anchoring on scenarios typical of Western individuals). For instance, English speakers may understand "amae" because the concept maps on to some of the situations that they can identify in their own lives (Niiya et al., 2006). That said, English speakers likely have a more narrow understanding of the concept than Japanese speakers, who use the concept to refer to more than just a state that is felt. "Amae" can refer to "an emotion that a person holds toward another person, an interpersonal relationship, a behavior, or even a belief" (Niiya et al., 2006, p. 281).

Similarly, despite not having a term for "schadenfreude" (pleasure at another's pain) in English, many English speakers easily understand the word. Indeed, "schadenfreude" has been imported into common English parlance and is now the topic of study by English-speaking researchers (e.g., Cikara & Fiske, 2012). By contrast, there are clearly other concepts that do not possess translational equivalents in English and which English speakers are not readily adopting into daily language, such as "liget" in Ilongot (an exuberence during aggressive acts, decribed as a force of life; Rosaldo, 1980), "fago" in Ifaluk (sharing features with the English-language terms of compassion, love, and sadness; Lutz, 1988), and "lajja" in India (sharing features with the English-language term "shame," often occuring in the context of publicly aired achievement; Menon & Shweder, 1994).

A lesser-known set of findings focuses on cultures in which there is a lack of translation for English-language emotion words (see Russell, 1991, for a review). For example, Russell (1991) reviewed (primarily ethnology) reports that some cultures lack terms for specific English-language emotion categories. Tahitians appeared to lack a term for "sadness" and "guilt" (Levy, 1973). A term for "guilt" also appeared to be lacking in the Sinhala language of Sri Lanka (Obeyesekere, 1981), the llongot language of the Philippines (Rosaldo, 1980), the Pintupi language of aboriginal Australians (Morice, 1978), the Samoan language (Gerber, 1975), and in the Ifalukians (Lutz, 1980). A term for "depression" appeared to be lacking in the Yoruba of Nigeria (Leighton et al., 1963), the Fulani in Africa (Riesman, 1986), the Xhosa of South Africa (Cheetham & Cheetham, 1976), the Kaluli of Papua New Guinea (Schieffelin, 1985), in indigenous North American languages (Leff, 1973; Termansen & Ryan, 1970), in the Malay (Resner, 1970), and Chinese (Chan, 1990). Similarly, the term "anxiety" is lacking in the Eskimos of North America and the Yoruba of Nigeria (Leff, 1973), the Chinese (Cheng, 1977), and the Machiguenga of Peru (Johnson, Johnson, & Baksh, 1986). More recently, it was also documented that the Yucatec Maya lack a term for "disgust" (Sauter, LeGuen, & Haun, 2011). This list is, of course, by no means comprehensive. The strong emphasis on cultural universality in the emotion lexicon literature may mean that there are many more instances in which cultural differences in emotion concepts have not been documented. Strikingly, some researchers who uncovered lack of translational equivalents still interpreted their findings within a universalism framework. For example, Levy (1973) suggested that crying (a behavior) in the Tahitians was evidence that they still experienced sadness, even if the emotion did not sediment into language.

The lack of *simple*, single-word translational equivalents for emotion categories between English and other languages suggest that English categories may be a limited "anchor" for explorations of the emotion lexicon across cultures. Not only is there variety in the terms for emotion across cultures but even the overall number of terms in any given lexicon varies widely. According to Levy (1984), cultures not only hypocognize emotions (e.g., the Chewong of Malasia appear to have an emotion lexicon with only seven terms; Howell, 1989), but some cultures hypercognize emotions, with thousands of words to mark different states (e.g., over 2,000 terms in the English language). Perhaps even more intriguing is the fact that cultures disagree on what constitutes an "emotion" in the first place—some cultures do not mark emotions with a single linguistic category and identify them as a special kind of mental state (e.g., the Samoans [Gerber, 1975]; the Gidjingali aborigines of Australia [Hiatt, 1978]; the Chewong of Malaysia [Howell, 1989]; the Tahitians [Levy, 1973]; the Ifalukians of Micronesia [Lutz, 1980]; and the Bimin-Kuskusmin of Papua New Guinea [Poole, 1985]).

At the intersection of extreme universalism and extreme relativism lies a literature that seeks fundamental commonalities among emotion lexicons. This research began with Osgood and colleagues, who assessed core commonalities that define emotion lexicons across cultures during the 1950s and 1960s. Osgood (1975) employed a semantic differential approach in which participants rated the meaning of emotion terms on a number of different bipolar adjective scales. For example, scales might range from "good" to "bad," or "strong" to "weak," with "neutral" as the midpoint. Using data reduction techniques, Osgood (1975) revealed that three dimensions—evaluation, potency, and activity—contributed to the connotation of emotion words across 20 different cultural contexts. Since this seminal work, the same or similar dimensions (e.g., valence and arousal; Russell, 1983) have been documented across many different studies, using a variety of methods (see Russell, 1991, for a review).

More recently, Fontaine and colleagues again assessed the dimensional space that best accounts for the meaning of emotion terms across multiple cultural contexts (Fontaine, Scherer, Roesch, & Ellsworth, 2007). Their approach was theoretically anchored in a "componential" framework for emotions. The authors thus asked participants to rate emotion words on a set of a priori scales assessing action tendencies, subjective experience, and regulatory aspects of emotion (i.e., the GRID instrument; Scherer, 2005). Dimension reduction of data collected across Belgium, the United Kingdom, and Switzerland revealed four dimensions that characterized the similarities among emotion terms: evaluation, potency, arousal, and unpredictability (Fontaine et al., 2007). Although these dimensions are quite similar to those derived in prior research (particularly the first three dimensions, which are largely consistent with Osgood's [1975] results), the fourth dimension of unpredictability was unique to Fontaine et al.'s (2007, 2013) findings. One explanation of the discrepancy between Fontaine et al.'s (2007, 2013) findings and the large literature that observes only two or three dimensions is methodological. Fontaine et al. (2007, 2013) used unipolar rating scales, whereas previous dimension reduction research used bipolar rating scales (see Russell, 1991, for a review). The nature of the scale can impact the correlations between items in factor analysis, with unipolar scales decreasing correlations between items and inflating the number of independent factors observed (see Russell & Carroll, 1999, for a discussion). There is justification for using bipolar scales because participants often implicitly impose a bipolar opposite on a unipolar scale, even if the endpoint is specified as "neutral" (e.g., they assume a scale ranges from "unpleasant" to "pleasant," even when the scale specifies "neutral" to "pleasant") and this causes measurement error (see Russell & Carroll, 1999, for a discussion). Second, prior research did not invoke an a priori set of "components" for emotions. As a result, the structure underlying emotion terms may differ when perceivers anchor on their internal representations of emotion in a relatively unstructured manner versus when cued about specific content as in Fontaine et al. (2007). For example, items related to the "regulation" of emotion appear to load highly on to the "unpredictability" dimension in Fontaine et al.'s (2007) analysis, but it is not clear that individuals standardly think of the regulatory implications of an emotion when they are not prompted to emphasize that meaning of an emotion term.

Wierzbicka's natural semantic meta-language (NSML) offers another approach to understanding the commonalities between emotion terms. Wierzbicka's (1999, 2009) linguistic research indicates that there is minimal universality in concepts across cultures and she argues that more fundamental concepts (e.g., "good," "bad,", "do," "happen," "know," etc.), should form the foundation for cross-cultural comparisons of emotion. The NSML approach is a useful tool for revealing whether words that are assumed to be translational equivalents in different languages (e.g., Russian "smertnaja muca" and English "sorrow"; Wierzbicka, 2009) really have the same underlying meaning. This approach has not been adopted into mainstream psychology (Wierzbicka, 2009), however.

Of course, cultural diversity is not the only factor that produces differences in emotion lexicons. A growing literature also explores the development of emotion words across the lifespan (see Widen, 2013). For instance, children follow a slow and fairly predictable trajectory of linguistic emotion category acquisition (e.g., Widen, 2013). This development is striking because it suggests that some emotion terms, and the corresponding perceptual representations of that emotion category, emerge much later than others. For instance, 2-year-old children reliably use the words “happy” and “angry” (or “happy” and “sad,” depending on the child) to describe faces and can correspondingly distinguish positive from negative faces. However, children do not become able to meaningfully use the word “fear” until later in childhood (around 4 years of age) and do not reliably differentiate fearful faces from other negative faces until this point (see Widen & Russell, 2008). As we note in the Summary, such findings are ultimately consistent with the psychological constructionist view, in which language helps to constitute emotion by driving category acquisition and online categorization of one’s experiences or others’ facial expressions.

Summary

Throughout this chapter, we reviewed three traditions that each explores the relationship between language and emotion. The psychological constructionist approach assumes that concept knowledge supported by words constructs emotions in the first place, when affect is made meaningful as an instance of an emotion category (that is relevant to the speaker of a given language). By contrast, the emotion regulation research assumes that words can modulate emotions, helping to regulate emotions after the fact. Finally, the work on the emotion lexicon typically assumes that feelings merely get put into words after the fact. The fact that so many approaches are concerned with the relationship between language and emotion underscores the importance of this topic area in contemporary psychology, neuroscience, linguistics, and anthrophology. However, the three approaches we discussed herein appear to be mechanistically inconsistent with one another, at least on the surface. We argue that despite their apparent inconsistencies, a psychological constructionist approach can in fact unite findings from across these seemingly diverse domains.

For instance, if language helps to constitute emotional feelings in the first place by shaping how people make meaning of affective states, then it follows that prompting people to make meaning of their states with linguistic categories (as in affect labeling), or to reconstrue the meaning of a feeling with a different linguistic category (as in reappraisal), will contribute to the regulation of emotions. Of course, there is debate about whether the processes involved in emotion regulation are the same or different from those involved in emotion generation (Gross & Barrett, 2011), but early evidence is suggestive that the neural mechanisms involved in emotion experience and regulation are similar (cf. Ochsner, Silvers, & Buhle, 2012). Furthermore, there are alternative interpretations of the affect labeling literature that are consistent with the psychological constructionist view. For instance, it is possible that putting feelings into words actually forces individuals to make meaning of their otherwise ambiguous feelings of affect (pleasantness/unpleasantness or activation/deactivation) toward stimuli (cf. Lindquist, Satpute, et al., 2015). For instance, the finding that explicitly labeling facial expressions with emotion words decreases activity in the amygdala (Lieberman et al., 2007) could be evidence that words help reduce the uncertainty of affective stimuli. The amygdala, although broadly involved in emotion, is thought to be specifically involved in signaling the brain to process uncertain stimuli further (Whalen, 2007). As such, an alternate, but not incompatible, interpretation of the affect labeling findings is that language helps to regulate emotion by reducing uncertainty about the meaning of sensations in the body (as in emotion experience) or the world (as in emotion perception). Once a person constructs an emotional experience or perception and knows what his or her sensations mean, he or she can successfully regulate them. Indeed, greater specificity about the meaning of one’s emotions in daily life (called “emotional granularity”) is associated with greater emotion regulation success across instances (e.g., Barrett, Gross, Conner, & Benvenuto, 2001), perhaps because knowing the meaning of one’s affective state makes it easier to regulate that state (Kashdan, Barrett, & McKnight, 2015; Lindquist & Barrett, 2008b). Indeed, emotional intelligence interventions in children first teach children about different emotion concepts (e.g., “anger,” “fear,” “disgust”) and how to differentiate between instances of those concepts. Once knowledge about the concepts has been learned, children are taught how to regulate their feelings (Rivers, Brackett, Reyes, Elbertson, & Salovey, 2013). The idea that the ultimate mechanism of affect labeling is the categorization of an affective state as an instance of emotion is more consistent with psychological constructionist accounts of emotion, than the assumption that language only feeds back to shape emotions after the fact. Of course, more research is needed to better understand whether the role of language differs in emotion regulation versus emotion construction.

Just as the emotion regulation literature is ultimately consistent with a psychological constructionist view, the emotion lexicon literature can be interpreted as consistent with the idea that language helps construct emotions in the first place. For instance, if words in part constitute emotions, then this might describe why different cultures possess different emotion categories, why there are imperfect translations among different languages about the meaning of emotion words, and why children do not have fully formed emotion concepts until they know the relevant emotion category words. We argue that instead of revealing imperfect linguistic concepts for natural kind categories that already exist in the world, research on the emotion lexicon instead reveals the conceptual content that has the power to shape emotions in the speakers of that language. Consistent with the psychological constructionist view, the emotion categories represented in language might thus be better considered "cognitive types" (Clore & Ortony, 2008, 2013), "nominal kinds" (Barrett, 2012; Lindquist et al., 2013), or situation-specific concepts (Wilson-Mendenhall et al., 2011, 2013) that have the power to shape how speakers of a language make meaning of affective experiences or perceptions in a given moment. This interpretation would explain why speakers of different languages literally "see" different emotions on faces (Gendron et al., 2014; Jack et al., 2012) or describe instances of the same emotion category differently (Wierzbicka, 2009). Until only very recently, researchers assumed that translations of English emotion categories (if they exist) are the same categories that are used by all cultures to describe day-to-day emotional experiences and perceptions. Yet the findings of Gendron et al. (2014) suggests that when studying emotional experiences and perceptions across cultures, researchers should use more open-ended methods to discover (rather than stipulate) what categories members of a culture spontaneously use to make meaning of affective experiences and perceptions in their own daily lives.

In total, the research reviewed in this chapter suggests that conceiving of words as constitutive of emotion charts a new path forward for the science of emotion, helping to unite seemingly disparate traditions of study and suggesting new implications. Taking into consideration that words get put into feelings, alongside the more common-sense notion that feelings get put into words, might just change what researchers discover about the role of language and emotion.

Notes

1. As we pointed out in the first section of this chapter, these same areas are also involved during the experience and perception of emotions (Lindquist, Satpute, et al., 2015), and suggest that language may play a constitutive role in the *generation* of emotional states in the first place.
2. Separate but related lines of research (see Majid, 2012, for a review) focus on how affect/emotion is conveyed in classes of words such as interjections (Gendron et al., 2014; Sauter, Eisner, Ekman, & Scott, 2010; Simon-Thomas, Keltner, Sauter, Sinicropi-Yao, & Abramson, 2009), ideophones (Oda, 2000), and metaphor (Kövecses, 2003; Lakoff, 1987). There is also research assessing the impact of grammar (e.g., syntax), the sound of language (e.g., prosody), and the distinct ways that words are combined in discourse on emotion. This latter topic is an increasing field of inquiry in computing. The growing field of "sentiment analysis" analyzes natural language use (typically in "big data"; Pennebaker, Páez, & Rimé, 2013), with the goal of deriving a measure of the subjective state of the individual (be it an attitude, affective state, or emotion; e.g., Kramer, Guillory, & Hancock, 2014).

CHAPTER 35

Emotion and Attention

Greg Hajcak, Felicia Jackson, Jamie Ferri,
and Anna Weinberg

The notion of a struggle between the rational mind and the capricious heart plays out across countless literary plots, monologues, and works of art throughout history. We have come to expect that emotions (e.g., fear, anger, elation) and cognitive processes (e.g., attention, logic, reasoning) are in conflict, vying to control our behavior. Despite this classic view, emotions and cognitive processes seem to work more symbiotically than previously acknowledged. The focus of this chapter is to explore the interaction of emotion and attention: to discuss the ways in which emotional stimuli rapidly and preferentially capture attention, but also how attention can be leveraged to impact the processing of emotional stimuli. To this end, we examine behavioral and electrophysiological measures, in addition to eye-tracking and functional neuroimaging data. We argue that attention–emotion interactions are highly dynamic, unfold over time, and are quite sensitive to context.

From Attention and Emotion to Motivated Attention

The amount of information in the environment far exceeds the processing capacity of the visual system (Anderson, Van Essen, & Olshausen, 2005; Driver, 2001; Parkhurst, Law, & Niebur, 2002; Rensink, O'Regan, & Clark, 1997; Treue, 2003); indeed, only a small portion of information in the environment is actually perceived (Driver, 2001; Raichle, 2010; Rensink et al., 1997). The brain is tasked with quickly sifting through an abundance of information to determine what is most important. The set of cognitive processes that enhance the perception and processing of specific information is referred to as attention (Hillyard, Vogel, & Luck, 1998). Somewhat akin to a spotlight, attention helps focus on specific input. Broadly speaking, attention can be thought of in terms of bottom-up, or exogenous processes, and top-down, or endogenous processes.

As an instance of top-down processes, an individual's goals and motivation can shape how attention filters information (Rock & Gutman, 1981; Tipper, Weaver, Jerreat, & Burak, 1994). Suppose someone was helping a friend look for a lost dog. In this scenario, endogenous attentional processes would facilitate the perception of dogs in the environment. In the laboratory, endogenous attention has been studied by asking participants to detect or locate specific stimuli while ignoring others. In this way, attention can facilitate the processing of specific target stimuli based on their task relevance. On the other hand, bottom-up attentional processes can be driven by perceptual properties of visual stimuli, such as motion or color (Bacon & Egeth, 1994; Parkhurst et al., 2002; Theeuwes, 1994). As an example, the sudden movement of an object captures attention—it is as if changes in certain perceptual properties of stimuli cause them to "pop out."

Stimuli with content that is biologically relevant, or crucial for survival, also seem to capture attention in a similar fashion: with little effort, and relatively automatically, regardless of their perceptual properties and often regardless of their relevance to ongoing tasks or goals (Anderson, Christoff, Panitz, De Rosa, & Gabrieli, 2003; Mohanty & Sussman, 2013; Vuilleumier, Armony, Driver, & Dolan, 2001; Vuilleumier & Driver, 2008). In this way, stimuli that convey potential danger, reproductive opportunities, or the availability of other rewards are especially effective at capturing attention; the relatively reflexive engagement of attention by motivational imperatives has been referred to as motivated attention (Lang, Bradley, & Cuthbert, 1997).

It is unclear whether motivated attention reflects bottom-up or top-down mechanisms of attention. One possibility is that stimulus features related to emotional content may capture attention in a bottom-up fashion. For instance, emerging data suggest that certain geometric shapes (e.g., downward-pointing triangles) may automatically convey potential threat and reflexively capture attention (Larson, Aronoff, Sarinopoulos, & Zhu, 2009). However, it is also possible that motivational imperatives direct attention to emotional content in a more top-down fashion: if emotional content is relevant to our survival, then we may constantly be on the lookout for potential threat and opportunity. Indeed, cognitive neuroscience is gradually acknowledging that the distinction between top-down and bottom-up attention is oversimplified, and emotional processing is more likely a combination of multiple top-down and bottom-up processes occurring synchronously and interactively (Mesulam, 1998; Mohanty, Egner, Monti, & Mesulam, 2009; Mohanty & Sussman, 2013; Oliveira et al., 2013; Pessoa, 2008, 2010; Pessoa & Adolphs, 2010; Raichle, 2010).

In what follows, we argue that attentional engagement with emotional content begins relatively automatically, but rapidly comes to reflect both universal motivational imperatives and an individual's idiosyncratic ongoing goals and motivation—that is, the nature of the attention–emotion interaction is dynamic and unfolds over time. We discuss evidence for this view derived from multiple behavioral and physiological methods, but focus primarily on event-related potentials (ERPs), a technique with excellent temporal resolution capable of tracking rapidly shifting patterns of attention over time.

ERPs are derived from the ongoing electroencephalogram (EEG), a continuous measure of the electrical activity generated by postsynaptic potentials and measured by electrodes at the scalp. ERPs represent elements of the EEG that are time-locked neural responses to specific events—elicited by the presentation of specific stimuli, or the commission of a motor response (Luck, 2005; Luck & Kappenman, 2012). The rate of electrical conduction from synapse to scalp approaches the speed of light, meaning the signal recorded at the electrode is virtually instantaneous with the underlying neural activity. The temporal resolution of ERPs thus makes them ideal for investigating when conditions differ from one another; this is particularly useful to researchers concerned with shifting and dynamic patterns of attention. Although multiple ERP components are sensitive to the presentation of emotional compared to neutral stimuli (Hajcak, Weinberg, MacNamara, & Foti, 2012; reviewed in Olofsson, Nordin, Sequeira, & Polich, 2008; Weinberg, Ferri, & Hajcak, 2013), we focus specifically on ERP components that have been studied in relation to visual–spatial and sustained attention.

The Allocation of Visual–Spatial Attention to Emotion

A number of behavioral paradigms have been utilized to measure the preferential allocation of visual–spatial attention to emotional content (reviewed in MacNamara, Kappenman, Black, Bress, & Hajcak, 2013). For instance, in a visual search task, a participant is asked to locate a target stimulus among a background of many distracters—imagine looking for your keys in a cluttered drawer. Now instead imagine that you are searching for a picture of a snake among an array of relatively benign objects. Research confirms that if the search target is emotional, participants are faster in visual search tasks; moreover, if distracters are emotional, search speed is slower (Öhman, Flykt, & Esteves, 2001; Öhman, Lundqvist, & Esteves, 2001). Emotional content appears to draw the spotlight of attention, which can facilitate or impede performance in visual search tasks.

Studies have also utilized eye tracking to examine how people attend to emotional compared to neutral stimuli. For instance, Calvo and Lang (2004) simultaneously presented participants with an emotional and neutral picture, and examined eye fixations. Consistent with reaction time measures from visual search tasks described above, participants were more likely to fixate first on emotional compared to neutral pictures. Note here, however, that there were no specific instructions—participants essentially "searched" for and automatically attended to the emotional stimulus using eye movements, even in the absence of a goal to do so.

Fixation location is a reasonable proxy for where attention is allocated (Findlay & Gilchrist, 2003; Parkhurst et al., 2002). However, it is possible to measure the covert allocation of attention using ERPs. Specifically, the N2 posterior contralateral (N2pc) is an early ERP component occurring between 150 and 300 milliseconds, which is thought to reflect the focus of visual–spatial attention on a target while filtering out distracters (Luck, 2012; Luck & Hillyard, 1994). The N2pc has been used to index covert visual attention in cognitive psychology for over 25 years (see Luck, 2012, for a recent review) and more recently has been used to examine the allocation of attention to emotion. These results demonstrate that attention is rapidly directed toward emotional content (Brosch, Pourtois, Sander, & Vuilleumier, 2011; Buodo, Sarlo, & Munafò, 2010; Eimer & Kiss, 2007; Fox, Derakshan, & Shoker, 2008; Ikeda, 2013; Shaw, Lien, Ruthruff, & Allen, 2011).

In a study from our lab, we measured behavior and ERPs during a dot-probe task. On each trial of the dot-probe task, an emotional and neutral picture was presented for approximately 500 milliseconds to the left and right of fixation. Then, a target was presented in either the location previously occupied by the emotional or neutral picture; the participants' goal was to categorize the target as quickly and as accurately as possible. Importantly, we explicitly instructed participants to maintain their gaze on the fixation cross, and we eliminated all trials with eye movements to either picture. Although participants were not faster to categorize the target when presented in the location of the emotional picture, the N2pc revealed an initial shift in attention to the location of emotional stimuli—a difference that was evident by 190 milliseconds after stimuli onset (Kappenman, MacNamara, & Proudfit, 2014).

There is also evidence that the increased allocation of visual attention to emotional stimuli accelerates perception. As in the studies described above, West, Anderson, and Pratt (2009) presented participants with two visual stimuli to the left and right of fixation. However, these stimuli were either presented simultaneously (as in all of the studies described above), or with a slight lag between them; participants were asked to indicate which picture was presented first. Interestingly, West and colleagues (2009) found that neutral faces had to be presented several milliseconds before an angry face in order for participants to perceive them as having simultaneous onset. In other words, if presented simultaneously, participants actually perceived the angry face as being presented prior to the neutral face. Across a range of behavioral, eye-tracking, and electrophysiological measures, these studies collectively suggest that when an emotional stimulus is pitted against a neutral stimulus, visual–spatial attention is directed toward the former.

It is important to note that the facilitated processing of emotional stimuli may depend on the availability of attentional resources (Bishop, Duncan, & Lawrence, 2004; Bishop, Jenkins, & Lawrence, 2007; Liberzon et al., 2000; Pessoa, McKenna, Gutierrez, & Ungerleider, 2002; Pessoa, Padmala, & Morland, 2005). Lavie (2005) proposed that when a task commands sufficient attentional resources, there may not be enough additional bandwidth for the processing of task-irrelevant stimuli, even if they are emotional (see Lavie, Beck, & Nikos, 2014, for a review). However, the impact of load on emotional processing may depend on the specific measure used to index visual–spatial attention to emotion. For instance, much of the evidence that load reduces attention to emotional distracters is based on behavioral (Erthal et al., 2005), functional magnetic resonance imaging (fMRI; Pessoa et al., 2002, 2005), and positron emission tomography (PET) neuroimaging measures (Liberzon et al., 2000). Many of these measures do not directly index visual–spatial attention. On the other hand, the N2pc does not appear to be impacted by concurrent task load (Ikeda, 2013). Moreover, the intensity of the emotional content may further determine whether load attenuates visual–spatial attention to emotion. In our view, future research is required to more definitively examine whether visual–spatial attention to emotion, in particular, is attenuated by cognitive load.

The Allocation of Sustained Attention to Emotion

In all of the studies described above, visual–spatial attention is examined in the context of competition between simultaneously presented emotional and neutral stimuli. However, a good deal of what we know about emotion and attention involves the impact of a single emotional stimulus on subsequent performance. Reaction time measures to targets are slower if they are presented after emotional compared to neutral stimuli (Mitchell, Richell, Leonard, & Blair, 2006; Verbruggen & De Houwer, 2007)—that is, emotional content not only directs visual attention, but engrosses us and sustains attentional engagement, which causes subsequent interference. In one example, Mitchell and colleagues (2006) utilized the emotional interrupt task, which requires participants to categorize a shape that is immediately preceded and followed by a task-irrelevant emotional or neutral picture. In this task, participants are slower to perform the categorization if the target stimulus is sandwiched between emotional compared to neutral pictures (see Weinberg & Hajcak, 2011b, for similar results).

Using an experimental design in which pictures are presented in rapid serial presentation, Wang and colleagues found that emotional stimuli can cause perceptual interference (Wang, Kennedy, & Most, 2012). In a traditional attentional blink paradigm, participants view a rapidly presented series of images, and are asked to look for two target pictures. If the second target is presented shortly after the first, the former is not "seen" by the participant—it is as if the capture of attention by the first target causes a temporary perceptual "blink." Wang and colleagues (2012) found that target detection is similarly impaired if presented in close proximity to an emotional stimulus; thus, emotional stimuli seem to automatically capture attention and elicit an attentional blink.

Other evidence similarly suggests that emotional stimuli engage attentional resources throughout the picture presentation duration. Specifically, Schupp, Cuthbert, Bradley, and Birbaumer (1997) had participants view emotional and neutral pictures for 6 seconds, and presented irrelevant loud tones either during or after the picture viewing period. These tones elicited a P300—a component of the ERP that is larger for attended than unattended stimuli (Polich, 1987). The P300 to auditory probes was reduced when participants were viewing emotional compared to neutral pictures (Schupp et al., 1997). These data suggest that sustained attention to emotional content reduced the available attentional resources that were allocated to the auditory tone.

Sustained Attention and the Late Positive Potential

When participants view emotional compared to neutral stimuli, the ERP at parietal electrode sites is characterized by a sustained slow wave that begins as early as 200 milliseconds (Hajcak, Dunning, & Foti, 2009) and persists for the duration of picture presentation—even up to several seconds beyond picture offset (Hajcak & Olvet, 2008; Pastor et al., 2008). This late positive potential (LPP) is enhanced to emotional images (Cuthbert, Schupp, Bradley, Birbaumer, & Lang, 2000; Foti, Hajcak, & Dien, 2009; Pastor et al., 2008; Schupp et al., 2000), emotional words (Fischler & Bradley, 2006; Kissler, Herbert, Winkler, & Junghofer, 2009; Tacikowski & Nowicka, 2010) and even emotional hand gestures (Flaisch, Häcker, Renner, & Schupp, 2011). Figure 35.1 depicts a typical LPP, enhanced during the first 3,000 milliseconds while participants view unpleasant compared to neutral pictures. We have argued that the protracted increase in the LPP to emotional compared to neutral pictures reflects sustained engagement with salient content—that the LPP reflects the dynamic interplay between attention and emotion (Hajcak et al., 2012; Weinberg et al., 2013).

The LPP bears a striking resemblance to the P300, which has been studied extensively in nonaffective research. Specifically, the P300 is larger in response to stimuli that have been designated as targets. In a typical P300 oddball paradigm, a participant might be instructed to count the appearances of an infrequently presented neutral target (e.g., a circle) that appears in a sequential stream of frequently presented (i.e., standard) stimuli (e.g., squares). The P300 is enhanced for these infrequent target stimuli relative to the frequently presented standards (Duncan Johnson & Donchin, 1977; Squires, Wickens, Squires, & Donchin, 1976). Moreover, the P300 is larger for targets even when targets and standards are equated for probability, suggesting that task relevance itself is sufficient to potentiate the P300 (Duncan Johnson & Donchin, 1977).

Early research found that emotional stimuli elicited an enhanced positivity between 300 and 600 milliseconds following picture presentation, similar in timing and topography to the P300 observed in oddball tasks (Johnston, Miller, & Burleson, 1986; Lifshitz, 1966; Radilova, 1982). Consistent results were reported for emotional adjectives (Naumann, Bartussek, Diedrich, & Laufer, 1992), faces (Allison, Puce, Spencer, & McCarthy, 1999; Cacioppo, Crites, Berntson, & Coles, 1993; Schupp, Öhman et al., 2004), and even lines conditioned to have emotional meaning (Begleiter, Porjesz, & Garozzo, 1979), suggesting that the processes indexed by the P300 may be linked broadly to motivation. In the language of the classic oddball task, we suggested that emotional stimuli may be considered natural targets (Hajcak et al., 2012).

Many of us have wondered whether the P300 and LPP are the same thing—manifestations of

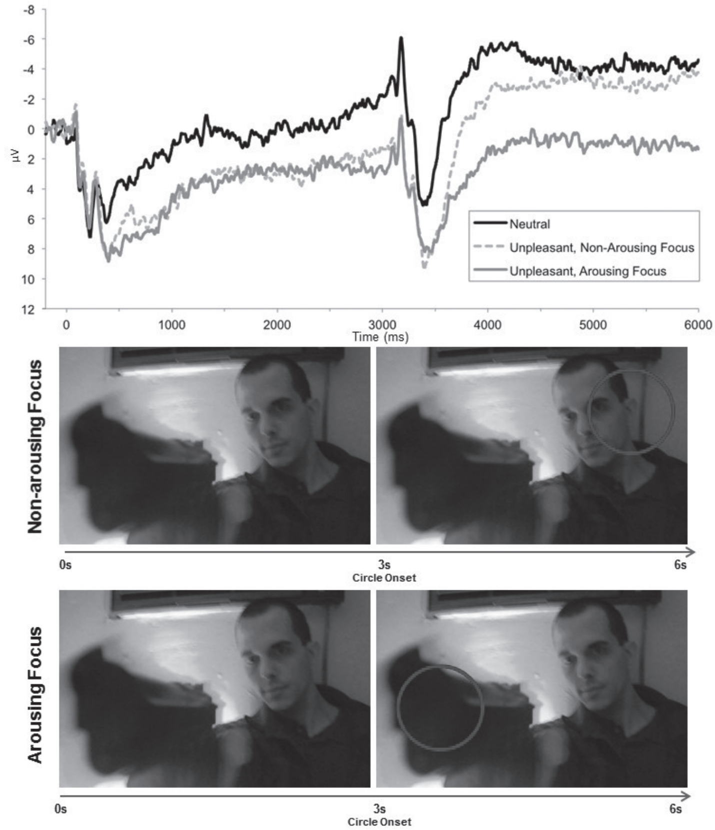

FIGURE 35.1. Data presented are from Dunning and Hajcak (2009), in which participants were instructed to passively view IAPS images for 3 seconds. During passive viewing, the LPP was enhanced to unpleasant relative to neutral images. After 3 seconds, a circle was presented that directed attention toward either an arousing or nonarousing portion of the image. When attention was directed toward an arousing portion of the image, the enhanced LPP was maintained. However, when attention was directed toward a nonarousing portion of the image, the magnitude of the LPP was reduced.

the same process. A key difference between the P300 and LPP is time course: the P300 appears relatively transient, whereas the LPP is more protracted. But why is the LPP a more sustained positivity than the P300? In a variant of a classic oddball paradigm, Gable and Adams (2013) instructed participants to either count the number of times a neutral image was presented, or to determine the duration the neutral target was on the screen. As such, targets in the "count" condition were attentionally salient for a short period of time, whereas "duration" targets were salient for more sustained periods of time. Importantly, Gable and colleagues found a relatively typical P300 to neutral targets in the "count" condition; however, neutral target images in the "duration" condition elicited a sustained LPP. These results demonstrate that the distinction between the P300 and LPP may reflect task-related differences in the time required to categorize target stimuli—that is, typical oddball paradigms only require fleeting engagement with target stimuli and produce a relatively transient LPP (i.e., the P300); however, the target-elicited LPP can be protracted if the oddball task requires more sustained engagement with target stimuli. Conversely, the time course of the LPP depends on the presentation duration of emotional stimuli. When emotional images are presented briefly (e.g., for 500 milliseconds), the LPP is relatively transient; on the other hand, a more sustained LPP is elicited when emotional images are presented for longer (i.e., 2,000 milliseconds; Gable, Adams, & Proudfit, 2014). If emotional stimuli are natural targets, then they are more akin to duration targets (see Gable & Adams, 2013, above) that sustain engagement for their entire presentation duration.

The sustained LPP is sensitive to motivational salience, defined in multiple ways. As mentioned above, target status also impacts the magnitude of the LPP (Azizian, Freitas, Parvaz, & Squires, 2006; Chong et al., 2008; Ferrari, Bradley, Codispoti, & Lang, 2010; Ferrari, Codispoti, Cardinale, & Bradley, 2008; Luck & Hillyard, 2000; Weinberg, Hilgard, Bartholow, & Hajcak, 2012), and nonemotional but personally salient stimuli (e.g., photographs of relatives, or one's own name and face) appear to elicit a larger LPP even than familiar celebrity faces (Grasso & Simons, 2010; Tacikowski & Nowicka, 2010). The amplitude of the LPP is not only sensitive to gross distinctions between emotional and neutral stimuli; it also appears to reflect more fine-grained distinctions between stimuli in terms of their biological relevance (e.g., threat, mutilation, and erotic images; Briggs & Martin, 2009; Schupp, Öhman, et al., 2004; Schupp, Junghöfer, Weike, & Hamm, 2003; Weinberg & Hajcak, 2010; Wheaton et al., 2013). Erotic pictures within the pleasant category elicit a larger LPP than "exciting" images (e.g., content related to sports, cars, or feats of daring), though both erotic and exciting images are rated as highly arousing and pleasant (Weinberg & Hajcak, 2010). This is presumably because exciting images have little direct bearing on survival or reproduction (Briggs & Martin, 2009).

If the LPP reflects sustained engagement with stimulus content, then it should predict subsequent interference from emotional distracters. In a study from our lab, we utilized a version of the emotional interrupt task (described above) in which participants were asked to identify a target—either a circle or a square—which was both preceded and followed by task-irrelevant pleasant, neutral, or unpleasant International Affective Picture System (IAPS) images. As in Mitchell and colleagues' (2006) work, responses to imperative targets were slowed by the presence of task-irrelevant emotional images (Weinberg & Hajcak, 2011b). Furthermore, the larger the LPP to the initial presentation of the emotional image, the slower the response to targets. This was true between participants, such that individuals with an enhanced LPP to task-irrelevant images were slower to respond to targets. And it was also true within participants: For each individual, slower trials tended to be preceded by pictures that elicited a larger LPP. Additionally, a larger LPP to task-irrelevant images was related to a reduction in the magnitude of the P300 elicited by targets. These results suggest that the sustained attentional engagement indexed by the LPP uniquely relates to interference with subsequent targets, as reflected in the subsequently slower response times and reduced P300 to targets in this task.

In terms of neurobiological substrates, the LPP appears to arise from the ongoing activation of, and communication among, multiple regions of the brain—including the visual, parietal, and frontal cortices (Keil et al., 2002; Sabatinelli, Keil, Frank, & Lang, 2013; Sabatinelli, Lang, Keil, & Bradley, 2007), as well as subcortical structures like the ventral striatum and the amygdala (Liu, Huang, McGinnis-Deweese, Keil, & Ding, 2012; Sabatinelli et al., 2013). These findings are consistent with the idea that the magnitude of these later components might reflect both bottom-up influences emerging from activation of the amygdala and visual cortex, as well as additive or competing influences of the frontoparietal attention networks (Bradley et al., 2003; Lang & Bradley, 2010; Lang, Bradley, & Cuthbert, 1998; Vuilleumier, 2005).

Modulating the LPP and Sustained Attention to Emotion

We have argued that the LPP indexes the time course of sustained attention (i.e., engagement) to visual stimuli based on motivational salience—determined both by emotional content and task relevance. Accordingly, the amplitude of the LPP should be sensitive to manipulations that alter the emotional significance of stimuli. Indeed, the LPP can be modulated by a range of strategies that impact how emotional content is appraised (reviewed in Proudfit, Dunning, Foti, & Weinberg, 2013). For instance, in one study, participants viewed emotional or neutral pictures, and had to make either an affective decision (i.e., Is it emotional or neutral?) or a nonaffective decision (i.e., How many people in the picture?) about each picture; the LPP was reduced when participants made nonaffective decisions about emotional pictures, consistent with the notion that these decisions impacted appraisal processes and reduced the salience of emotional content (Hajcak, Moser, & Simons, 2006).

Likewise, manipulations that ask participants to explicitly adjust their thinking about emotional stimuli have been shown to impact the magnitude of the LPP (e.g., Proudfit et al., 2013). One popular experimental technique to study this is cognitive reappraisal, which involves attending directly to emotional content and altering emotional response by reinterpreting the meaning of the stimulus (Sheppes & Gross, 2011). For instance, a participant might view a distressing picture of a sinking ship and think, "The ship is sinking, but everyone aboard survives." Thus, in reappraisal paradigms, the emotional content of stimuli is not made less relevant. Instead, reappraisal is achieved while engaging directly with emotionally arousing aspects of stimuli. Cognitive reappraisal appears to engage frontal brain regions in order to downregulate regions of the brain including the amygdala (Beauregard, Levesque, & Bourgouin, 2001; Ochsner, Bunge, Gross, & Gabrieli, 2002; Phan et al., 2005), and has been shown to reduce both subjective and peripheral physiological indicators of emotional arousal (Urry, 2010). It also effectively reduces the magnitude of the LPP.

In one of the first investigations of cognitive reappraisal using the LPP, Hajcak and Nieuwenhuis (2006) had participants view a series of unpleasant IAPS images; an instruction to "reinterpret" (i.e., reappraise the picture in order to reduce one's negative response) or "attend" (i.e., focus on one's natural feelings about the picture) was then presented, after which the same picture was again presented. Compared with unpleasant pictures presented after the attend instructions, those presented after reappraisal instructions were associated with a reduced LPP—an effect that lasted for the duration of picture presentation. Furthermore, greater reduction in the LPP was related to greater reduction in self-reported arousal ratings of the images. These results have been replicated several times (e.g., Krompinger, Moser, & Simons, 2008; Paul, Simon, Kniesche, Kathmann, & Endrass, 2013; Thiruchselvam, Blechert, Sheppes, Rydstrom, & Gross, 2011), and there is even evidence that reappraisal can have a longer-term impact on the LPP to emotional stimuli. For instance, Thiruchselvam and colleagues (2011) found that participants who reappraised unpleasant images demonstrated a reduced LPP in response to these same pictures when they were viewed again 30 minutes later (see MacNamara, Ochsner, & Hajcak, 2011, for similar results). Combined, these data suggest that the magnitude of the LPP can be modulated by changing the way participants think about emotional stimuli.

It is possible that the observed reduction in the LPP associated with reappraisal reflects the fact that the reappraisal condition is associated with increased cognitive load, which also reduces the magnitude of the LPP (MacNamara, Ferri, & Hajcak, 2011). Thus, in a series of studies we refer to in terms of preappraisal, we attempted to separate the effect of load from the effect of meaning change (Foti & Hajcak, 2008; MacNamara, Foti, & Hajcak, 2009). In these studies, participants were again shown neutral and unpleasant images, but here they were given a brief description prior to viewing each image. These descriptions could also be either neutral or unpleasant—participants might see an image of a soldier pointing a gun in the direction of a child preceded by either "This soldier notices the child and does not shoot" (neutral description) or "This child is about to be shot and killed by this soldier" (unpleasant description). Even when the cognitive load of having to generate reappraisals was lifted, these preappraisals modulated the LPP, such that unpleasant images preceded by neutral descriptors elicited a smaller LPP than unpleasant images preceded by unpleasant descriptors. These findings demonstrate that the reduction of the LPP in these reappraisal designs was not a result of the additional cognitive load involved in reappraising each image; rather, elaborative processes associated with stimulus meaning impact the magnitude of the LPP (Foti & Hajcak, 2008; MacNamara et al., 2009; Mocaiber et al., 2010).

Meaning-based manipulations can impact the LPP, even when emotional stimuli are completely irrelevant to the primary task. In one study, participants were asked to identify the spatial orientation of geometric shapes while irrelevant mutilation and neutral scenes were presented as distractors (Mocaiber et al., 2010). These images were described beforehand as being either real or fictitious, thereby shaping the initial appraisal. Consistent with previous research, unpleasant images in the "real" condition elicited a larger LPP than neutral images, and were associated with significantly slower reaction times to the targets, indicating attentional capture that interfered with performance on the primary task. On the other hand, no affective modulation of the LPP was observed in the "fictitious" condition, and there were no differences in reaction time, suggesting that the distractor images in the fictitious condition—while equally gruesome—were less salient and produced less behavioral interference.

Up to this point, we have discussed sustained attention to emotion, reflected in the LPP, as if it was independent of visual–spatial attention. However, there is increasing evidence that even in the absence of competition from other stimuli, visual attention is directed to the most arousing aspects of emotional images. For instance, even when viewing a single unpleasant picture, participants tend to fixate first—and dwell longer—on the most emotionally intense portion of the picture (e.g., the victim's face and the knife in an image depicting an assault; Ferri, Schmidt, Hajcak, & Canli, 2013). Moreover, individuals who are instructed to decrease negative emotion using reappraisal simultaneously shift their gaze away from unpleasant information (van Reekum et al., 2007) and shifting the gaze away from unpleasant information is associated with reduced negative affect as well as reductions in neural indices of emotional processing (Ferri et al., 2013; van Reekum et al., 2007). Thus, how attention is deployed within emotional pictures appears to be a powerful determinant of subjective and physiological measures of emotion.

A line of work from our lab has examined the impact of directed attention on the magnitude of the LPP. For instance, we have asked participants to both passively view emotional and neutral pictures during a portion of each trial; however, we have also directed their attention to more or less emotionally evocative aspects of unpleasant pictures. When participants focus on neutral and nonarousing parts of emotional pictures, the LPP is reduced; when the attention is focused on highly emotional regions of the image, the LPP is increased and appears similar to what we observe during passive viewing (Dunning & Hajcak, 2009; Hajcak, MacNamara, Foti, Ferri, & Keil, 2013). The impact of directed attention on the LPP is rapid—reliably reducing the LPP within about 600 milliseconds (Hajcak et al., 2009). Figure 35.1 presents data from a paradigm in which participants first passively viewed neutral and unpleasant images for 3,000 milliseconds; then, their attention was directed to a specific portion of the image for an additional 3,000 milliseconds (Dunning & Hajcak, 2009). In an exciting extension of this work, Thiruchselvam and colleagues found similar effects on the LPP when attention was directed to more or less emotional aspects of images that participants were holding in working memory (Thiruchselvam, Hajcak, & Gross, 2012).

In other words, the emotional modulation of the LPP appears to track—even within pictures—the dynamic allocation of sustained attention to emotional content. These data are also consistent with previous studies that fail to find emotional modulation of the LPP when pictures are presented in unattended spatial locations (MacNamara & Hajcak, 2009, 2010). Indeed, modulation of the LPP by emotional content likely requires awareness of stimulus content. One study used masking to obscure awareness of emotional images (Codispoti, Mazzetti, & Bradley, 2009). Emotional stimuli masked after 25 to 40 milliseconds failed to modulate the LPP, yet when the same stimuli were presented for 80 milliseconds before the mask, the LPP was enhanced. In addition, Codispoti and colleagues found that some participants were able to accurately report the valence and arousal of images shown for approximately 50 milliseconds, and those participants ("discriminators") showed affective modulation of the LPP at this latency, while "nondiscriminators" did not.

Even when emotional content is consciously perceived, the magnitude of the LPP appears to depend on the availability of resources based on concurrent task demands. For instance, greater cognitive load has been shown to decrease the LPP (MacNamara, Ferri, et al., 2011; Wangelin, Löw, McTeague, Bradley, & Lang, 2011). In MacNamara, Ferri, et al.'s (2011) study, participants were given 5 seconds to memorize a string of consonants; an aversive or neutral task-irrelevant IAPS image was then presented in the retention interval for 2 seconds.

At the end of each trial, participants were asked to type in the letters they had memorized. Working memory load was manipulated via the number of letters, such that on some trials participants were asked to memorize two letters, and on others they were asked to memorize six letters. The magnitude of the LPP decreased as a function of increasing working memory load: When participants were asked to memorize six letters, the LPP to both neutral and aversive images was attenuated. However, working memory load did not eliminate the effect of emotion. Along the same lines as the working memory study described above, several studies have examined the impact of distraction on emotional picture viewing (Paul et al., 2013; Thiruchselvam et al., 2011)—in other words, what happens when individuals maintain their visual attention on emotional stimuli but are instructed to think of something unrelated to the image on the screen (e.g., "mental imagery of complex geometric designs or elaborate scenes around their neighborhood"; Thiruchselvam et al., 2011, p. 86)? In each of these studies, the magnitude of the LPP elicited by unpleasant images in the distract condition was reduced relative to unpleasant images in an unconstrained viewing condition, suggesting cognitive distraction may be sufficient to modulate the LPP, even when visual attention is maintained on the target emotional stimuli. However, as in the working memory studies described above (e.g., MacNamara, Ferri, et al., 2011), emotional modulation of the LPP by unpleasant pictures was observed even in the distract condition, suggesting that distraction and cognitive load may not abolish the emotional modulation of the LPP.

Individual Differences in Attention to Emotion

The majority of the studies we have discussed above were conducted in unselected samples and did not examine individual differences. Yet, the motivational salience of emotional stimuli varies widely across individuals. Although a full review of individual differences in attention to emotion is not possible here, we highlight some interesting instances of the ways in which idiosyncratic goals and biases can impact attention to emotion.

For instance, there is evidence that transitory differences in motivational states can impact the ways in which individuals attend to visual stimuli. Several studies have demonstrated that hunger compared with satiety can impact the processing of food cues: Hunger can increase attention to food-related stimuli (Mogg, Bradley, Hyare, & Lee, 1998), direct spatial attention to irrelevant food cues (Mohanty, Gitelman, Small, & Mesulam, 2008), improve memory for food-related stimuli (Morris & Dolan, 2001), and restrict attentional shifting away from those stimuli (Piech, Hampshire, Owen, & Parkinson, 2009). Hunger can even make food-related stimuli behave like more potent emotional distractors in emotional attentional blink paradigms, decreasing accuracy for targets, even when target detection is associated with monetary reward (Piech, Pastorino, & Zald, 2010). Likewise, food deprivation appears to specifically enhance the magnitude of the LPP elicited by food compared with flower images (Stockburger, Schmälzle, Flaisch, Bublatzky, & Schupp, 2009).

There is also evidence for developmental shifts in motivated attention. For example, older, but not younger, adults appear to attend more to pleasant and less to unpleasant information when they are in a negative mood (Isaacowitz, Toner, Goren, & Wilson, 2008), and these shifts in gaze are positively related to improvements in mood (Isaacowitz, Toner, & Neupert, 2009). Consistent with this, there is evidence that older participants display a smaller LPP than younger participants to unpleasant stimuli, as well as a larger LPP to pleasant stimuli (Kisley, Wood, & Burrows, 2007; Langeslag & Van Strien, 2010).

Stable individual differences can also impact visual spatial attention. There is a wealth of evidence, for example, that phobic individuals, relative to nonphobic individuals, are able to more rapidly detect phobic objects, even in very crowded visual fields (Bar-Haim, Lamy, Pergamin, Bakermans-Kranenburg, & van IJzendoorn, 2007; Öhman, Flykt, et al., 2001). Additionally, individuals with blood phobia exhibit a larger early N2pc to disorder-themed photos paired with either neutral or non-disorder-themed unpleasant images, compared with non-phobic individuals (Buodo et al., 2010). Moreover, there is increasing evidence that individual differences in motivated attention can impact sustained attention to emotional stimuli. For instance, individuals with psychopathy do not show behavioral interference from the emotional distractors in the emotional interrupt task (Mitchell et al., 2006), consistent with evidence that psychopathy may be in part characterized by extreme insensitivity to emotional content. The LPP may be a particularly useful tool for studies of individual differences in sustained emotion processing, in that it is an increasingly well-validated measure and appears to be trait-like in nature. The LPP appears to be a reliable signal with as few as 12 trials (Moran, Jendrusina, & Moser, 2013), and its magnitude is stable over a period of up to 2 years, even in late childhood (Kujawa, Klein, & Proudfit, 2013). Moreover, there is evidence that the magnitude of the overall LPP is substantially heritable (i.e., the LPP to pleasant, neutral, and unpleasant images; Weinberg, Venables, Proudfit, & Patrick, 2014), but also that emotional modulation—the degree to which the LPP differentiates emotional from neutral images—is subject to significant genetic contributions.

The LPP also relates in sensible ways to self-reported differences in motivated attention. For example, Wheaton and colleagues found that the LPP was enhanced by disgust-related images across all participants; however, it was most enhanced among individuals who reported high levels of disgust sensitivity (Wheaton et al., 2013). Likewise, larger LPPs are elicited by idiographic substance cues in alcohol- (Namkoong, Lee, Lee, Lee, & An, 2004), heroin- (Franken, Stam, Hendriks, & van den Brink, 2003), and cocaine-addicted individuals (Dunning et al., 2011; Franken, Hulstijn, Stam, Hendriks, & van den Brink, 2004; van de Laar, Licht, Franken, & Hendriks, 2004). On the other hand, currently depressed individuals (Foti, Olvet, Klein, & Hajcak, 2010) and children at risk for depression (Kujawa, Hajcak, Torpey, Kim, & Klein, 2012) appear to display an attenuated LPP to emotional stimuli, consistent with the notion that depression reflects motivational disengagement from the environment (Rottenberg, 2007; Rottenberg, Gross, & Gotlib, 2005).

The relationship of the LPP to anxiety, on the other hand, appears to be somewhat context dependent. For instance, anxiety has been associated with an increased LPP when pictures are task irrelevant (MacNamara, Ferri, et al., 2011), suggesting deficits among anxious individuals when disengaging attention from irrelevant emotional stimuli. Yet there is also evidence from passive-viewing tasks—in which the pictures are task relevant—that anxiety is instead characterized by initial vigilance for threat images, as indicated by enhancement of early ERP components, followed by a failure to engage in sustained processing of these images, as indicated by an attenuation of the LPP (e.g., Leutgeb, Schäfer, & Schienle, 2009; Weinberg & Hajcak, 2011a). In the study from Leutgeb and colleagues (2009), the anxious individuals completed exposure therapy and were again brought into the lab. Following successful treatment, they no longer showed enhanced early activity to images of their phobic objects, and likewise, the sustained LPP to these images had normalized, providing further evidence that sustained attention to emotional stimuli is flexible and multiply determined.

Conclusions and Future Directions

In this chapter, we have reviewed literature that pertains to emotion and both visual and sustained attention, as reflected in the N2pc and LPP, respectively, as well as behavioral, fMRI, and eye-tracking research. Several measures are uniquely suited for tracking the time-course attention to emotion. Visual–spatial attention is reflexively allocated to emotional content—in this way, emotional stimuli are quite akin to target stimuli in cognitive research. However, emotional stimuli uniquely sustain engagement. Much of the chapter focused on the LPP, as an index of sustained attention to salient visual stimuli, based on the integration of emotional content and broader goals. Indeed, shifting attention can be leveraged as a powerful way to impact the processing of emotional content—that is, emotion and attention are highly related, integrated, and interactive.

PART VI

HEALTH-RELATED PERSPECTIVES

CHAPTER 36

EMOTIONS AND HEALTH

Laura D. Kubzansky and Ashley Winning

This big stout fellow had simply melted away. He had cares and worries a great many. He came up from the country moribund. Doses of optimism lavishly administered by the house physician cured him.
—SIR WILLIAM OSLER (in Bean, 1950, p. 84)

A Brief History of Emotions and Health

Links between emotion and health have long been observed and described. In ancient times, Hippocrates considered the four bodily humors (blood, black bile, yellow bile, and phlegm) to be the basis of personality and related emotional experiences (e.g., feeling melancholy), and these elements were also believed to influence disease (Allport, 1961). In the 12th century, Maimonides, a medieval Jewish philosopher, rabbi, and physician, wrote that the purpose of a physician was to help patients keep their emotions in balance at all times because cheerfulness can help to alleviate and cure illness (Rudavsky, 2010). William Harvey (1628/1928), a pioneer in cardiovascular physiology, wrote, "A mental disturbance provoking pain, excessive joy, hope or anxiety extends to the heart, where it affects its temper, and rate, impairing general nutrition and vigor" (p. 106).

In the middle of the 20th century, psychoanalysts suggested that psychological conflicts could trigger or contribute to disease processes, whereby somatic manifestations were considered to represent symbolic expressions of underlying repressed psychological conflicts. Particular types of unconscious conflict were linked with specific health outcomes. For example, conflicts about expressing anger were posited to lead to heart disease, and conflicts about dependency needs to ulcers (Alexander, French, & Pollack, 1968). Empirical tests of these psychoanalytically inspired hypotheses were inconsistent at best, and research on emotion and health fell out of favor. Around this time Hans Selye (1955), an endocrinologist, introduced the term "stress," and then described its physiology and its possible linkages to health and disease. The notion that the experience of stress may be linked to health and disease was taken up in a number of disciplines, and several formulations concerning the relationship between stress and health were put forward. Perhaps due in some measure to these discussions, interest in linkages between emotion and health was revitalized. Investigators with a primary interest in emotion noted several problems with the initial formulations of the stress–health relationship. Thus, research on emotion and health developed partly in parallel with, and partly in reaction to, research on stress and health. Consequently, a challenge for research on emotion and health has been to distinguish conceptual models of stress and health from those on emotion.

Another challenge for this research is that emotions are hypothesized to influence and be influenced by health in a number of ways. Perhaps the least controversial hypothesis is that illness causes distress and negative emotions in various forms. Distress might in turn affect the progression or exacerbation of the illness through effects on health-related behaviors or compliance with a recommended medical regimen (see Elderon & Whooley, 2013, for more discussion of these issues). The most controversial hypothesis is that emotions play a role in maintenance of health or development of disease. While this idea continues to reverberate across medical and psychological sciences, there is skepticism as to whether mental states can indeed influence physical health (Angell, 1985; Coyne & Tennen, 2010).

The focus of this chapter is on the role of emotions in the etiology of disease (and health), rather than as a consequence of disease or as part of the disease management process. While there are likely distinct pathways by which emotion influences the development, triggering, exacerbation, or progression of disease, there may also be overlap among mechanisms affecting these different stages of illness. However, effects of emotion in an already damaged biological system may be quite different from effects in an initially healthy system. Thus, careful consideration of both the affect experience (i.e., valence, intensity, duration, frequency) and the disease (type, stage, onset vs. progression, severity, and biological alterations) is needed when evaluating research in this area. Findings on effects of emotion on health in patient versus in healthy populations should not be considered to inform the same questions equally (although in practice, findings are often used interchangeably). As a result, we consider primarily research conducted with healthy populations aimed at understanding whether emotions influence the likelihood of developing disease. Over the last several decades investigators have amassed substantial empirical evidence strongly suggesting a causal relationship. The most recent findings suggest effects of emotion are not uniform in that negative emotions increase susceptibility to disease while positive emotions protect health beyond simply mitigating effects of negative emotions (Boehm & Kubzansky, 2012).

Theoretical Perspectives Informing the Relationship between Emotion and Health

While theories of emotion were not developed to address relationships between emotions and health, models that build on insights derived from these theories have been developed (described in more detail in the section "Differentiating Between Stress and Emotion"). Emotion theorists suggest that emotions may be conceptualized as having cognitive, neurobiological, and behavioral components (Frijda, 1986). Specific emotions are thought to be biologically based, arising as a product of the interaction between the person and the environment, and mediating between continually changing situations and the individual's behavior (Lazarus, 1968). Emotions, whether positive or negative, are functionally necessary. In part, this is because emotions serve to communicate a person's emotional state and likely behaviors to others in the social environment. The state of subjective feeling also serves to signal that the person is faced with a particular type of challenge and motivates a response (Frijda, 1986). For example, fear motivates escape from danger, sadness motivates disengagement from loss, and so on (Lazarus, 1991b). Emotions are associated with action tendencies that facilitate coping with environmental demands (Fredrickson, 1998; Frijda, 1986). In turn, specific action tendencies are associated with physiological activity patterns that support adaptive behavior (Frijda, 1986). Important to note, however, is that while particular urges to act may be associated with specific emotions, people do not invariably act out these urges.

Antecedents and consequences of emotions vary widely as a function of environmental demands; resources and constraints; by the imminence, duration, and uncertainty of events; and by individuals' motives and beliefs about themselves and the world (Lazarus, 1991b). Each emotion depends on the appraisals and evaluations individuals make in response to events that occur (Lazarus, 1991b). Individuals evaluate the importance of each event, as well as their ability to cope with the demands imposed, and if individuals feel taxed beyond the limits of their capability, emotions with dysfunctional consequences can emerge. It has also been theorized that specific patterns of physiological responses are associated with each emotion (Lazarus, 1991b), but empirical evidence has not conclusively identified such patterns. Despite this heterogeneity, the cognitive, neurobiological, and behavioral components of emotions do vary systematically, and can be identified (Smith & Pope, 1992).

Although emotions are considered separate psychological entities from moods or attitudes, health research sometimes refers to them interchangeably. Unlike moods that are more diffuse, lower in intensity, and of longer duration, emotions generally have a referent. Emotions can also be distinguished as one component of attitudes, defined as learned predispositions to respond in a consistent manner to a given object. Most emotions may be seen as transitory *states* brought on by specific situations, or as *traits* (i.e., stable dispositions to experience particular emotions). Certain personality types are hypothesized to be vulnerable to disease partly because these individuals are predisposed to experience particular emotions (Scheier & Bridges, 1995). Thus, because hostile individuals engage in cynical, mistrusting, and aggressive behavior, they create more opportunities to experience anger.

A separate line of theoretical work has specifically sought to understand positive emotion. The Broaden and Build Model (Fredrickson, 1998), a dominant theoretical perspective, suggests that positive emotions actually produce optimal functioning. This model identifies four positive emotion families including *joy*, *interest*, *contentment*, and *love*, and proposes that positive emotions lead to a broader range of thought and action tendencies. Broadening these tendencies over time builds personal resources and thereby facilitates successful adaptation to ongoing demands. Another relevant theory is the evaluative space model (ESM), which posits that the affect system is defined by separable systems that process positivity and negativity. The ultimate output of the affect systems are behavioral predispositions (Cacioppo, Gardner, & Berntson, 1999). The ESM assumes that positive affect is linked with appetitive motivation, while negative affect is linked with aversive motivation. What is relevant about these theories is that positive and negative emotions are posited to occur in a bivariate space not on a bipolar continuum. Thus, the absence of negative feelings may not be equivalent to the presence of positive feelings, and what is learned by studying negative emotional processes may not transfer to positive emotional processes. This suggests that studying each class of emotion may yield novel insights in relation to health.

Differentiating between Stress and Emotion

Because research on emotion and health has occurred in close conjunction with the stress–health research, it is useful to distinguish between these lines of work. The physiological basis of stress was first proposed by Hans Selye (1950), whose conceptualization had its origins in physics whereby stress was defined as the force exerted on a material structure. According to this definition, if the load is more than the structure can bear, it will lead to structural strain, damage, and possibly collapse (DeSteno, Gross, & Kubzansky, 2013). Following this formulation, Selye hypothesized that external circumstances or events characterized as environmental demands or stressors can cause psychological and/or physical stress, which in turn may cause physiological changes related to disease processes. Selye did not distinguish between physical and psychosocial stressors, and suggested that both elicit the same physiological response pattern (Selye, 1950). Further, stress is presumed harmful because repeated experience leads to the accumulation of damaging physiological changes.

This research played out in two lines of investigation that often clashed over which was more powerful: comparing health effects of the accumulation of stressors of high magnitude characterized by life events (e.g., moving house, birth of a baby), or of lower magnitude but high chronicity, characterized as daily hassles (e.g., concern about paying bills; DeLongis, Coyne, Dakof, Folkman, & Lazarus, 1982; Dohrenwend & Dohrenwend, 1974). In both domains, while findings supported some of the hypothesized associations, they were not as reliable as expected. Problems with the original theory have been identified: It focuses primarily on biological *response* to stressful experiences, makes no distinction between stressor types (e.g., loud noise vs. death of a spouse), and fails to address the psychological appraisals of the demands imposed by the stimulus, or the individual's capacity to meet those demands. A more psychologically oriented theory of stress was developed to explain *when* an individual will experience stress (Lazarus, 1990). In this formulation, stress is experienced when individuals perceive (appraise) that external demands exceed their ability to cope. Links to health occur because the interpretation of an event as stressful triggers a series of physiological changes. This theory incorporated greater emphasis on the capacity of the individual to meet the demands imposed. Because some individuals have more resources than others, the same stressor may be appraised and experienced differently. However, measures have not reliably captured when demands exceed an individual's capacity to cope; as a result, some individuals appear to undergo many stressful events with few health consequences, while others with seemingly trivial problems experience poor health. In fact, knowing an individual's interpretation of any given event and the meaning it has seems to provide stronger insight into predicting whether a stimulus is likely to have a negative impact. In his seminal article on measuring stress, Lazarus (1990) argued that activation of an emotional reaction indicates that an important value or goal has been engaged, which will be harmed, at risk, or advanced. He further posited that no other concept in psychology is as richly revealing of how an individual relates to the physical and social environment, and suggested considering emotions rather than stress per se in relation to health.

To be clear about the distinction between emotion and stress in this chapter, environmental events are considered stressors and emotions are considered responses to stressors. A negative emotion response occurs if demands are perceived to exceed one's ability to cope. Important to note is that any given stressor can be associated with different emotions. For example, losing one's job may provoke anger in some individuals and depression in others. Thus, emotions can be considered products of stressors as well as mediators of their effects. Theories of stress and emotion in relation to health are relatively silent on effects of positive emotions (Cohen, Kessler, & Gordon, 1995), and less detailed about the role of emotional traits. Lazarus (1990) noted that frequently recurring emotions indicate that emotion experience is partly due to properties of the individual (i.e., personality trait) where the trait may transcend specific events in the environment. Thus, emotional traits provide more information about how individuals interact with their environments over time.

Models of Emotion and Health

Figure 36.1 presents a heuristic model designed to illustrate the links among the social environment, emotion, and health. While it is not the focus of the current chapter, the figure incorporates an un-

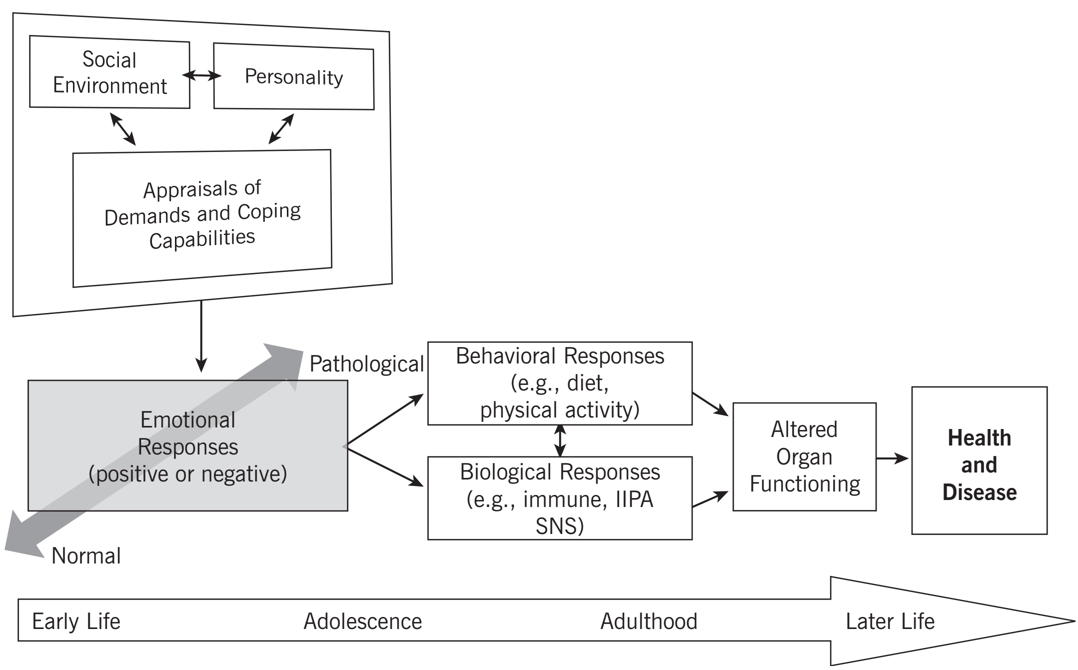

FIGURE 36.1. A model of the stress–emotion–health process. *Note*. HPA: hypothalamic–pituitary–adrenal; SNS: sympathetic nervous system.

derstanding that the social context plays an important role in determining which emotions are likely to be experienced, how they are expressed, and what their consequences will be (Kemper, 1993). Kemper has suggested that emotions also arise in response to power and status differentials embedded within social situations. As a result, even emotions that feel highly personal and unique to the individual can be conditioned by external social factors and are therefore socially patterned. To be parsimonious we have presented a unidirectional model, but failure to include alternative paths is not designed to imply these relations are static or to indicate hypotheses about their existence.

Emotions are hypothesized to influence health directly because they evoke physiological processes (e.g., activation of the hypothalamic–pituitary–adrenocortical [HPA] axis and the sympathetic nervous system [SNS]), and indirectly because they influence health-relevant behaviors via motivation and decision making (see Figure 36.1). Pathways by which negative emotions directly alter biological processes have been identified and evaluated in animal models and human populations. For example, elevated serum norepinephrine levels associated with negative emotions may increase blood lipids, free fatty acids, blood pressure, and heart rate, and lead to constriction of peripheral blood vessels. Negative emotions may also lead to altered autonomic regulation of the heart (e.g., Kawachi, Sparrow, Vokonas, & Weiss, 1995). Other direct biological effects of emotion on health may occur through altered immune functioning. Immune cells have receptors for cortisol, epinephrine, and norepinephrine. Thus, activation of the HPA axis and the SNS occurs, which results in elevated serum levels of cortisol and catecholamines and can also lead to immune function dysregulation. Over time, recurring activation of these systems may initiate disease-related physiological processes (Cohen, Janicki-Deverts, & Miller, 2007). Direct biological effects of positive emotions are less well studied, but emerging evidence points to salutary effects on several parameters like lipids, inflammation, and vagal tone (Boehm & Kubzansky, 2012).

Emotions may also have an indirect effect on health by influencing thoughts, decisions, and behaviors that in turn influence pathophysiology. By altering perceptions of risk, emotions can influence health-relevant decisions such as seeking medical treatment or screenings, or adhering to exercise or diet regimens, which in turn shape subsequent physical health (Rothman, Kelly, Hertel, & Salovey, 2003). Recent research has further suggested that emotion valence (i.e., positive vs. negative) alone cannot adequately capture the specificity of effects. Rather, a more fine-grained view of how specific emotions impact risk perception is needed (DeSteno et al., 2013). Emotions may influence decision making in other ways as well. Many health-relevant decisions are characterized by intertemporal choice, as they have different consequences depending on when they are enacted over time. For example, exercising now may provide health benefits later but may be less enjoyable in the moment than watching television. Emotions can influence how dilemmas of intertemporal choice are resolved—for example, recent research has suggested that positive social emotions increase the odds that people will accept short-term hedonic reductions to make future gains possible (DeSteno, 2009). Other effects may occur because emotions alter biological processes that influence decision making. For example, negative emotions may activate dopamine reward centers of the brain among smokers, leading them to take another cigarette (e.g., Brody et al., 2009). Emotions also influence social processes including the quality and quantity of an individual's social relationships, which in turn influence health (see Cohen & Rodriguez, 1995). Moreover, any affective state has the potential to influence several decision-relevant processes occurring concurrently, thereby leading to outcomes that can enhance, diminish, or even reverse the expected outcome resulting from any one isolated process (DeSteno et al., 2013).

While much of the initial research on emotions and health has focused on either positive or negative emotions, negative and positive emotions and the interplay between them are products of an *emotion regulation* process, which involves monitoring and managing one's emotional experience and response (Gross & Thompson, 2007). Recognizing that this process may provide insight into why positive and negative emotions both matter for health, investigators have increasingly focused on the importance of emotion regulation for health (see Appleton & Kubzansky, 2014, for a recent review of the literature). In fact, emotion regulation is a key component of the broader concept of "self-regulation," which encompasses the ability to focus attention, resist impulses, and delay gratification, and has also been identified as a critical factor influencing health. Early theories speculated that aspects of emotion regulation might be linked to health because the effort involved in suppressing or inhibiting (vs. expressing) emotions was posited to be biologically costly, thereby leading to increased susceptibility to illness over time (Pennebaker & Beall, 1986). Numerous studies suggest that inhibiting expression of emotion impairs symptom recognition, delays help-seeking behavior, and compromises communication about problems (e.g., de Ridder, Geenen, Kuijer, & van Middendorp, 2008). Studies have also examined if disclosing strong emotional feelings can improve health outcomes (broadly defined) by avoiding the cumulative stress of inhibition. Positive health effects have been demonstrated (Consedine, Magai, & Bonanno, 2002), with findings suggesting that health will be optimized when emotion regulatory strategies facilitate acknowledging, expressing, and processing emotions appropriately (de Ridder et al., 2008). More recent formulations have moved away from defining regulation as expression versus suppression, and suggest that emotion regulation is a dynamic process involving both up- and down-regulation of positive and negative emotions (Gross & John, 2003). Some strategies are antecedent focused, employed *before* an emotion occurs (e.g., reappraisal). In contrast, response-focused strategies are employed *after* an emotion has occurred (e.g., suppression), which may be taxing and fail to mitigate fully a negative emotional experience. The appropriateness of any given strategy is context dependent, though recent research has suggested that greater reliance on antecedent-oriented regulation may be more adaptive in the context of health (Appleton & Kubzansky, 2014).

Approaches for Investigating Emotion and Health

A number of study design issues present challenges for research on emotion and health. Some research has focused on immediate physiological responses posited to be relevant to health (e.g., cardiovascular reactivity) that are associated with emotion experiences. This work is informative if one assumes that short-term physiological effects as measured in the laboratory are related to long-term health consequences; recent work suggests that this may be a reasonable assumption (e.g., Chida & Steptoe, 2010).

Whether acute emotion states might trigger a health event or exacerbate underlying disease has also been considered, with most research conducted in the context of coronary heart disease (CHD) events. In contrast, research on emotion traits seeks to evaluate long-term health effects of recurring emotion experiences. Due to logistic and feasibility issues (i.e., it is difficult to assign individuals to experience chronically one emotion or another prior to disease development), true experiments cannot directly test if emotion is causally associated with increased risk of disease. Numerous randomized control trials have sought to alter emotional functioning (e.g., reduce anxiety or depression) within patient populations to see if effective treatment slows disease progression or reduces risk of a secondary event or early death (Elderon & Whooley, 2013). While important in their own right, such studies cannot directly assess the contribution of emotion to disease onset because they are conducted in patient as opposed to healthy populations and because they assess primarily the treatment of emotional disorders.

Epidemiological research, focused on the study of the distribution and determinants of disease, has rigorous methods for assessing and evaluating factors that contribute to health. As a result, many of the strongest studies on emotion and health have been conducted using epidemiological methods and frameworks. The most convincing designs measure emotions when individuals are healthy, include objective measures of health (reducing concerns about self-report bias), and include measures of an array of potential confounders. However, even these designs remain susceptible to concerns about hidden sources of reverse causality (i.e., prodromal disease influences emotion) and that some unmeasured variable (e.g., a genetic risk factor) in fact drives the apparent emotion–health relationship.

Emotion is most commonly measured via self-report, which can be subject to social desirability and assumes individuals have sufficient insight to give accurate reports of their emotional experience (Shedler, Mayman, & Manis, 1993). A further issue is that many measures of emotion include somatic symptoms (e.g., racing heart), which may confound assessment of the emotion–health relationship (Leventhal & Patrick-Miller, 2000). Because emotion is not commonly the focus of epidemiological research, psychological measures, when utilized, are limited. Thus, much of the work has been truly opportunistic, using whatever assessment may be available, ranging from measures of emotional disorders (e.g., major depressive disorder) to symptom measures to single-item measures. Epidemiological studies often consider depression and anxiety as representing single emotions; in contrast, psychologists have suggested that while these states are characterized by dysregulated emotion, they also reflect complex constellations of maladaptive cognitions and behaviors (Lazarus, 1991a). Given the primacy of the emotion component and the insight an emotion-oriented framework may bring to understanding their role in health, for the purposes of this chapter we refer to each of these states (depression and anxiety) simply as an "emotion." Moreover, because of the focus on pathophysiology, some epidemiological research has presumed that emotion-related effects on health are primarily due to psychopathology. However, the experience of most emotions occurs along a continuum (Kubzansky, 2007). For example, anxiety is a commonly experienced emotion that can also underlie a clinical disorder. Pathological and normal anxiety reactions are similar in their cognitive, neurobiological, and behavioral components (Frijda, 1994). This may help to understand why health effects are evident across the spectrum, and moreover, why emotions appear to have a dose–response (i.e., with higher frequency or intensity of emotional experience, effects are stronger) association with risk of disease onset.

Evidence for an Association between Emotion and Health

Experimental Research

The physiological impact of acute states of distress has largely been studied in relation to indicators of cardiovascular function and risk, such as heart rate and blood pressure reactivity, inflammatory responses, and vascular endothelial function, assessed under controlled laboratory conditions. By incorporating experimental manipulation of stress stimuli, and eliminating or monitoring confounding factors, the ability to make causal inferences is enhanced. Several studies have demonstrated that acute laboratory-induced mental stress impairs endothelial function (e.g., Spieker et al., 2002), although the finding is not uniform (see Poitras & Pyke, 2013, for a review). Other studies have examined whether acute mental stress influences inflammatory processes, considering increases in circulating proinflammatory cytokines. A meta-analysis of 30 studies reported robust effects of acute stress on several cytokines including significant increases in interleukin-1 beta (IL-1β) ($r = .58$, $p < .001$) and IL-6 ($r = .19$, $p = .001$), and marginal increases in C-reactive protein (CRP; $r = .12$, $p = .088$; Steptoe, Hamer, & Chida, 2007). In another meta-analysis, poorer cardiovascular outcomes were predicted by greater reactivity to laboratory-induced mental stress (36 articles; $r = .091$, $p < .001$) and poor poststress recovery (five articles; $r = .096$, $p < .001$; Chida & Steptoe, 2010). More recently, Carroll et al. (2012) demonstrated that exaggerated systolic and diastolic blood pressure reactions to acute mental stress were subsequently associated with cardiovascular disease (CVD) mortality over a 16-year follow-up. Findings suggest long-term (e.g., heightened reactivity on vasculature erosion) and short-term (e.g., acute event triggering) effects (Carroll et al., 2012).

Several studies have explored potential mediators and moderators of the acute stress–cardiovascular reactivity relationship. This work suggests that effects differ somewhat by age with older individuals exhibiting higher systolic blood pressure reactivity but lower heart rate reactivity in response to emotionally evocative laboratory tasks (Uchino, Birmingham, & Berg, 2010). Other studies suggest that individuals who are already distressed may have a stronger acute stress response (Miller, Rohleder, Stetler, & Kirschbaum, 2005). Stress reactivity in the laboratory has also been considered in relation to emotion regulation. Some studies suggest that actively inhibiting or suppressing emotion is associated with deleterious autonomic functioning, including increased activation of the autonomic system (Gross & Levenson, 1997) and reduced heart rate variability (Denson, Grisham, & Moulds, 2011); in contrast, actively expressing or disclosing emotions was associated with beneficial cardiovascular effects, including lower blood pressure (Willmott, Harris, Gellaitry, Cooper, & Horne, 2011) and lower levels of proinflammatory cytokines.

One limitation of laboratory-induced stress reactivity studies is that the acute stimuli may lack ecological validity. In response, some studies have used ambulatory monitors to capture cardiovascular responses to real-life stressors (such as school examinations), self-reported emotions, or perceived stress. A recent qualitative review of representative papers in this area concluded that cardiovascular responses to real-life stress are often larger than those obtained in laboratory settings, suggesting that laboratory findings may be conservative estimates of effects (Zanstra & Johnston, 2011).

Nonexperimental Research

Much of the research on the role of emotion in maintaining health or in the etiology of disease has been carried out in the context of CVD with a particular focus on CHD (i.e., myocardial infarction, sudden death, and angina). This is due to a number of factors: (1) CVD is the leading cause of death globally (World Health Organization, 2011); (2) onset, triggering, and exacerbation can be clearly identified; and (3) other CHD risk factors are well known and can be evaluated. Evidence for associations between emotions (particularly positive emotions or emotion regulation) and the development of other health outcomes is sparser. Thus, in the following sections we focus on the emotion–CHD relationship, recognizing that this research can serve as a strong model (albeit incomplete) for understanding the role of emotions in health more broadly.

Coronary Heart Disease

In the 1950s, two cardiologists, Friedman and Rosenman (1959), described a behavior pattern that seemed to increase risk of developing CHD, the type A behavioral (TAB) pattern. TAB was characterized as an action–emotion complex that requires an environmental challenge to serve as the trigger for expression. Overt manifestations of the behavior include a free-floating but well-rationalized hostility, hyperaggressiveness, and a sense of time urgency. While large-scale epidemiological studies conducted during the 1960s and 1970s appeared to corroborate the TAB hypothesis, a series of studies in the mid-1980s failed to find a relationship with CHD (see Matthews, 1988, for a review). As a result, investigators began to consider related factors that could explain the mixed findings, and the research focus shifted toward examining specific negative emotions. Associations between risk of incident CHD and specific emotions like anxiety, anger, and depression have now been reliably demonstrated. The volume of research on the topic increased dramatically in the last decade, leading to the publication of numerous reviews and meta-analyses on depression (e.g., Rugulies, 2002), anxiety (e.g., Roest, Martens, de Jonge, & Denollet, 2010), and anger (e.g., Chida & Steptoe, 2009). Research on positive emotion has also increased exponentially (Boehm & Kubzansky, 2012), though research on emotion regulation per se remains somewhat limited (but see Appleton & Kubzansky, 2014, for a detailed review of the findings).

Given the volume of work available, in the following sections we briefly describe the research on these emotions focusing on landmark studies and key findings (Kubzansky, Winning, & Kawachi, 2014). We prioritize studies using the strongest methods available. These are prospective studies designed to look at development of CHD, that consider objective measures of disease outcomes among individuals who are either disease free at the start of the study or whose initial health status is known and controlled in statistical analyses. By convention, demographic (e.g., gender), health-related (e.g., hypertension), and behavioral (e.g., cigarette smoking) risk factors are included in models evaluating the role of emotion in disease. However, if behaviors partially mediate the relation of emotion with CHD, then risk estimates derived from these studies are likely to be underestimates.

Anger. Chronic anger and hostility have long been implicated in the etiology of CHD. Anger and hostility are strongly associated with each other and have been identified as "toxic" components of the TAB pattern (Matthews, 1988). Hostility and anger are distinguishable, where hostility is a long-standing attitudinal disposition, while anger is the emotional component. Research in this area has focused more on hostility than on anger per se (see Chida & Steptoe, 2009, for a comprehensive review of this work). In an early study, Kawachi, Sparrow, Spiro, Vokonas, and Weiss (1996) examined the association between anger and incident CHD (including nonfatal myocardial infarction [MI], fatal CHD, and angina pectoris) using Cox proportional hazards models to estimate the relative risk of a cardiac event occurring in a 7-year follow-up of 1,305 men. Coronary events were over 2.5 times as likely during the follow-up period among men reporting the highest levels of anger compared with those reporting the lowest levels (hazard ratio [HR] = 2.66; 95% confidence interval [CI]: 1.26–5.61). A dose–response association was found between level of anger and overall CHD risk, even after taking account of other major cardiovascular risk factors. A 6-year follow-up study of 12,990 men and women also found that individuals with a strong tendency toward quick, minimally provoked or unprovoked anger had significantly increased risk of acute MI and fatal CHD over the follow-up period, with a multivariate adjusted HR of 2.28 (95% CI: 1.29–4.02; Williams, Nieto, Sanford, & Tyroler, 2001). However, not all studies find an effect of anger. Overall, while several meta-analyses suggest that chronic anger and hostility are independent risk factors for developing CHD (Chida & Steptoe, 2009; Miller, Smith, Turner, Guijarro, & Hallet, 1996), the overall effect size in the most recent meta-analysis was modest (HR = 1.19; 95% CI: 1.05–1.35). Moreover, effects were no longer significant when considering only studies that adjusted for key covariates, and the authors' suggested effects of anger on CVD may be primarily mediated by behavioral pathways (Chida & Steptoe, 2009).

Anxiety. The most recent meta-analysis of 20 prospective studies concluded that anxiety is an independent risk factor for CHD with a pooled HR for incident CHD of 1.26 (95% CI: 1.15–1.38; Roest et al., 2010). Five of the studies also adjusted for depression and in four of them an independent effect of anxiety was maintained. The Northwick Park Heart Study was one of the earliest studies to consider this association using a prospective design, following 1,457 initially healthy men over 10 years. This study reported a striking association between self-reported symptoms of phobic anxiety and fatal CHD, such that compared with men with the lowest level of anxiety, those with the highest levels had almost four times the risk of fatal CHD (HR = 3.77; 95% CI: 1.64–8.64; Haines, Imeson, & Meade, 1987). Findings have since been replicated in women. For example, in a substudy within the Women's Health Initiative Observational Study, 3,369 healthy postmenopausal women who reported their panic symptoms over the prior 6 months were followed for an average of 5 years (Smoller et al., 2007). Women reporting at least one full-blown panic attack were at three times the risk of developing CHD or a stroke (95% CI: 1.6–5.94) with increased risk still evident among women with less severe panic attacks. Findings were maintained after adjusting for standard risk factors as well as depression. Other research has reported elevated risk associated with different forms of anxiety, including worry, general symptoms of anxiety, and posttraumatic stress disorder (PTSD; Thurston, Rewak, & Kubzansky, 2013). For example, among 39,324 World Trade Center Health Registry participants followed for an average of 2.9 years, those who reported PTSD at study enrollment were at 60–70% excess risk of developing CHD over the follow-up (Jordan, Miller-Archie, Cone, Morabia, & Stellman, 2011). Of note, the effect sizes vary because the "dose" of anxiety is characterized differently across studies.

Depression. The majority of the research on negative emotions and CHD has focused on depression as a potential risk factor for both development and progression of the disease (see Elderon & Whooley, 2013, for an extensive review). Here we briefly highlight relevant research on the role of depression in CVD incidence. In an early prospective study, Anda and colleagues (1993) examined the relationship between depressed affect and ischemic heart disease incidence in 2,832 healthy adults. Depressed affect was associated with a significantly increased risk of fatal (HR = 1.5; 95% CI: 1.0–2.3) and nonfatal (HR = 1.6; 95% CI: 1.1–2.4) heart disease. In 2007, a meta-analysis including 28 published studies demonstrated a positive association with incident CHD, with a relative risk (RR) of 2.54 (95% CI: 2.07–3.10) for individuals with clinically relevant depression and an RR of 1.39 (95% CI: 1.26–1.54) for individuals with depressed mood (Van der Kooy et al., 2007). A meta-analysis of depression and incident stroke similarly reported a pooled adjusted HR of 1.45 (95% CI: 1.29–1.63; Pan, Sun, Okereke, Rexrode, & Hu, 2011). Generally, few studies have found evidence of a threshold effect; studies more commonly find a dose–response relationship whereby risk increases as depressive symptoms increase.

Positive Emotion. More recent epidemiologic work has begun to evaluate systematically whether positive emotions are health protective. Using rigorous methods, including adjustment for negative affect, studies have consistently reported reduced risk of incident CHD in relation to positive affect (see Boehm & Kubzansky, 2012, for a comprehensive review). For example, several population-based studies have considered emotional vitality (a composite measure capturing a sense of interest, enthusiasm, and capacity to regulate emotion) in relation to incident CHD and found a 20–30% reduction in risk after adjusting for potential confounders as well as psychological ill-being (Boehm, Peterson, Kivimaki, & Kubzansky, 2011; Kubzansky & Thurston, 2007). In another study, positive emotions were assessed based on structured interviews and evaluations of positivity displayed on participants' faces during these interviews (Davidson, Mostofsky, & Whang, 2010). In this sample of 1,739 men and women, those who displayed more positive affect were at 22% lower risk of developing heart disease over a 10-year period, after controlling for major coronary risk factors and negative affect. Investigators have suggested that continued effort to understand the role of positive psychological functioning in health is warranted, suggesting that such efforts will provide enhanced understanding of how mental and physical health processes interact, and give greater insight into how to build resilience (Boehm & Kubzansky, 2012).

Emotion Regulation. Early empirical work provided suggestive evidence that aspects of regulation matter for coronary health. For example, in the Framingham Heart Study, the single item "inability to discuss angry feelings" was associated with subsequent CHD risk (Haynes, Feinleib, & Kannel, 1980). Recently, researchers are considering the regulation of emotions more broadly as a higher-order feature of emotional functioning that might help to explain diverse findings linking both positive and negative emotions with cardiovascular outcomes (see Appleton & Kubzansky, 2014, for a more detailed review). A prospective study of 1,122 older men considered the relation between self-regulation and the development of CHD (Kubzansky, Park, Peterson, Vokonas, & Sparrow, 2011). Self-regulation was assessed by the men's ability to manage impulses, feelings, and behaviors, with emotion regulation identified as a central feature. Compared with men who had the lowest levels of self-regulation, those with the highest levels had 62% reduced risk of CHD over 13 years of follow-up. Findings were maintained after adjusting for known coronary risk factors and for positive and negative affect. Another study of middle-age adults found differential effects of two regulatory strategies, reappraisal and suppression, on CVD risk (Appleton et al., 2013). One standard deviation higher in reappraisal scores was associated with a 6.8% lower 10-year CVD risk, while 1 standard deviation higher in suppression scores was associated with an 11.6% higher risk. Associations were particularly robust for women. This emerging work suggests emotion regulation contributes significantly to cardiovascular health.

Acute Emotions and CHD

A separate set of mechanisms by which emotion may lead to CHD involves acute or "triggering" effects (see Bhattacharyya & Steptoe, 2007, for a comprehensive review). For example, acute anxiety states may lead to hyperventilation, which then may trigger coronary vasospasm. It has also been hypothesized that acute hemodynamic stress caused by transient, intense emotional states may lead to rupture of atherosclerotic plaques on the vessel wall of coronary arteries and initiate acute coronary events (Bhattacharyya & Steptoe, 2007). Triggering in this framework is hypothesized to occur in the context of existing damage, occurring as a result of stimuli that induce acute pathophysiological changes that in turn lead to a cardiac event (Tofler & Muller, 2006). A variety of studies have provided evidence that acute episodes of anger, anxiety, or depression (as well as stress) may serve as triggers for a cardiac event. For example, one study found increased risk of MI in the 2 hours after an acute anger episode (RR = 2.3; 95% CI: 1.7–3.2), and after an acute anxiety episode (RR = 1.6; 95% CI: 1.1–2.2; Mittleman et al., 1995). Investigators have also identified another form of acute myocardial dysfunction related to sudden emotional stress that appears to occur in the absence of significant coronary disease. This syndrome is commonly referred to as stress cardiomyopathy. Though the precise pathophysiologic mechanisms have not yet been delineated, there is increasing consensus that this is a recognizable clinical syndrome occurring often in the context of severe emotional stress (Wittstein, 2012).

Other Cardiometabolic Diseases

Hypertension. Numerous studies have observed elevated blood pressure levels and higher prevalence of hypertension among individuals with anxiety or depressive disorders (e.g., Hayward, 1995) or who report high levels of anxiety, depression, or anger (e.g., Yan et al., 2003). However, several recent studies have reported a null or inverse association (e.g., Hildrum, Romild, & Holmen, 2011). The mixed findings have prompted thought as to whether there may be circumstances whereby underlying pathophysiology alters both emotions and capacity to regulate blood pressure. Also worth noting is that many studies in this area are limited by methodologic problems (e.g., cross-sectional designs, low statistical power). A recent meta-analysis of nine prospective studies with 22,367 individuals and mean follow-up of 9.6 years found 42% excess risk of hypertension in depressed individuals (Meng, Chen, Yang, Zheng, & Hui, 2012). Results also suggested that effects are stronger as sample sizes increase and with longer duration of follow-up, but investigators noted inadequate control for confounding across studies. Moreover, they did not reconcile these findings with earlier work reporting inverse associations with blood pressure levels (regardless of hypertension status) over time. A more systematic consideration of negative emotions in relation to incident hypertension can provide additional insight. For example, one study was able to consider trajectories of depression in relation to incident hypertension over 24 years of follow-up (Nabi et al., 2011). Individuals with recurring depressive episodes compared with those with transient or persistently low depression had a faster age-related increase in hypertension. Such effects would not be detectable in a cross-sectional study. Overall, it appears poorly regulated blood pressure often occurs with dysregulated emotion, but the direction of effects is not yet conclusive.

Diabetes. Type 2 diabetes (T2D) is a serious health condition in its own right, a major risk factor for the development of CVD, and is also influenced by many of the risk factors associated with CVD, including inflammation, neuroendocrine dysfunction, poor diet, sedentary lifestyle, and excessive alcohol consumption. Thus, T2D has increasingly been a focus for investigators interested in the emotion–health relationship. Most work to date has investigated risk associated with depression. Three meta-analyses of the literature have been conducted, all reporting a consistent positive association (Knol et al., 2006; Mezuk, Eaton, Albrecht, & Golden, 2008; Rotella & Mannucci, 2013). The most recent meta-analysis summarized across 23 prospective studies, which included 424,557 participants, a mean follow-up of 8.3 years, and considered 19,977 incident diabetes cases. Results indicated an increased risk of developing T2D among depressed versus nondepressed individuals, with an RR of 1.56 (95% CI: 1.37–1.77) that attenuated somewhat after adjusting for other risk factors. Several meta-analyses also found evidence for bidirectional effects, whereby having diabetes was also associated with higher risk of developing depression. Less work has considered anxiety or anger in relation to T2D onset

Metabolic Syndrome and Obesity. Much of the work linking negative emotions with other cardiometabolic outcomes has focused on depression, and directionality of effects are debated (e.g., Goldbacher, Bromberger, & Matthews, 2009). A small meta-analysis of four prospective studies, with a total sample size of 3,834 participants, reported a 52% (95% CI: 1.20–1.91) excess risk of developing metabolic syndrome associated with depressive symptoms. However, a meta-analysis of studies examining possible effects of metabolic syndrome on depression also reported a significant effect (RR = 1.49; 95% CI: 1.19–1.89; Pan et al., 2012). Findings for depression and obesity are similar (Luppino et al., 2010). Anxiety and anger are less well studied in relation to metabolic syndrome and its component conditions, but given the work to date bidirectional effects are also likely (Goldbacher & Matthews, 2007). Somewhat surprisingly, studies in this area remain limited. Few studies have considered anger in relation to weight status changes or developing obesity; somewhat more have considered anxiety, suggesting elevated obesity risk among highly anxious individuals (Kubzansky, Bordelois, et al., 2014).

Cancer

Despite the long-held beliefs about a link between emotion and cancer, empirical support for the role of emotion in the *development* of cancer continues to be sparse. There is evidence that distress influences the progression of and adjustment to cancer (e.g., Mitchell et al., 2011), but mechanisms linking emotion to cancer etiology may differ from those related to progression or survival. For instance, disease progression may be related to psychosocial adjustment to the diagnosis and illness, treatment adherence, and the availability of social support. Based on work with cancer patients, Temoshok (1987) proposed a model of the cancer-prone individual (Type C personality), as one who is stoic, has difficulty expressing emotions, and has an attitude of resignation or helplessness. Empirical support for this model was reported in several studies (Grossarth-Maticek, Kanazir, Schmit, & Vetter, 1985); however, subsequent work has failed to replicate the findings and identified serious methodological problems with these studies (Ranchor, Sanderman, & Coyne, 2010).

Methodologically rigorous examination of the role of psychological factors in cancer incidence is challenging because of the long latency in the development of cancer and difficulty in ascertaining the true date of onset. In addition, cancer comprises a heterogeneous group of diseases of multiple etiologies that vary in their tissue of origin, cell type, biological behavior, anatomic site, and degree of differentiation. Because it takes 18 years for tumor cells to develop into detectable tumors, a minimum of 18 years follow-up has been recommended for studies of cancer incidence (Possel, Adams, & Valentine, 2012). That said, stress-related biological alterations may be detectable prior to tumor development. For example, extensive research, largely molecular and animal studies, has shown that psychosocial stress and related distress is associated with alterations in a range of processes that play an important role in carcinogenesis, including immunity, inflammation, insulin resistance, DNA repair capacity, cellular apoptosis, proliferation, angiogenesis, and telomere shortening (Thaker & Sood, 2008). Such findings suggest that studies investigating emotional processes directly in relation to biological processes known to be relevant in carcinogenesis may provide additional insight.

Numerous studies of depression and cancer mortality have shown that higher depression levels predict cancer mortality even after adjusting for potentially confounding medical variables (Pinquart & Duberstein, 2010). However, these studies cannot distinguish between the effects of emotion on *incidence* versus *survival* following a cancer diagnosis. Prospective studies of negative emotions and cancer incidence are suggestive but limited, with most studies focused on depression. For example, one study found higher depressive symptoms associated with increased colorectal cancer incidence (HR = 1.43; 95% CI: 0.9 –2.11) among 81,612 initially healthy women followed for 8 years (Kroenke et al., 2005). Several meta-analyses have considered the literature. One reported increased risk of incident cancer associated with depression when looking across multiple cancers, with effects stronger in studies with large sample sizes ($n \geq$ 100,000) and a longer follow-up period (≥ 10 years; Chida, Hamer, Wardle, & Steptoe, 2008). Findings, however, varied depending on the specific cancer considered.

Some studies have considered positive emotional functioning in relation to cancer progression or survival (Chida & Steptoe, 2008), but the idea that positive feeling and a "fighting spirit" can slow the progression and rate of disease development has been controversial (e.g., Aspinwall & Tedeschi, 2010; Coyne & Tennen, 2010). Almost no work has considered positive emotions effects in relation to incident cancer. Overall, direct evidence that emotions, either positive or negative, are involved in the etiology of cancer in humans is limited. Most work positing a relation between emotion and cancer incidence hypothesizes that effects are mediated either through health behavior or altered immune functioning. However, other mechanisms are possible, and the known biological consequences of recurring distress and their relevance to cancer initiation and promotion suggest this relationship deserves closer attention.

Infectious or Immune-Mediated Diseases and Other Health Outcomes

Negative emotions are thought to alter susceptibility to infectious diseases via effects on immune function (Cohen, Doyle, et al., 1995). Psychological distress and stressors appear to be reliably associated with immune function down-regulation (O'Leary, 1990). For example, one study of healthy middle-age adults examined levels of psychological distress in relation to changes in markers of immune function over a 1-year period, including natural killer (NK) cell, B, and T cell counts (Nakata, Irie, & Takahashi, 2011). Higher distress was associated with suppression of NK cell immunity (and not the other cell types), but not the reverse, suggesting that emotions may induce alterations in cellular immunity.

Whether findings with immune functioning provide insight into likely effects of distress on immune-related health outcomes has been tested among healthy individuals in several ways. One line of work has used a viral challenge methodology to examine associations between emotion and the common cold. In these studies, healthy subjects are exposed to a common cold virus, quarantined, and monitored for the development of biologically verified clinical illness. Prior to exposure, emotion levels are measured. Results demonstrate that after controlling for various potential confounders, individuals with higher negative emotion levels are more likely to develop clinical illness (Cohen, Tyrrell, & Smith, 1993), while those expressing more positive emotions are at reduced risk (Cohen, Alper, Doyle, Treanor, & Turner, 2006). Other work has found that psychological distress is associated with a less robust immune response to vaccination (Segerstrom, Hardy, Evans, & Greenberg, 2012) and an amplified inflammatory response after vaccination (Glaser, Robles, Sheridan, Malarkey, & Kiecolt-Glaser, 2003). Due to methodological and logistical complexities, research in this area is not extensive and few studies have examined emotions other than general distress or depressive symptoms in relation to these outcomes.

Most research on emotion and other immune-mediated outcomes (e.g., HIV/AIDS, herpes simplex virus, asthma) has considered disease progression, recurrence, or exacerbation, with less work assessing disease onset. Several studies have suggested that early-onset mental disorders (specifically anxiety and depression) are associated with increased risk of adult-onset arthritis (Von Korff et al., 2009) and asthma (Scott et al., 2011). These studies relied on retrospective reporting of mental disorder. Findings were corroborated in a prospective study that assessed mental health problems among boys ages 8 years and followed them into adulthood; boys with more depressive symptoms or other mental health problems in childhood demonstrated a higher risk of developing asthma (Goodwin et al., 2009).

Future Directions

Specificity in Emotion–Health Relationships

There has been long-standing debate as to whether effects of emotion might be largely systemic and nonspecific or if they are distinctive and relevant only to particular health outcomes (Friedman & Booth-Kewley, 1987; Macleod & Davey Smith, 2003). Many epidemiologists argue that lack of specificity in detectable effects signals confounded rather than causal associations (Macleod & Davey Smith, 2003), though others suggest that systemic effects are common (e.g., smoking influences both heart disease and lung cancer). A related debate is whether a specific emotion versus a dimensional approach is appropriate. Similar effects across multiple emotions have been noted for a number of health outcomes (Suls & Bunde, 2005). Shared effects could be due to overlap that occurs in the components of various emotions, but unique effects might also be possible due to nonshared aspects.

The notion that specific emotions could have distinctive health effects is partly predicated on the assumption that each emotion is associated with a unique physiological pattern. However, whether such differences reliably occur is a topic of ongoing debate. Proponents of the hypothesis suggest that with increased access to a broader array of biological parameters, differences will become more apparent. Regardless, even among emotions that seem to call forth similar physiological responses (e.g., heightened autonomic arousal) such as anxiety and elation, reliable distinctions can be made. For example, in the presence of a stressor, negative emotions are associated with appraisals of threat, while positive emotions are associated with appraisals of challenge (Tomaka, Blascovich, Kelsey, & Leitten, 1993). Laboratory studies have demonstrated that individuals who feel threatened by a stressful task exhibit less cardiac reactivity and more vascular resistance, whereas those who feel challenged exhibit more cardiac reactivity and less vascular resistance (Tomaka et al., 1993).

Whether or not specific emotions have distinct neurobiological profiles, the behaviors they motivate are often quite different, and thus effects on health may differ regardless of the underlying neurobiology. For example, anxiety is associated with heightened vigilance and active efforts to cope with difficult situations, whereas depression is more often characterized by behavioral retardation and withdrawal (Barlow, 1988). Anger is often associated with an impulse to approach others and be aggressive, while anxiety is more often associated the desire to escape. Appraisal tendency theory (Lerner & Keltner, 2000) further suggests that emotions with the same valence (e.g., fear and anger) can lead to differential judgments about risk as well as opposing action tendencies. For example, elicitation of fear leads to a heightened assessment of the risk associated with the behavior, whereas anger leads to a more optimistic appraisal of the future. Thus, if graphic warning labels on cigarettes elicit fear, individuals may assess smoking as more risky, but if they elicit anger, individuals may assess smoking as less problematic. These behavioral patterns have important implications for health as they may differentially influence the likelihood that individuals subsequently engage in health-promoting or -impairing behaviors.

Though emotions rarely occur in isolation, the majority of studies evaluate the effect of a single emotion in relation to a single health outcome. For example, while anxiety and depression often co-occur, studies that examine the association of anxiety with health outcomes often fail to account for their overlap (Suls & Bunde, 2005). This is partly due to methodological challenges—for example, considering multiple emotions in a single model presents issues of multicollinearity. More recent studies (largely in the realm of CHD) have begun to use creative methods to try to tease apart emotion-specific effects with some success. For example, a study of Vietnam veterans examined the effects of depression, anxiety, and their co-occurrence in relation to CVD mortality (Phillips et al., 2009). Each emotion was separately associated with increased risk, but high levels of both conferred the greatest risk for earlier death during follow-up. To date, there is sufficient evidence of separable effects to suggest it is prudent to continue to consider specific emotions separately, while acknowledging and actively investigating their shared components.

A Deeper Understanding of Mechanisms

Research on emotion–health links has consistently suggested both biological and nonbiological pathways as jointly explaining how recurring emotion experience may cumulatively influence health outcomes. Despite widespread agreement that behavioral pathways are relevant, strategies for influencing behavioral choices via the differential elicitation of emotions remain limited. In part this may be because emotions are rarely considered as modifiable upstream determinants of health-related behaviors. Moreover, behavior and biology are often considered as completely separable pathways, when in reality they are highly interconnected. Regardless, there is continued skepticism by many in mainstream biomedicine as to whether mental states can directly influence health-related biology. This perspective was most clearly articulated by a past editor of the *New England Journal of Medicine*:

> In my 1985 editorial (Angell, 1985) . . . I wrote "the literature contains very few scientifically sound studies of the relation, if there is one, between mental state and disease" . . . What I was talking about was the view that mental state can *directly* cause or substantially modify organic disease independent of personal habits . . . I am afraid my assessment of the literature has not changed very much in the 16 years since I wrote that. (Relman & Angell, 2002)

Skeptics claim that any apparent causal relationship between emotions and health is spurious or a result of wishful thinking, and that research fails to make a convincing case. Two critiques of the existing evidence have been offered: (1) lack of plausible biological mechanisms (despite recognized behavioral mechanisms) and (2) methodological concerns. Countless studies have documented associations of emotions with biological mediators that are arguably linked with health, such as inflammatory biomarkers, heart rate variability, and glucose control. Moreover, a great deal of work has considered links between stress-related physiological substrates (e.g., cortisol, catecholamines) and disease outcomes. But because studies rarely directly demonstrate biological mediation, such evidence may still be considered inconclusive. For example, anxiety is hypothesized to influence CHD in part via chronically elevated inflammation, but studies that evaluate anxiety in relation to altered inflammation levels along with subsequent development of disease have not been done. Perhaps as a result, the controversy around whether emotions directly influence disease development continues (Relman & Angell, 2002). That said, recent technological advances and more interdisciplinary cross-talk have led to exciting work on potential biological mechanisms. This includes exploring relevant neurobiological substrates or cellular processes, and examining the role of social and emotional processes in regulating gene products involved in human pathogenic resistance and disease development (see Kubzansky, Seeman, & Glymour, 2014, for a detailed discussion). Here we describe a few examples of this type of research.

Thayer and colleagues have proposed a theory of neurovisceral integration, based on the premise that when emotions are effectively regulated they provide the means for a flexible adaptation to constantly changing environmental demands (Thayer & Brosschot, 2005). This regulatory capacity has a biological counterpart, as reflected in the beat-to-beat variability in heart rate. Heart rate is determined by autonomic balance between two systems: the sympathetic and the parasympathetic nervous system. The sympathetic system is associated with energy mobilization, while the parasympathetic system (via inputs from the cardiac vagal nerve) is associated with restorative "calming" functions. In a healthy system, optimal functioning is associated with a high degree of variability to permit flexibility in meeting demands for energy expenditure. Less effective parasympathetic control is reflected in reduced heart rate variability, which has been linked with both poorer emotion regulation capacity (e.g., Di Simplicio et al., 2012) and higher risk of developing a range of diseases and premature mortality (Thayer & Brosschot, 2005). Thus, Thayer and colleagues have proposed that heart rate variability provides a biological link between poor emotion regulation and adverse health outcomes (Thayer, Yamamoto, & Brosschot, 2010).

Other recent work has considered emotion in relation to speed of cellular aging. Accelerated cellular aging, as measured by shortened telomere length and reduced telomerase activity in leukocytes, has been identified as a marker of increased risk for early morbidity and mortality across a range of disease outcomes (Aubert & Lansdorp, 2008). One study found that individuals with high levels of emotion dysregulation, as defined by chronic mood disorders, had significantly shorter telomere length as compared with age-matched controls without mood disorders. Another potentially relevant biological substrate is oxytocin, a hormone identified as being part of a key neurobiological system that may underlie the link between positive social and emotional processes and health (Singer, Friedman, Seeman, Fava, & Ryff, 2005). Research in humans has linked oxytocin to emotion and stress processes, noting its apparent stress-buffering effects (e.g., Heinrichs & Domes, 2008), though these effects do not occur uniformly (e.g., Kubzansky, Mendes, Appleton, Block, & Adler, 2012). Capacity for characterizing the mechanisms through which genes and their products function and interact with one another and with the environment has also increased. As a result, studies have begun mapping the actions of genes and their biochemical pathways to psychological phenomena, suggesting that psychological experiences can modulate the expression of specific genes, the proteins they code for, and the physiological pathways they regulate (Miller et al., 2008). For example, one study found highly versus less lonely individuals had increased expression of genes involved in immune activation, transcription control; and cell proliferation, and decreased expression of genes involved in innate antiviral resistance, supporting antibody production, and mature B lymphocyte function (Cole et al., 2007).

Within research on pathways linking emotions and health, a focus on deteriorative processes has overshadowed the potential role of restorative processes (Boehm & Kubzansky, 2012; Robles & Carroll, 2011). This has been the case even when thinking about positive emotions and related constructs (Boehm & Kubzansky, 2012). To date, most work has considered positive emotions as providing "antistress" effects or mitigating toxic effects of stress and distress. For example, such work has reported evidence that higher positive emotion levels are associated with reduced likelihood of chronic inflammation or hypertension (Steptoe & Wardle, 2005). However, greater consideration of restorative processes, either behavioral or biological, might provide important insight. For example, positive emotions may increase antioxidant activity (e.g., Boehm, Williams, Rimm, Ryff, & Kubzansky, 2013) or increase the likelihood of engaging in regular physical activity and getting better-quality sleep.

A Life Course Perspective: Emotions and Trajectories of Risk or Resilience

Research thus far has focused largely on emotion and health in adulthood. While informative, these studies may miss many processes already set in motion early in life. A life course perspective can help to clarify how and why emotions influence later health outcomes. Recent epidemiological and other work has begun to build compelling evidence that early childhood environments critically influence adult physical health. Repetti, Taylor, and Seeman (2002) proposed a framework for how early family environments influence physical health, and highlighted the critical nature of emotional processes that develop early in life. A major task of childhood is developing the capacity to regulate emotions, learned through socialization and experience over time. During childhood, temperament, biology, and social factors interact to build regulatory skills and strategies that are used over the life course (John & Gross, 2004).

Research on emotion regulation has been conducted both in the developmental and adult literatures, but integration among them is still limited, particularly regarding the relation with physical health. However, greater consideration of the role of emotion regulation in the maintenance of health or development of disease over the life course is warranted. Dysregulation in childhood emotional functioning has been demonstrated to persist well into adulthood (e.g., Caspi, 2000). These findings suggest that effects of emotions on adult disease processes may initiate much earlier in life than has generally been considered. For example, failure to learn appropriate strategies for emotion regulation in childhood may set up a lifelong pattern of yielding to temptation, immediate gratification, and the use of maladaptive behavioral coping responses to stress. Conversely, appropriate regulation may lead to accruing resilience. The classic marshmallow test suggests that variations in the ability to delay gratification is already apparent in 4-year-old preschoolers, and lower delay discounting predicts academic achievement and health behaviors (like smoking, drug abuse, obesity) more than a decade later (Mischel et al., 2011).

Studies examining the effects of emotion regulation on health starting in childhood are limited. However, to assess how early in the life course health risks associated with dysregulated emotion may manifest, a growing body of work considers emotional functioning assessed prior to midlife in relation to disease risk. In these studies, because individuals are too young to develop full-blown disease, biomarker outcomes provide a measure of risk. These biomarkers are often "silent"—that is, even in ranges considered to confer disease risk they often do not produce a sense of illness. Thus, such evidence can help to reduce concerns about reverse causality. Most work has focused on the relation between depression and inflammatory biomarkers, with studies primarily cross-sectional and conducted among adults. A meta-analysis of this relationship reported an overall effect size of 0.15 for CRP (95% CI: 0.10–0.21) and 0.25 for IL-6 (95% CI: 0.18–0.31) across 51 cross-sectional clinical and community studies (Howren, Lamkin, & Suls, 2009). Limited work has reported associations between anxiety or anger and higher levels of inflammation or coagulation factors (Pitsavos et al., 2006). While it is likely that effects are bidirectional, increasing evidence suggests that emotional distress, when it occurs earlier in life, may precede and trigger inflammatory processes. For example, one study reported that poor emotional functioning assessed at age 7 years was associated with higher inflammation levels at age 42 years even after adjustment for relevant covariates, including child health status (Appleton et al., 2011). One of the strongest studies reported a unidirectional effect of depression on CRP in a population-based study of youth with repeated measures of depression and CRP over nine waves of data; cumulative depressive episodes predicted subsequent CRP levels, but CRP levels were not associated with later depression status (Copeland, Shanahan, Worthman, Angold, & Costello, 2012). Similarly, another study found high distress levels at age 8 years were associated with elevated inflammation at age 10, but age 10 inflammatory levels were not associated with subsequent increases in distress (Slopen, Kubzansky, & Koenen, 2013).

Conclusions

Research increasingly supports the role of emotions in pathogenesis or disease protection. Much of the strongest evidence for the relationship is derived from longitudinal observational cohort studies that rely on self-report of emotion. To avoid concerns about self-report bias, studies have emphasized health outcomes that can be determined objectively and for which there is a relatively clear onset, leading to a preponderance of evidence in the domain of CVD. While emotions are almost certainly involved in the development of other outcomes such as cancer, autoimmune disease, or pain syndromes, because these outcomes are often diagnosed by self-reports of symptoms or have long latency periods, studies of these outcomes are more vulnerable to criticism and perhaps as a result have been pursued less vigorously. With the expansion of our capacity to measure biological surrogates for a range of disease outcomes, future work will be able to assess these relationships more systematically and rigorously. Another key question that is amenable to empirical inquiry (but has not yet been considered) is whether successful mitigation of emotional distress or setting up positive states within a healthy population effectively reduces risk of developing heart disease or other health conditions. Applying a life course perspective to this work will lead to important insights. Much of the field has focused on effects of negative emotions. However, significant gains in knowledge can be obtained from considering the full spectrum of emotions—both positive and negative—and the deteriorative or restorative processes they may initiate, as well as the critical role of emotion regulation in health. The effect of emotions on health maintenance or disease development has often appeared to be an emergent phenomenon. However, with technological and methodological advances and the integration of multiple disciplinary perspectives, we may better understand the underlying systems that give rise to these phenomena. This added insight may provide greater understanding into the nature of emotions as well as lead to new strategies for disease prevention and treatment.

Acknowledgments

Portions of this work are based on Kubzansky, Winning, and Kawachi (2014). We also thank Ichiro Kawachi, who provided invaluable insight and expertise on many aspects of this work.

CHAPTER 37

Neuroendocrine and Neuroimmunological Mechanisms of Emotion

Aric A. Prather

Affective experiences are intimately related to physical states of the body. Whether one subscribes to a top-down or bottom-up (or somewhere in between) theory of emotion (reviewed in Barrett & Lindquist, 2008), basal levels and acute fluctuations in peripheral biology play a role in the emotional process. Advances in neuroscience continue to illuminate the neural circuitry that underlies emotion generation and regulation, and while anatomical pathways linking the brain and body have been readily identified (e.g., autonomic nervous system [ANS], hypothalamic–pituitary–adrenal [HPA] axis), surprisingly less is known about how emotions affect downstream biology. This is especially true for outputs of the neuroendocrine and immune systems. In part, this may be due to the fact that the bulk of the empirical research has been carried out under the auspice of "stress" with less attention paid to the emotional responses that arise during stressful experience (Cohen, Kessler, & Gordon, 1997; Lazarus & Folkman, 1984). As such, this undifferentiated view of stress may fail to reveal the nuanced, affect-driven pathways through which stress impairs health (Kemeny, 2003; Weiner, 1992).

Emotions refer to a narrowly defined set of states that arise in response to specific challenges and goals, and are shaped through incorporation of conceptual and contextual information (Barrett, 2012). Emotions fall along various dimensions, such as by valence (positive vs. negative), arousal (high vs. low), and approach–avoidance motivation. In regard to the latter dimension, approach motivation facilitates approach toward stimuli (as would be observed in response to excitement or anger), while avoidance motivation leads an individual to avoid stimuli (as would be observed in response to fear, anxiety, and disgust). Inevitably, emotions are constituted by multiple, situationally defined and individually variable processes comprising experiential, physiological, and behavioral factors (Mauss & Robinson, 2009).

Several decades of research informs our understanding of how emotions affect health. Both large-scale epidemiological investigations and well-controlled experimental trials suggest that emotional processes are associated with the incidence and progression of numerous health conditions, including coronary heart disease, metabolic ailments (e.g., type 2 diabetes), autoimmune conditions, and infectious illness (DeSteno, Gross, & Kubzansky, 2013; Kiecolt-Glaser, McGuire, Robles, & Glaser, 2002). The underlying biological mechanisms through which emotions contribute to illness are complicated and not well understood. However, the neuroendocrine and immune systems serve as prime candidates (Miller, Chen, & Cole, 2009).

The connections between emotions and the neuroendocrine and immune systems are dynamic and recursive and do not run in only one direction (i.e., only top-down). Rather, harking back to the pioneering work of William James and Carl Lange (James, 1884; Lange, 1887), physiological states have substantial influence on the brain and, consequently, affective experience and behavior. Innovations in the pharmacological manipulation of certain physiological states can provide new insight into how specific biological processes influence emotion. This chapter focuses on both directions in the context of the neuroendocrine and immune systems. It is notable that the ANS also plays an important part in the embodiment of emotion; however, that discussion can be found in Chapter 9, "Emotion and the Autonomic Nervous System," in this volume.

In this chapter, a selective overview of the literature linking negative and positive emotional states with neuroendocrine and immune outcomes is provided. Due to the constraints of what can be included in a chapter, this vast literature has been distilled down to the key biological processes for which emotions appear to be most strongly related. In this regard, a focus is placed on cortisol, testosterone, and oxytocin (OT), as well as enumerative/functional parameters of the immune system, inflammation, and *in vivo* models of immunity (e.g., vaccination responsiveness). It should be noted, however, that other biological outcomes (e.g., estradiol, progesterone) also play a role in these growing literatures. While cross-sectional (i.e., nonlongitudinal) studies make up a large portion of the extant literature, this review is largely devoted to findings from laboratory-based studies that either attempt to manipulate emotional experience so as to measure changes in neuroendocrine and immune outcomes *or* experimentally manipulate neuroendocrine and immune systems, pharmacologically or otherwise, to investigate effects on emotional states. A brief discussion of the literature as a whole, including criticisms and future directions, is provided at the end of this chapter. First, however, a brief overview of the neuroendocrine and immune systems is provided to orient the reader.

A Brief Overview of the Neuroendocrine and Immune Systems

Neuroendocrine System

The neuroendocrine system plays a critical role in adaptation to environmental challenges, such as stress, and is necessary for survival. Under nonstressful conditions, this system facilitates growth, development, and reproduction. In response to a stressor, the neuroendocrine system undergoes a series of steps leading to the release of cortisol, a primary hormone of the neuroendocrine system. In response to a perceived challenge, the hypothalamus secretes corticotropin-releasing hormone (CRH) into the pituitary stalk where it travels to the pituitary gland. The anterior pituitary then secretes adrenocorticotropic hormone (ACTH) into peripheral circulation, which stimulates the release of cortisol from the adrenal cortex into the blood stream. Cortisol regulates the production, storage, and utilization of glucose, one of the body's primary sources of energy, as well as modulates the magnitude of the immune system response. Cortisol shows a distinct circadian pattern with the highest level occurring in response to awakening (i.e., cortisol-awakening response) that declines precipitously over the remainder of the day. Cortisol is regulated via a negative feedback loop. Glucocorticoid receptors are replete in many areas of the brain, including the hypothalamus and hippocampus. Binding of cortisol to these receptors signals the brain to discontinue the production and release of CRH and ACTH, which ultimately leads to a decrease in cortisol release from the adrenals. Importantly, it is postulated that prolonged stress or psychopathology (e.g., depression) can lead to dysregulation of this feedback system.

The anterior pituitary is the source of a host of other hormones, including growth hormone, prolactin, thyroid-stimulating hormone, luteinizing hormone, and follicle-stimulating hormone. OT and arginine vasopressin, in contrast, are produced by neurons of the hypothalamus and stored in the posterior pituitary until they are released into peripheral circulation. OT is a neuromodulator in the brain important for sexual reproduction and, in females, released in high amounts during childbirth to stimulate contractions and postpartum to facilitate maternal–child bonding and lactation. As described later in this chapter, OT has also been implicated in social behavior.

The reproductive system is closely related to the neuroendocrine system, and its reproductive hormones fluctuate in response to challenge and emotion. While all of the reproductive hormones (e.g., progesterone, estrogen) have some influence on stress and emotion, the strongest evidence involves testosterone (T). T is an androgen steroid hormone produced in the testes in men and ovaries in women. Despite the fact that men produce substantially higher levels of T than women, it serves important roles across gender, including growth of muscle mass and bone density. T also facilitates the development of secondary sex characteristics in men. Androgen receptors exist in the brain providing means for T to influence emotion and behavior. In this regard, T is believed to modulate anger experience and aggressive behavior, the latter of which has been most clearly substantiated in animals (e.g., Trainor, Bird, & Marler, 2004).

Immune System

The immune system comprises cells and soluble molecules that work together to protect the body from insult and injury. Though intimately related, the immune system is typically separated into two arms: the innate and acquired immune system. The innate arm is present at birth and acts as the body's first line of defense against microbial infection and tissue damage. Components of the innate immune system include macrophages and granulocytes, such as neutrophils and basophils, among others. Macrophages are phagocytic, meaning that they eat their targets (i.e., unwanted invaders). They also release proteins known as cytokines that facilitate inflammation. During an inflammatory response, innate immune cells congregate at an area of injury (e.g., a wound) releasing toxic molecules and signaling proteins to neutralize the threat and call other surrounding immune cells to their aid. Natural killer (NK) cells are another type of innate immune cell. NK cells play an important role in halting the early phases of viral infections and attacking cells that have become malignant. NK cells release a toxic substance to lyse unwanted cells. Laboratory techniques have been developed to quantify the ability of NK cells to lyse, known as NK cell cytotoxicity (NKCC).

The acquired immune system, as the name suggests, develops over time in response to antigen exposure. This arm of the immune system is slower acting compared to the innate immune system and comprises various lymphocytes (e.g., helper T cells, cytotoxic T cells, and B cells) with receptors on their cell surfaces that respond to one and only one invader. Once activated, these lymphocytes divide (i.e., proliferate) to mount an army of cells to help clear the body of the invader. The primary function of helper T cells is to produce cytokines that modulate the rest of the immune response. In contrast, cytotoxic T cells seek out and lyse infected cells (e.g., virally infected cells). Finally, B cells produce antibodies, which are soluble proteins important for neutralizing bacterial toxins and tagging free-floating viruses and infected cells so as to signal to the innate arm a need for destruction. Antibodies levels are clinically meaningful as they are the end product of vaccinations. Activated T and B cells maintain immunological memory and can circulate in the blood for years to provide a rapid response if challenged by the same antigen once again.

Communication between the brain and the immune system is facilitated primarily via the ANS and the HPA axis (Irwin & Cole, 2011). Immune cells have receptors specific to catecholamines and cortisol, among other hormones. Communication between different aspects of the immune system is also facilitated through cytokines. Of particular relevance to stress and emotion are proinflammatory cytokines (PICs). As noted above, PICs, such as interleukin (IL)-6, IL-1 beta, and tumor necrosis factor (TNF) alpha, play an integral role in wound healing and destroying foreign pathogens; however, when overactive (i.e., prolonged elevations of PICs), systemic damage can occur leading to early onset of chronic health conditions (e.g., coronary heart disease; Ridker, Rifai, Stampfer, & Hennekens, 2000; Ross, 1999). Regulation of the inflammatory system occurs at multiple levels. Activated immune cells release anti-inflammatory cytokines (e.g., IL-10) and receptor antagonists that down-regulate PIC production locally. Cortisol also down-regulates inflammation by binding to glucocorticoid receptors (GRs) on activated immune cells that then translocate to the nucleus to down-regulate inflammatory gene transcription. Finally, the parasympathetic nervous system (PNS) regulates inflammation (Tracey, 2002) via the vagus nerve. It is believed that the vagus nerve serves as a primary pathway through which systemic levels of PICs influence the brain.

Emotions and Neuroendocrine Function

Cortisol

Effects of Emotions on Cortisol

There is some evidence to suggest that negative emotions can serve as instigators of HPA axis activation and subsequent cortisol release; however, the data are far from conclusive. Within clinical samples, exaggerated HPA axis functioning (i.e., higher cortisol, especially in the evening) is observed in some but not all patients with depression (Stetler & Miller, 2011), with stronger evidence for subtypes of depression (e.g., melancholic depression). Patients with posttraumatic stress disorder (PTSD) also show alterations in cortisol, often marked by a blunted diurnal cortisol rhythm (Daskalakis, Lehrner, & Yehuda, 2013). In the context of stress, accruing evidence indicates that timing and severity of stressors play a role in driving deviations in cortisol rhythms (Miller, Chen, & Zhou, 2007). Data from a meta-analytic review of 107 studies demonstrated that cortisol rises in response to a chronic stressor but decreases as that stressor persists. Further, contextual factors, such as how an individual responds to the stressful situation and the extent to which the stressor is socially evaluative in nature and perceived as uncontrollable, significantly shapes cortisol dynamics.

In nonclinical samples, changes in daily affect have been linked to alterations in cortisol rhythms in a number of studies. For example, in a large sample of midlife adults, higher cortisol levels across the day were associated with higher levels of average negative affect; however, this was true only for older adults (Piazza, Charles, Stawski, & Almeida, 2013). Adam and colleagues (2006) found that negative affective states, such as loneliness, sadness, threat, and lack of control, on any given day predicted higher cortisol-awakening responses the following day. In addition, a flatter cortisol slope across the day was associated with same-day feelings of tension and anger (Adam et al., 2006). Other studies, however, have failed to observe associations between state negative affect and cortisol (e.g., Polk, Cohen, Doyle, Skoner, & Kirschbaum, 2005).

Diurnal cortisol tends to be lower in those reporting more positive emotions (reviewed in (Dockray & Steptoe, 2010; Pressman & Cohen, 2005). Using daily diaries, higher reports of happiness were related to lower cortisol levels early in the day and increased cortisol upon awakening in a small sample of 72 healthy men (Steptoe, Gibson, Hamer, & Wardle, 2007). Similar associations were observed in several larger samples (Steptoe, O'Donnell, Badrick, Kumari, & Marmot, 2008; Steptoe, Wardle, & Marmot, 2005). Like neuroendocrine links with negative emotions, these associations between positive affect and cortisol often vary as a function of age and gender (Dockray & Steptoe, 2010). For instance, Polk and colleagues (2005) found that higher positive affect, aggregated over 7 days, was associated with higher flatter diurnal rhythm in men but a lower flatter rhythm in women. This finding among women is consistent with prior research (Ryff, Singer, & Dienberg Love, 2004).

Cortisol is acutely responsive to changes in environmental demands. The largest and most robust effects on cortisol reactivity are observed in response to acute threats, often modeled in humans using acute laboratory tasks. The most common of these tasks is the Trier Social Stress Test (TSST; Kirschbaum, Pirke, & Hellhammer, 1993). The TSST is a laboratory task where a participant is exposed to a social evaluative speech task and mental arithmetic in front of a panel of evaluators. This paradigm, and modified versions of it, results in high levels of perceived social evaluation and reliably induces HPA activation, including a significant increase in cortisol (Dickerson & Kemeny, 2004; Kirschbaum et al., 1993).

Understanding the task characteristics and stress-related affective experiences that predict HPA responsiveness has been an area of active scientific inquiry (see Campbell & Ehlert, 2012; Denson, Spanovic, & Miller, 2009; Dickerson & Kemeny, 2004, for reviews). A seminal meta-analysis of 208 acute laboratory studies suggested that two key task characteristics contributed to greater HPA activation: the uncontrollability of the task and the extent to which the task was social evaluative in nature (Dickerson & Kemeny, 2004). Importantly, type of task (i.e., being a public speaking/cognitive task vs. not), duration of task, and the subjective distress and negative affect initiated by the tasks did not explain these findings. These results align with social self-preservation theory that argues that one of the central motives of humans and other animals is to maintain social status (Dickerson, Gruenewald, & Kemeny, 2004). Within this framework, shame has been proposed as the affective experience driving HPA functioning in response to acute social threat (Dickerson et al., 2004; Gruenewald, Kemeny, Aziz, & Fahey, 2004). A subsequent study supported this notion such that increases in self-reported shame and decreases in social self-esteem corresponded to greater cortisol reactivity to a social evaluative stressor (Gruenewald et al., 2004). Of note, a more recent meta-analysis of the cortisol reactivity literature failed to find strong support for the role of self-conscious emotions predicting cortisol responses (Denson et al., 2009).

It is well documented that self-report measures of emotion are often weakly correlated with objectively assessed measures of physiology, including cortisol (Mauss, Levenson, McCarter, Wilhelm, & Gross, 2005). One explanation for this is that self-reported emotions, by their very nature, rely on conscious self-reflection. Implicit measures of affect, in contrast, may improve this coherence. For instance, emotional facial expressions, which are thought to reflect automatic unconscious processes, may yield more consistent findings. In this regard, Lerner, Dahl, Hariri, and Taylor (2007) investigated the coherence between facial expressions in response to the TSST and cortisol reactivity. Participants displaying more fearful facial expressions during the task showed a greater increase in salivary cortisol. In contrast, those displaying expressions of anger and/or disgust showed a blunted cortisol response. Self-report measures of emotion were largely unrelated to cortisol. In a separate study of implicit negative affectivity, participants completed the Implicit Positive and Negative Affect Test (IPANAT) and found that those who displayed more implicit (i.e., presumably below conscious awareness) negative affect showed greater cortisol responsiveness to an uncontrollable noise stressor (Quirin, Kazen, Rohrmann, & Kuhl, 2009).

Effects of Cortisol on Emotions

There is a long and storied literature implicating HPA hyperactivity and the pathogenesis of psychiatric conditions. For instance, patients with Cushing's syndrome, which is marked by unregulated and excessive cortisol release, are at increased risk of anxiety disorders (generalized anxiety and panic) and major depression (Pereira, Tiemensma, & Romijn, 2010). Further, prospective evidence in otherwise healthy participants also supports such associations, with higher diurnal cortisol, particularly a greater cortisol-awakening response, related to incidence of depression and anxiety disorders (Adam et al., 2010, 2014; Vrshek-Schallhorn et al., 2013).

GRs densely populate brain regions critical to emotional processing, providing a mechanism through which cortisol could influence emotion. Attempts to document the effects of exogenous cortisol on emotion have been mixed, however (reviewed in Putman & Roelofs, 2011). Several trials have failed to find effects of synthetic cortisol on measures of affect (Abercrombie, Kalin, & Davidson, 2005; Buchanan, Brechtel, Sollers, & Lovallo, 2001; Wachtel & de Wit, 2001). However, one study found that acute treatment with cortisol led to mood improvement (Reuter, 2002). In the context of an acute laboratory stressor, exogenous cortisol was found to attenuate negative affective responses to stress in several studies (Het & Wolf, 2007; Soravia et al., 2006). These data suggest that perhaps cortisol aids in effective coping with stress. Unfortunately, variability in study designs and dosages of cortisol make it difficult to draw any strong conclusions.

There is growing evidence that the effects of cortisol on emotion are situationally dependent. For instance, Wirth, Scherer, Hoks, and Abercrombie (2011) found that participants who received intravenous hydrocortisone and were exposed to unpleasant pictures reported more negative affect compared with those on placebo when they were in a familiar environment. In contrast, when in a novel environment, participants reported elevated levels of negative affect similarly regardless of study condition (i.e., hydrocortisone or placebo; Wirth et al., 2011). In addition, sex effects have also been observed. Women exposed to intravenous hydrocortisone showed reductions in attentional bias toward positively valenced stimuli; this effect was not observed in men (Breitberg et al., 2013). Dose of cortisol also appears important in some circumstances (Buchanan et al., 2001).

Summary

Cortisol remains one of the most consistently measured neuroendocrine outcomes in stress and emotion research. While there is fairly robust evidence that cortisol increases acutely under socially evaluative stress, too few studies exist to know whether specific negative emotions, such as shame, truly drive these fluctuations. Findings in support of affect-related changes in diurnal cortisol are also promising; however, evidence that these associations can vary by gender and age suggest that more granular investigations are needed. Similarly, more studies employing cortisol administration are required to make sense of how increases drive situationally dependent changes in emotion, and how such changes fit with the existing literature linking cortisol and psychopathology.

Testosterone

Effects of Emotions on T

T is a critical sex hormone that contributes to the development of secondary sex characteristics and facilitates mating behavior; however, emerging evidence suggests that T also plays an important role in socioemotional functioning. In this regard, much of the existing literature on T has focused on responses to and anticipations of competitive and aggressive interactions, which are closely tied to anger (Carre, McCormick, & Hariri, 2011; Eisenegger, Haushofer, & Fehr, 2011). It is well accepted that T helps drive aggressive behavior in animals (Gleason, Fuxjager, Oyegbile, & Marler, 2009; Trainor et al., 2004). In humans, however, aggressive behavior is incredibly complex, as most aggressive behaviors are not overtly violent. As such, correlations between self-reports of aggression and T are weak, though positive (Archer, Graham-Kevan, & Davies, 2005).

A handful of studies have investigated whether competitive interactions contribute to reactivity in T and related aggressive behaviors. Overall, the findings suggest that among participants who show an increase in T, there is a related increase in either willingness to engage in further competition (if the task was competitive in nature) and/or aggressive behavior (reviewed in Carre et al., 2011). This may have clinical implications as a recent study found that T reactivity in response to a social provocation task statistically mediated the effects of an early life intervention on future aggressive behavior (Carre, Iselin, Welker, Hariri, & Dodge, 2014).

Importantly, not all participants in these laboratory studies display the expected increases in T, and in fact, in some cases there were no main effects of the task on changes in T (e.g., (Mehta & Josephs, 2006). Accordingly, there is increasing interest in identifying individual differences and contextual factors that modulate these associations. Characteristics that may explain some of the variability in T reactivity range from differences in gender, contextual cues, basal levels of T, and social status (Carre et al., 2011; Josephs, Sellers, Newman, & Mehta, 2006; Klinesmith, Kasser, & McAndrew, 2006; Mehta & Beer, 2010). For instance, participants with low basal T report more emotional arousal and worse cognitive functioning when placed in an experimentally manipulated high-status position, while those with high T show more decrements when placed in a low-status position (Josephs et al., 2006). In addition, researchers have proposed a dual-hormone hypothesis, which posits that levels of cortisol moderate the effects of T on aggression such that the effects are stronger when levels of cortisol are low (Mehta & Josephs, 2010). Support for this hypothesis comes from data on several highly aggressive male clinical populations (i.e., violent offenders and adolescents with conduct disorder; Dabbs, Jurkovic, & Frady, 1991; Popma et al., 2007), and experimental studies of dominance (Mehta & Josephs, 2010). Interestingly, there is some evidence for a reverse pattern in females such that greater aggression is seen in women with high T and high cortisol (Denson, Mehta, & Ho Tan, 2013). The extent to which other hormones or biological processes may further modulate social processes remains a fruitful area of investigation.

Surprisingly little is known about the relationship between T and emotional experience beyond aggressive behavior. There is cross-sectional evidence that shows that higher levels of self-reported anger and hostility are associated with higher T (Hohlagschwandtner, Husslein, Klier, & Ulm, 2001; Persky, Smith, & Basu, 1971). Indeed, one study of 32 healthy student volunteers found that higher salivary T obtained 4 and 6 hours prior to a mood assessment was associated with greater self-reported anger (van Honk et al., 1999). However, other studies fail to find associations (e.g., King, Rosal, Ma, & Reed, 2005). In the laboratory, men exposed to an acute stressor showed increases in T and this increase was positively correlated with trait hostility (Girdler, Jammer, & Shapiro, 1997). More recently, a study examining social rejection supported a link between anger and T. Here, individuals who participated in a cyberball task reported increases in self-reported anger, the magnitude of which was associated with increasing levels of salivary T (Peterson & Harmon-Jones, 2012). In another study, a task designed to induce anger (Engebretson, Sirota, Niaura, Edwards, & Brown, 1999) was also related to increasing T. Participants read a series of anger-laden phrases. This resulted in the expected increases in anger as well as significant increases in T (Herrero, Gadea, Rodriguez-Alarcon, Espert, & Salvador, 2010). Notably, there was no significant relationship between increases in anger and T, again highlighting the lack of coherence across self-report and physiologic measures.

Effects of T on Emotions

The implementation of single and multidose sublingual administration of T has led to careful inquiry into how T affects complex social interactions and the behaviors and emotions that arise in response. In laboratory studies of "reactive aggression," where a participant has the opportunity to "steal away" points from a fictitious opponent, higher basal T is associated with a greater likelihood of carrying out such a "harm" behavior in some (reviewed in Carre et al., 2011) but not all studies (Eisenegger, Naef, Snozzi, Heinrichs, & Fehr, 2010). T administration also appears to have some effect on self-reported emotion. O'Connor, Archer, and Wu (2004) found that men treated for 8 weeks with T in a cross-over design reported modest, but significant, increases in anger and hostility on T compared with placebo; however, there were no increases in aggressive behavior. Such mood changes are consistent with the fact that some anabolic steroid abusers develop steroid rage, hypomania, irritability, and in some cases, depressive episodes (Hartgens & Kuipers, 2004).

While the effects of T on aggressive behavior remain controversial, there is more consistent data suggesting that T drives motivation behaviors related to obtaining higher social status (i.e., dominance; Mazur & Booth, 1998). Using an approach–avoidance framework, it is hypothesized that T administration can lead to increased anger and social vigilance (approach) and reduction in fear (avoidance) in contexts where social status can be promoted (Terburg & van Honk, 2013). In regard to the latter, behavioral and neuroimaging studies in animals and humans suggest that T administration reduces fear processing and behavior (van Honk, Peper, & Schutter, 2005). Additionally, T administration leads to suppressed facial mimcry in response to emotional facial expression (Hermans, Putman, & van Honk, 2006), decreased trust in others, and decrements in emotional inference capacity (van Honk et al., 2011). In a sample of women, T administration compared with placebo led to a modest reduction in emotional inference (i.e., cognitive empathy), which was assessed using the Reading the Mind in the Eyes Test (RMET). This finding was moderated by fetal T exposure, such that higher fetal exposure resulted in further reduction in cognitive empathy for those receiving exogenous T (van Honk et al., 2011). While reduction in cognitive empathy in the face of competition for status is likely adaptive, the moderation effect is notable as it further highlights contextual and/or biological factors that can illuminate otherwise minor associations.

T also appears to affect the way our brains interpret potential threats, with implications for emotional processing. In a recent neuroimaging study, those who received an acute dose of T showed heighted reactivity of the amygdala, hypothalamus, and periaqueductal gray in response to viewing angry faces compared with those on placebo (Goetz et al., 2014). The amygdala is rich with androgen receptors, as are other brain regions implicated in threat processing (Sarkey, Azcoitia, Garcia-Segura, Garcia-Ovejero, & DonCarlos, 2008). Animal studies also support that T has anxiolytic effects, mediated by gamma-aminobutyric acid A ($GABA_a$) receptors (Fernandez-Guasti & Martinez-Mota, 2005). Additionally, exogenous T has been shown to increase the heart rate of participants when exposed to angry faces but not happy facial expressions (van Honk et al., 2001), providing evidence that T confers effects of peripheral physiology in the context of threat.

Summary

There is clear animal evidence that T modulates behavior, particularly aggression. Investigation of T in humans, however, has been hampered by available methods and the complexity of the human experience. While there is some evidence that suggests negative emotions, particularly anger, can lead to increased T, experimental studies that use T administration and measure downstream effects are more compelling. In this regard, there is mounting evidence that T affects the brain to modulate emotion, decision making, and ultimately, behavior. The relationship among T and emotional experience and behavior are complex and appear moderated by basal levels of T, context and demands, gender, and other biological processes, including cortisol.

Oxytocin

Effects of Emotions on OT

Over the past decade, research on the actions of OT in facilitating social interaction and emotion has exploded. In public forums, oxytocin has become known as a "love hormone" as well as a virtual panacea for treating loneliness, mistrust and social disconnection. This has led to interest in using OT as a pharmacological treatment for improving social functioning and prosocial behavior in a variety of clinical populations where social functioning is compromised, including schizophrenia, autism, anxiety, and depression (Bakermans-Kranenburg & van IJzendoorn, 2013). While often exaggerated, such claims are founded on elegant animal research and emerging human studies. OT may play an important role in regulating the stress response with implications for emotional experience.

To date, only a handful of studies have investigated the effects of stress or negative emotion on downstream levels of OT in peripheral blood. In part, this is because OT in peripheral blood is challenging to measure accurately (McCullough, Churchland, & Mendez, 2013). Nevertheless, several cross-sectional studies show that greater relationship distress in women is associated with higher peripheral levels of oxytocin (Taylor et al., 2006; Taylor, Saphire-Bernstein, & Seeman, 2010; Turner, Altemus, Enos, Cooper, & McGuinness, 1999). Higher levels of oxytocin are also associated with greater anxiety, depressive severity, and history of childhood maltreatment (Cyranowski et al., 2008; Hoge, Pollack, Kaufman, Zak, &

Simon, 2008; Holt-Lunstad, Birmingham, & Light, 2011; Olff et al., 2013). While on the surface one would expect that OT levels would be inversely related with negative emotion given the large literature supporting OT as a prosocial hormone, Taylor and colleagues (2010) speculate that OT rises in response to distress as a signal to increase affiliation with others. OT is also at the center of the "tend and befriend" response posited to explain sex differences in responses to stress (Taylor et al., 2000). More specifically, it is proposed that OT, along with estrogen and endogenous opioids, facilitate increased caring, especially for offspring, and enhanced affiliation under stress in females.

The effects of acute laboratory stress on peripheral levels of OT have been mixed with a couple of studies reporting significant stress related increases (Moons, Way, & Taylor, 2014; Sanders, Freilicher, & Lightman, 1990), while other studies fail to find an effect (Altemus et al., 2001; Cyranowski et al., 2008; Taylor et al., 2006). There is also emerging evidence that genetic factors may modulate the link between OT and emotion, at least in response to stress. In a recent study of men and women exposed to a TSST, women who showed a greater stress-related increase in OT and were GG homozygous for the rs53576 polymorphism of the oxytocin receptor gene (OXTR) reported higher levels of positive affect post stressor (Moons et al., 2014). Interestingly, men who showed increases in vasopressin, a hormone similar to OT, and were a carrier for the RS1 polymorphism of the vasopressor receptor gene reported more anger in response to the TSST. While this finding requires further replication, such genetic effects point to yet another factor that can significantly modulate associations between biological outcomes, in this case OT, and affective experience.

Effects of OT on Emotions

Whether OT administration affects emotions continues to be an area of active scientific inquiry. Accruing evidence demonstrates that OT promotes positive social emotions such as trust and altruism (Israel, Weisel, Ebstein, & Bornstein, 2012; Kosfeld, Heinrichs, Zak, Fischbacher, & Fehr, 2005), and better emotion recognition (Domes, Heinrichs, Michel, Berger, & Herpertz, 2007), which have led many to associate OT as a prosocial hormone. In animals, exogenous OT administration results in enhanced sedation and relaxation, reduced fearfulness, and attenuated sympathetic arousal (reviewed in Carter, 2014).

Intranasal OT can also modulate responses to acute laboratory stressors. OT administration prior to a public-speaking task resulted in decreased anticipatory anxiety compared with placebo and increased feelings of sedation (de Oliveira, Zuardi, Graeff, Queiroz, & Crippa, 2012). Increased calmness was also observed in another study (Heinrichs, Baumgartner, Kirschbaum, & Ehlert, 2003). Kubzansky, Mendes, Appleton, Block, and Adler (2012) found the OT administration prior to the TSST resulted in physiological indices that characterize a more "challenged" (vs. "threatened") state compared with placebo. Moreover, OT promoted lower levels of stress-induced negative emotion in men but not women. More specifically, men showed reduced levels in stress-induced anger in the OT condition compared with placebo, while women experienced an increase in anger compared with placebo. While the decrease in distress observed in men is consistent with a prior study (Heinrichs et al., 2003), the authors speculate that the increase observed in women aligns with the notion that OT may promote approach-related behavior, of which anger often facilitates.

Neuroimaging studies tend to support threat-reducing effects of intranasal OT. Several studies have found that OT reduces amygdala reactivity to threatening stimuli (e.g., angry and fearful faces; reviewed in Meyer-Lindenberg, Domes, Kirsch, & Heinrichs, 2011). The effect of OT on attenuating the amygdala has also been shown to mediate OT-related increases in trust during an economic trust game (Baumgartner, Heinrichs, Vonlanthen, Fischbacher, & Fehr, 2008). Importantly, other brain areas have also been implicated in mediating OT effects, including the caudate and other subcortical regions (Kanat, Heinrichs, & Domes, 2013), which suggests the influence of OT on the brain is complex and likely context specific.

Recent studies suggest that OT can also facilitate negative emotions, such as envy (Shamay-Tsoory et al., 2009), and reduce an individual's willingness to help "outgroup" members (De Dreu et al., 2010; Shalvi & De Dreu, 2014). Explanations for the OT-related enhancement of negatively valenced emotions include thoughts that OT increases social salience as well as reflect approach–avoidance behavior (Kemp & Guastella, 2010, 2011). Future studies testing these competing explanations and related contextual factors will go a long way in illuminating the influence of OT on human behavior.

Summary

The evidence linking OT to emotion is accruing but not without controversy. Intranasal administration studies demonstrate that OT affects self-reported emotion, behavior, and brain activity; however, many of these findings are context specific. Consequently, competing theories about how OT is related to socioemotional functioning have emerged. While OT can reduce anxiety and fear, it has also been shown to enhance negatively valenced constructs, such as envy. Additional studies are needed to clarify the nature of these findings. In regard to the effects of emotion on peripheral OT, another story emerges. Overall, the data suggest that greater negative emotion is related to higher levels of peripheral OT. Like the OT administration data, findings are often a function of gender and, in some cases, genetics. Challenges in measuring peripheral OT accurately likely contribute to some of the mixed findings in this literature.

Emotions and the Immune System

Effects of Emotions on the Immune System

Enumerative and Functional Immune Measures

Like cortisol, much of what is known about emotion and the immune system falls under the umbrella of stress research (Glaser & Kiecolt-Glaser, 2005; Herbert & Cohen, 1993b; Marsland, Bachen, Cohen, & Manuck, 2001; Segerstrom & Miller, 2004). The biological mediators of the stress response (i.e., HPA and ANS activity) modulate the immune system to adapt to challenges and environmental demands; however, under prolonged stress, the efficiency of the immune system begins to wane. As reviewed by Segerstrom and Miller (2004), there are a number of consistent findings linking stress and immunity. In response to acute laboratory stressors, such as the TSST, there are transient increases in total number of lymphocytes, cytotoxic T cells, and NK cells as well as concomitant reductions in the ability for T cells to proliferate when challenged *in vitro*. This pattern suggests an up-regulation in innate immunity and suppression of acquired immunity. Studies employing brief naturalistic stressors, such as assessing students immediately prior to and following academic examinations, demonstrate reductions in NKCC and T cell proliferative capacity along with increased reactivation of latent viruses, the latter of which indicates suppression of cell-mediated immunity. To date, the most robust immune effects are observed in those undergoing chronic stress, such as being a caregiver of a spouse with dementia (e.g., Kiecolt-Glaser, Glaser, Gravenstein, Malarkey, & Sheridan, 1996; Kiecolt-Glaser et al., 2003). These individuals show substantial immune suppression, including decreased T cell proliferative capacity and enhanced latent virus reactivation, along with increased levels of inflammation.

Depression is another area where enumerative and functional measures of immunity have been extensively investigated. Overall, compared with a nondepressed control group, individuals diagnosed with clinical depression show fewer NK cells and T cells but higher levels of B cells and T helper cells (Zorrilla et al., 2001). Depressed patients also show lower NKCC and a reduced capacity for cell proliferation (Herbert & Cohen, 1993a; Zorrilla et al., 2001). Beyond depression, there is some evidence that anger and hostility are related to functional measures of immunity. For instance, in a sample of cardiac patients, better anger control was associated with higher NKCC (Ishihara, Makita, Imai, Hashimoto, & Nohara, 2003), whereas lower NKCC was associated with higher anger suppression in a separate cancer population (Penedo et al., 2006).

Positive emotions have been related to aspects of immunity (reviewed in Dockray & Steptoe, 2010; Marsland, Pressman, & Cohen, 2007). Higher dispositional positive affect was associated with greater NKCC in a sample of older adults (Lutgendorf et al., 2001). In addition, several mood induction studies have found that humorous stories or films result in increased NKCC, increased number of T and B cells, and increased T cell proliferation (Berk, Felten, Tan, Bittman, & Westengard, 2001; Futterman, Kemeny, Shapiro, & Fahey, 1994); methodological considerations, such as the lack of control conditions in some cases and lack of specificity (i.e., modulation by both positive and negative emotion conditions), should temper interpretations of these findings.

The degree to which enumerative and functional immune measures respond to acute changes in emotions has not been well studied. In a recent meta-analysis of the literature using high-inference coding, Denson and colleagues (2009) reported that sadness and disgust were associated with decreases in numbers of NK cells. Studies designed to elicit embarrassment and rumination, specifically brooding, were associated with reductions in total T cell number while anticipation was associated with reductions in number of T helper cells. None of the emotional variables considered were related to acute changes in cytotoxic T cell or B cell numbers. In contrast, emotions related to immediate threats, including anticipation and surprise, were associated with an increase in total number of lymphocytes. Unfortunately, the only functional measure included in this meta-analysis was NKCC; none of the emotional variables were associated with NKCC. It is unclear what to make of these findings. While there is theoretical grounding for expecting that emotions, such as fear or anger, may be coupled with immune changes related to immediate threats in the environment (e.g., possible wounding from a predator; Kemeny, 2003), transient changes in cell type number are unlikely candidates to substantiate such a theory (see Miller, 2009, for a commentary). Additional integration of other functional immune measures, including cellular production of proinflammatory cytokines and the proliferative capacity of T cells, will aid in future investigations.

Inflammation

Inflammation, as indexed by levels of PICs in peripheral circulation, has emerged as a biological pathway linking psychological phenomenon and health. There is a large literature linking higher levels of state and trait measures of negative emotions with elevated inflammatory activity, including self-reported anger/hostility, anxiety, and depression (Howren, Lamkin, & Suls, 2009; Kiecolt-Glaser et al., 2002). Further, a series of studies have documented increases in systemic inflammation and cellular production of PICs in response to acute laboratory stressors (Dickerson, Gable, Irwin, Aziz, & Kemeny, 2009; Steptoe, Hamer, & Chida, 2007). Regarding positive emotions, higher levels of dispositional positive affect have been related to lower levels of systemic inflammation (e.g, IL-6) and attenuated cellular production of PICs (Prather, Marsland, Muldoon, & Manuck, 2007; Steptoe et al., 2008); however, an association was observed in women alone in one study (Steptoe et al., 2008). Types of positive emotion may matter more than others when it comes to inflammation. For instance, Ryff and colleagues (2004) found that higher eudaimonic well-being (i.e., striving toward a purpose in life) was associated with lower levels of the IL-6 soluble receptor. This is in line with a recent study that found eudaimonic well-being was related to a down-regulated proinflammatory gene profile, while hedonic well-being was associated with an up-regulation in these genes (Fredrickson et al., 2013).

To date, only a couple of studies have carefully investigated the extent to which stress-related changes in specific emotions drive concomitant changes in inflammation. Moons, Eisenberger, and Taylor (2010) reported that greater levels of self-reported fear following a speech task were associated with statistically significant increases in levels of IL-6 and a marginal increase in the soluble receptor for TNF alpha, both measured in oral mucosal transudate (OMT). Self-reported anger, in contrast, was unrelated to cytokine levels. This is in contrast to two other recent studies. In a sample of 102 healthy midlife adults, greater reports of anxiety and anger, but not fear, in response to a similar speech task were associated with greater task-related increases in circulating levels of IL-6 measured in blood (Carroll et al., 2011). This association between task-related increases in anger and levels of IL-6 was recently replicated (Puterman, Epel, O'Donovan, Prather, Aschbacher, et al., 2014). Notably, the latter finding linking anger and IL-6 reactivity was true only for those reporting low social support, which may suggest a need to more carefully assess contextual variables when investigating affect-immune relationships.

Suarez, Boyle, Lewis, Hall, and Young (2006) employed an anger recall interview (ARI) to investigate the effects of negative arousal on inflammation. Analyses revealed an intriguing three-way interaction such that greater negative affect in response to the ARI predicted greater increases in stimulated production of IL-6 and TNF alpha among those with high levels of insulin resistance. Using a similar paradigm, greater negative emotional arousal was related to greater increases in C-reactive protein but unrelated to changes in levels of IL-6 (Brummett et al., 2010). Finally, elevated levels of IL-1beta, obtained in saliva, were observed in grieving participants who carried out a grief-elicitation task (i.e., describing how their loved one died), and these levels of IL-1 beta were related to activation of brain regions implicated in emotional processing (subgenual anterior cingulate cortex [sACC] and orbitofrontal cortex [OFC]; M. F. O'Connor, Irwin, & Wellisch, 2009). Unfortunately, the lack of a control condition or baseline assessment of inflammatory activity prior to grief task makes it impossible to know whether this grief paradigm resulted in enhanced inflammatory activity.

In Vivo *Immune Processes*

The immune system is more than the sum of its parts. Accordingly, documenting whether changes in emotion or stress result in concomitant changes in cell number or function often have limited clinical utility. Therefore, researchers have turned to *in vivo* models of the immune system—such as estimating one's susceptibility to the common cold following viral challenge, response to immunization, and proficiency in wound healing—to better characterize the role of negative emotions.

In a series of experimental studies, Sheldon Cohen and colleagues have investigated the psychosocial predictors of upper respiratory infections (URIs) using a viral challenge model. Here, participants are experimentally exposed to a cold or influenza virus or placebo and then quarantined and monitored for the development of infection and illness. Findings from these studies largely support more stressful life events and greater perceptions of current stress, and greater reports of negative affect increase the probability of a biologically verified cold (Cohen, Tyrrell, & Smith, 1993; Cohen & Williamson, 1991). Several factors have also been effective in lowering the probability of cold development, including a larger social network size, greater sociability, more social support, and a positive emotional style (Cohen, Doyle, Skoner, Rabin, & Gwaltney, 1997; Cohen, Doyle, Turner, Alper, & Skoner, 2003a, 2003b).

Antibody levels mounted in response to immunization provides another clinically relevant metric of immune function. To date, the strongest psychosocial predictors of vaccination response tend to be long-lasting experiences rather than acute changes in emotion. For instance, poorer antibody responses have been observed among chronically stressed individuals, those reporting more stressful life events and higher levels of perceived stress compared with less stressed participants (Cohen, Miller, & Rabin, 2001; Pedersen, Zachariae, & Bovbjerg, 2009). Individual differences in negative affect have also been linked to immunization response (A. L. Marsland, Cohen, Rabin, & Manuck, 2001; Phillips, Carroll, Burns, & Drayson, 2005). For instance, Marsland and colleagues (2001) found that greater trait negative affect predicted lower antibody responses to the hepatitis B (HB) vaccination series. In another study of HB vaccination, more depressive symptoms were associated with increased likelihood of being a nonresponder (anti-HB < 10 IU/L [International Units/Liter]) to the vaccine (Afsar, Elsurer, Eyileten, Yilmaz, & Caglar, 2009). Similarly, Petry, Weems, and Livingstone (1991) observed associations among depression, anxiety, and irascibility with peak antibody titers in an earlier study. Finally, greater reports of loneliness, measured by daily diary over 2 weeks, were associated with poorer antibody response to the influenza vaccine in a sample of college students (Pressman et al., 2005). Notably, greater dispositional positive affect has also been related to higher antibody production to the HB vaccine (Marsland, Cohen, Rabin, & Manuck, 2006).

One of the primary roles of the immune system is to facilitate wound healing. There is now a large body of evidence supporting the role of stress, particularly prolonged or chronic stress, in slowing the healing of wounds (Christian, Graham, Padgett, Glaser, & Kiecolt-Glaser, 2006). In a seminal example, chronically stressed women caring for a spouse with dementia showed healing of a punch biopsy wound 24% slower than low-stress noncaregivers (Kiecolt-Glaser, Marucha, Malarkey, Mercado, & Glaser, 1995). In addition, slower wound healing has been observed in individuals reporting more depressive symptoms and lower anger control (Bosch, Engeland, Cacioppo, & Marucha, 2007; Gouin, Kiecolt-Glaser, Malarkey, & Glaser, 2008). Using a martial interaction paradigm, couples characterized as having high hostile interactions showed blister wound healing at 60% the rate of couples with low hostile interactions (Kiecolt-Glaser et al., 2005). Lower local wound-specific levels of cytokines (e.g., IL-8, IL-1 alpha) are thought to mediate some of the effects of emotion on healing (Glaser et al., 1999). In addition, recent evidence supports the mechanistic role of cortisol and OT (Christian et al., 2006; Gouin et al., 2010). For instance, again using a martial interaction paradigm, participants with higher OT had more positive couple interactions and faster healing times compared to those with low OT (Gouin et al., 2010).

Effects of Immune System on Emotions

Perhaps the most impressive advance made in the field of human psychoneuroimmunology (PNI) in the last decade has been recognition and empirical substantiation of the influence inflammatory mediators have on the brain and affective experience (Dantzer, O'Connor, Freund, Johnson, &

Kelley, 2008; Miller, Maletic, & Raison, 2009). Clinical data have long suggested that inflammatory activity is up-regulated in individuals with psychopathology, most notably, major depression (Dowlati et al., 2010; Smith, 1991) and to some extent anxiety (O'Donovan et al., 2010; Vogelzangs, Beekman, de Jonge, & Penninx, 2013). Animals treated with PICs or agents that activate the inflammatory response, such as systemic administration of endotoxin, display a characteristic "depression" behavioral phenotype termed "sickness behavior." These behaviors include reduced motor activity, social withdrawal, decreased interest and consumption of food and water, increased slow-wave sleep, and altered cognition (Dantzer et al., 2008).

Experimental human studies employing endotoxin administration results in similar affective changes in humans. Indeed, participants treated with low-dose endotoxin show increased levels of systemic inflammation (TNF, IL-6) and related, transient, increases in symptoms of anxiety and depression (Reichenberg et al., 2001); however, some evidence suggests these findings may be stronger in women than men (Eisenberger, Inagaki, Rameson, Mashal, & Irwin, 2009). Endotoxin-treated participants also display attenuated activation of neural correlates that underlie reward (e.g., ventral striatum activity, which has implications for anhedonia—a hallmark of depression; Eisenberger et al., 2010). Other researchers have used typhoid vaccination to study the effects of immune activation on mood. In this regard, compared with placebo, individuals who received a single typhoid injection report more negative mood (Wright, Strike, Brydon, & Steptoe, 2005) in some but not all studies (Paine, Ring, Bosch, Drayson, & Veldhuijzen van Zanten, 2013; Strike, Wardle, & Steptoe, 2004).

Administration of interferon (IFN) alpha, which is routinely utilized to treat chronic hepatitis C and some cancers, produces larger inflammatory effects relative to those observed in response to acute endotoxin. Though efficacious, a substantial proportion of patients (10–40%) develop clinical depression during IFN alpha treatment (Capuron & Miller, 2004; Prather, Rabinovitz, Pollock, & Lotrich, 2009). Higher basal levels of inflammation, such as IL-6, increase the likelihood of developing depression during IFN alpha therapy (Prather et al., 2009). Pretreatment with selective serotonin reuptake inhibitors (SSRIs), like paroxetine, are effective in reducing onset of major depressive disorder in these patients (Musselman et al., 2001), suggesting that PICs may interact with the serotonergic system to disturb mood. Relatedly, use of a PIC antagonist (infliximab), specific to TNF alpha, has shown some success in reducing depressive symptoms among patients with elevated levels of C-reactive protein, another index of systemic inflammation (Raison, Rutherford, Woolwine, Shuo, Schettler, et al., 2013).

Summary

The immune system is sensitive to environmental demands. Enumerative and functional measures change rapidly in response to acute stress and there is also some evidence to suggest group differences between those with and without depression. The role of particular emotions on immune function is less well characterized. While there is accruing data that suggest that aspects of the immune system, particularly inflammation, may be modulated by acute changes in emotions such as anger and anxiety, too few studies are available to make any strong conclusions. Dispositional differences in emotion, including trait-positive and -negative affect, have been linked to susceptibility to infectious illness and modulation of vaccination responses, both of which have important clinical implications. In regard to bottom-up effects, inflammation can modify affect in ways that mimic depressive symptomatology. While this early evidence is promising, mechanistic work identifying how immune parameters get in the brain to alter affective experience is needed. Furthermore, like other neuroendocrine and immune measures, additional clarity is needed to explain the variability in links between emotions and immunity.

Discussion

The belief that emotions push and pull on our bodily systems is embedded in our collective psyche. Empirical evidence to support such associations is emerging but incredible challenges lie ahead. As reflected in this review, there are some well-documented effects of stress on neuroendocrine and immune outcomes, but isolating strong influences of specific emotions have been less successful. As highlighted by OT, T, and inflammatory challenge studies, the ability to experimentally manipulate biology to examine emotional effects has led to new theory and innovative studies that continue to transform our understanding of the mind–body union. Nevertheless, methodological inconsistencies and contextual effects make it difficult to draw clear conclusions.

Some of the inconsistency in coherence between emotions and biology may be due to a reliance on self-report measures that confound affective experience with expectations, motivations, and regulatory processes. Further, individual differences in emotional intensity, duration, frequency, and sensitivity to context in response to emotional stimuli (Gross & Jazaieri, 2014) may result in varied effects on biology. Future research incorporating more objective measures of emotional behavior (e.g., facial coding) and paradigms that take advantage of unconscious processes (e.g., implicit tasks) may aid in obviating self-report concerns. Similarly, based on the extant literature, tasks designed to produce particular emotions, such as anger inductions, have been underutilized in neuroendocrine and immune research. While such paradigms often rely on self-report, correlations between emotions and biological outcomes will likely be improved by this more targeted approach.

Advances in neuroimaging may aid in illuminating the neural networks of emotion. A recent meta-analytic review argues against the idea that discrete emotions are embedded in local distinct brain areas, in favor of the idea that interacting brain regions contribute to emotional processing across all emotions (Lindquist, Wager, Kober, Bliss-Moreau, & Barrett, 2012). With this framework, the next step may be to integrate brain data with task-related changes in neuroendocrine and immune outcomes. Some of this work is currently being conducted. For instance, Muscatell and colleagues (2014) reported greater coupling of the amygdala and dorsal medial prefrontal cortex (DMPFC) in response to a social rejection task that was related to task-related increases in inflammation. Similar brain–body links are being made in the cardiovascular psychophysiology arena (e.g., Gianaros & Sheu, 2009).

As highlighted throughout this review, the data reveal that greater care is needed in the accounting of potential moderating factors. This includes invariant group differences (e.g., sex), contextual factors, and underlying biology (e.g., genetics, basal levels, interactions with other biological systems). Of course this is not always possible, but strides toward integrating such factors will aid in making sense of this rapidly growing literature. Relatedly, because the associations between emotions and biology are bidirectional and recursive, future investigators will benefit from integrating the "systems" literature that is only recently becoming more visible in affective science and stress research. Understanding the system dynamics (e.g., kinetics) through which emotional experience drives physiology—and in turn affects emotion generation, regulation, and perception—will provide a fuller picture of the mind–body connection (Aschbacher & Kemeny, 2011).

It is without question an exciting time for the convergence of the biological and affective sciences. There is a clear need to move beyond "stress" to understand how emotional processes contribute to health and disease risk. New technologies and innovative methods are providing unique windows into the embodiment of emotion. As we move forward, a focus on systematic scientific inquiry with an eye toward careful assessment of key moderators will aid in illuminating the incredible connections between emotions and the neuroendocrine and immune systems.

CHAPTER 38

Emotion Disturbances as Transdiagnostic Processes in Psychopathology

Ann M. Kring and Jasmine Mote

Emotion disturbances are ubiquitous in psychopathology. Even a cursory glance at the most recent American diagnostic system—the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5; American Psychiatric Association, 2013)—reveals that nearly all the diagnostic categories include symptoms that tap one type of emotion disturbance or another (see Table 38.1). These disturbances span positive and negative emotions, and they have traditionally been described as excesses of emotion (as in the case of specific phobias, with marked and persistent fear); deficits in emotion (as in the case of narcissistic personality disorder, with a lack of empathy); social-emotional problems (as in autism spectrum disorder, with diminished emotional reciprocity); and regulation problems (as in borderline personality disorder, with difficulties in controlling anger). The pervasiveness of emotion disturbances in psychopathology suggests the potential for commonalities across disorders. In this chapter, we consider the utility of adopting a transdiagnostic approach to understanding emotion disturbances in psychopathology across several levels, including descriptive phenomenology, etiology, and treatment. We also consider the potential of the National Institute of Mental Health's Research Domain Criteria (RDoC) initiative, which at its core is conceived as a transdiagnostic means of (re) classifying mental disorders for research purposes based on neurobiology and behavior rather than clinical symptoms within diagnostic categories (Insel et al., 2010; Sanislow et al., 2010).

We argue that there are several advantages to a transdiagnostic approach, including the RDoC, with respect to identifying causal mechanisms and meaningful treatment targets. Nevertheless, the current research evidence and clinical utility to support a fully transdiagnostic approach are incomplete. Indeed, there are similar emotional disturbances that are central to different disorders; yet the manifestation of these disturbances may nevertheless differ from disorder to disorder, thus helping to account for the different symptom constellations across disorders. For example, diminished emotion awareness is associated with both depression and social anxiety symptoms. However, for depression symptoms, this linkage is mediated by difficulties in shifting attention, whereas for social anxiety symptoms, the linkage is mediated by difficulties in accepting emotions (Vine & Aldao, 2014). With the advent of the RDoC, the field is shifting more toward a transdiagnostic approach, and we also argue that affective science research has a great deal to offer with respect to the development of domains that will be clinically useful in psychopathology research and treatment.

TABLE 38.1. Emotion-Based Symptoms in DSM-5 Disorders

Disorders	Symptoms
Neurodevelopmental disorders	
Autism spectrum disorder	Deficits in social–emotional reciprocity; lack of facial expressions and nonverbal communication
Schizophrenia and other psychotic disorders	
Schizophrenia	
Schizoaffective disorder	
Schizophreniform disorder	Diminished emotional expression
Bipolar and related disorders	
Bipolar I disorder	Elevated, expansive, or irritable mood
Bipolar II disorder	
Cyclothymic disorder	
Depressive disorders	
Disruptive mood dysregulation disorder	Irritability
Major depressive disorder	Depressed mood, anhedonia
Persistent depressive disorder	Depressed mood
Premenstrual dysphoric disorder	Affective lability, irritability or anger, depressed mood
Anxiety disorders	
Separation anxiety disorder	Excessive fear or anxiety, persistent worry
Panic disorder	Intense fear or discomfort, persistent worry
Agoraphobia	Anxiety
Specific phobias, social anxiety disorder	Marked and persistent fear, anxious anticipation
Generalized anxiety disorder	Excessive anxiety and worry, irritability, restlessness
Obsessive–compulsive and related disorders	
Obsessive–compulsive disorder	Marked anxiety or distress
Body dysmorphic disorder	Significant distress
Hoarding disorder	Significant distress with thought of discarding objects
Trichotillomania, excoriation	Significant distress; boredom or anxiety
Trauma- and stressor-related disorders	
Reactive attachment disorder	Emotionally withdrawn behavior; limited positive affect; irritability, sadness, or fearfulness
Posttraumatic stress disorder	Distress, persistent negative emotional state, persistent inability to experience positive emotions, irritable behavior and angry outbursts
Acute stress disorder	Distress, persistent inability to experience positive emotions, irritable behavior, and angry outbursts
Somatic symptom and related disorders	
Somatic symptom disorder, and illness anxiety disorder	Persistently high level of anxiety about health or symptoms
Feeding and eating disorders	
Anorexia nervosa	Fear of gaining weight
Sleep–wake disorders	
Non-rapid-eye-movement sleep arousal disorders, sleep terror type	Intense fear and signs of autonomic arousal
Insomnia disorder, circadian rhythm sleep–wake disorders, restless legs syndrome	Clinically significant distress

(continued)

TABLE 38.1. *(continued)*

Disorders	Symptoms
Disruptive, impulse-control, and conduct disorders	
Oppositional defiant disorder	Angry/irritable mood, often loses temper, often touchy or easily annoyed
Intermittent explosive disorder	Recurrent aggressive outbursts
Pyromania	Tension or affective arousal; pleasure, gratification, or relief when setting fires
Kleptomania	Tension; pleasure, gratification, or relief at time of theft
Personality disorders	
Paranoid personality disorder	Quickness to react angrily
Schizoid personality disorder	Emotional coldness, detachment, or flattened affectivity
Schizotypal personality disorder	Inappropriate or constricted affect, excessive social anxiety
Antisocial personality disorder	Lack of remorse; irritability and aggressiveness
Borderline personality disorder	Affective instability due to marked reactivity of mood, inappropriate anger, or difficulty controlling anger
Histrionic personality disorder	Rapidly shifting and shallow expressions of emotion, exaggerated expression of emotion
Narcissistic personality disorder	Lack of empathy
Avoidant personality disorder	Fear of being shamed or ridiculed
Dependent personality disorder	Fear of loss of support or approval, being unable to care for self, being left alone
Substance-related and addictive disorders	
Alcohol withdrawal	Autonomic hyperactivity, anxiety
Caffeine intoxication	Restlessness, nervousness, excitement
Caffeine withdrawal	Dysphoric mood, depressed mood, or irritability
Cannabis intoxication	Euphoria, anxiety
Cannabis withdrawal	Irritability, anger, or aggression; nervousness or anxiety; restlessness; depressed mood
Other hallucinogen intoxication	Marked anxiety or depression
Phencyclidine intoxication	Belligerence
Inhalant intoxication	Belligerence; euphoria
Opioid intoxication	Initial euphoria followed by apathy, dysphoria
Opioid withdrawal	Dysphoric mood
Sedative, hypnotic, or anxiolytic intoxication	Mood lability
Sedative, hypnotic, or anxiolytic withdrawal	Autonomic hyperactivity; anxiety
Stimulant intoxication	Euphoria or affective blunting; anxiety, tension, or anger
Stimulant withdrawal	Dysphoric mood
Tobacco withdrawal	Irritability, frustration, or anger; anxiety; restlessness; depressed mood
Gambling disorder	Excitement; feeling restless or irritable
Amphetamine, cocaine intoxication	Euphoria or affective blunting; anxiety, tension, anger
Amphetamine, cocaine withdrawal	Dysphoric mood
Neurocognitive disorders	
Major or mild frontotemporal neurocognitive disorder	Apathy; loss of sympathy or empathy

Theoretical Advances in Emotion

Contemporary emotion theories share the perspective that emotions, under most circumstances, serve a number of important intra- and interpersonal functions (e.g., Barrett, 2006a; Frijda, 1986; Lang, Bradley, & Cuthbert, 1990; Levenson, 1994). Although these functions are the same for people with and without psychopathology (Keltner & Kring, 1998; Kring & Bachorowski, 1999), the most common emotion disturbances in psychopathology can interfere with the achievement of emotion-related functions. For example, diminished facial expressions in a person with schizophrenia may evoke negative responses from others (Krause, Steimer-Krause, & Hufnagel, 1992), thus adversely impacting his or her social relationships and interactions (e.g., Hooley, Richters, Weintraub, & Neale, 1987).

Traditional views of emotion suggest that emotions have multiple components, such as expression, experience, and physiology, and some functionalist accounts of emotion suggest that coherence among components is expected and adaptive (e.g., Levenson, 1994), but the empirical data supporting coherence are mixed (Barrett, 2006a; Mauss, Levenson, McCarter, Wilhelm, & Gross, 2005). Although there are methodological reasons that might account for the mixed findings on coherence, at a more fundamental level, recent theoretical advances in emotion suggest that such variability in coherence specifically and in emotion more generally are in fact the essence of emotion (Barrett, 2006a; Barrett, Wilson-Mendenhall, & Barsalou, 2015). Indeed, in this view emotions (and their coherence) vary depending upon situational context, prior instances of emotions and contexts, different concepts and vocabularies for emotion, structure, and connectivity of core brain networks and regions that support our ability to make meaning of sensory input from the world and our bodies (Barrett, 2014; Barrett & Satpute, 2013; Barrett, Wilson-Mendenhall, & Barsalou, 2013; Barrett et al,2015; Lindquist & Barrett, 2012). Previous perspectives on emotion disturbances in psychopathology, including my own (e.g., Kring, 2001), that pointed to the lack of coherence across multiple emotions, situations, and contexts in different mental disorders (e.g., schizophrenia, psychopathy) as deficits, are perhaps better understood as descriptions of natural variation, albeit at the tail ends of the distribution.

The Transdiagnostic Approach

In a prescient and influential book, Harvey, Watkins, Mansell, and Shafran (2004) reviewed the literature on cognitive and behavioral maintaining processes in psychopathology. Rather than organizing their book by disorder, they adopted a transdiagnostic perspective, reviewing the evidence for common processes across different disorders. Their analysis reviewed the evidence of disruptions in processes—such as attention, memory, reasoning, and avoidance—that are common across more than one adult disorder and that serve to maintain or exacerbate the symptoms of these disorders. Similar conclusions have been reached regarding common cognitive maintaining processes across the eating disorders (Fairburn, Cooper, & Shafran, 2003), and treatment approaches that target transdiagnostic processes across disorders have been developed for depression, anxiety, and eating disorders (e.g., Barlow, Ellard, et al., 2011; Barlow, Farchione, et al., 2011; Fairburn et al., 2003; Norton, Hayes, & Hope, 2004).

Harvey et al. (2004) highlighted several advantages to adopting a transdiagnostic perspective in psychopathology, two of which we describe here. First, the transdiagnostic perspective may help to account for the high rates of comorbidity among the current DSM disorders. Indeed, comorbidity is the norm rather than the exception. In the National Comorbidity Survey (NCS), Kessler et al. (1994) found that nearly 80% of people with a lifetime diagnosis of one disorder had received at least one other lifetime diagnosis. In the NCS replication study, 45% of people who met criteria for one diagnosis in the prior 12 months met criteria for at least one more diagnosis (Kessler, Chiu, Demler, & Walters, 2005). The high level of comorbidity reflects problems in the current diagnostic system (e.g., poor discriminant validity). At the same time, the rampant comorbidity also suggests that there are likely common processes across disorders, including emotional processes.

Second, a transdiagnostic approach ought to be useful for developing and evaluating treatments. For example, theoretical and empirical evidence indicate that available treatments for anxiety and depression are changing common aspects of these disorders, rather than disorder-specific aspects (Barlow, 2004; Hayes, Strosahl, & Wilson, 1999; Kring, Persons, & Thomas, 2007; Persons, Roberts, & Zalecki, 2003). In addition, evidence from treatment outcome studies suggests that interventions for one disorder (e.g., depression) are also effective in treating other disorders (e.g., generalized anxiety disorder; e.g., Brown & Barlow, 1992; Tsao, Mystkowski, Zucker, & Craske, 2002). A transdiagnostic perspective may illuminate the common mechanisms or processes across disorders, which may then be more directly targeted in treatment.

Adoption of a transdiagnostic approach to emotion disturbances in psychopathology has gathered momentum in the past several years (e.g., Kring & Sloan, 2009), despite the fact that the prevailing paradigm in psychopathology research over the past several decades has been disorder centric—that is, most investigations are designed to answer questions about the symptoms, causes, and treatments of individual disorders. In the realm of emotion and psychopathology, studies are typically designed to study a particular emotion disturbance in a particular disorder. For example, the literature is packed with studies of particular emotion disturbances (e.g., facial emotion perception deficits) in putatively distinct disorders (e.g., depression, borderline personality disorder, schizophrenia), with little consideration of the possibility that the emotion disturbance may cut across these diagnostic categories. This disorder-centric research was perpetuated in part by the field's relatively greater emphasis on internal validity (e.g., tightly controlled study of one disorder) over external validity (e.g., naturalistic study of comorbid disorders), and was (and still is, to some extent) reflected in editorial practices at top-flight journals and funding priorities at granting agencies. The disorder-centric focus turned a blind eye to the fact that most disorders do not occur in "pure" form, and thus conclusions regarding specificity of emotion disturbances in *X* disorder may not be particularly informative with respect to understanding *X* disorder as it more commonly occurs in combination with *Y* disorder.

However, the winds have shifted, particularly with respect to granting agencies. Indeed, troubled by the fact that our current diagnostic systems have yet to lead to important breakthroughs in revealing causes and developing effective treatments for mental disorders, scientists at the National Institute of Mental Health (NIMH) have advocated for a new approach to classifying mental disorders, at least for research purposes, that leverages advances in neuroscience and genetics over the past two decades to identify behavioral and neurobiological mechanisms that cut across the current symptom-based diagnostic categories. The RDoC are currently conceived as a road map for research spanning molecules, genes, neural circuits, and behavior that will in turn lead to the development of a new classification system that is based, in part, on neuroscience and genetic data rather than just clinical description, which would then ideally shine a more direct light on treatment targets (Insel, 2009; Insel et al., 2010; Sanislow et al., 2010). The NIMH is taking the long view here, recognizing that although there have been many advances in neuroscience and genetics in the past decade, we are still a ways off from clearly linking disruptions in genes or brain circuits to psychopathology. Perhaps somewhat idealistic, the hope is that by "lumping" syndromes based on common genetic and neural problems rather than "splitting" syndromes based on clinical symptoms (as our current diagnostic system does), we will be better positioned to develop more effective treatments that directly target the neurobiological deficit(s) contributing to disorders.

The RDoC approach is at once transdiagnostic as it aspires to account for the full range of behavior from normal to abnormal and is untethered to current diagnostic categories. There are currently five broad RDoC domains or constructs that reflect particular functions, and these domains are expected to be relevant to many different diagnostic categories.[1] The domains are (1) negative valence systems (e.g., fear, anxiety), (2) positive valence systems (e.g., reward valuation, effort, reward prediction), (3) cognitive systems (e.g., attention, perception, cognitive control, working memory), (4) social processes (e.g., attachment, facial expression recognition, understanding others' mental states), and (5) arousal/regulatory systems (e.g., sleep, arousal). All domains can be studied across multiple units of analysis, including genes, molecules, cells, circuits, physiology, behavior, and self-report (see Table 38.2 for the RDoC domains and units of analysis). Importantly, NIMH is agnostic with respect to the primacy of any single unit of analysis—that is, all units of analysis are considered to be equally informative, and one (e.g., circuits) is not presumed to "underlie" or be more fundamental to another (e.g., self-report).

Each of the current RDoC constructs consists of several processes, and many of these processes have already been studied within diagnostic categories. For example, the positive valence systems domain includes processes such as reward valuation and expectancy/reward prediction; these have been separately studied in schizophrenia (Kring

TABLE 38.2. Research Domain Criteria Matrix

	Units of analysis						
Constructs	Genes	Molecules	Cells	Circuits	Physiology	Behavior	Self-report
Negative valence systems (*e.g. fear, anxiety*)							
Positive valence systems (*e.g., reward prediction, effort valuation*)							
Cognitive systems (*e.g., attention, cognitive control*)							
Social processes (*e.g., social communication, attachment*)							
Arousal and regulatory systems (*e.g., sleep*)							

& Barch, 2014), addiction (Berridge, Robinson, & Aldridge, 2009; Robinson & Berridge, 2008), depression (Bogdan, Nikolova, & Pizzagalli, 2013), attention-deficit/hyperactivity disorder (Nigg, 2013), and bipolar disorder (Caseras, Lawrence, Murphy, Wise, & Phillips, 2013; Gruber, 2011; Johnson, Edge, Holmes, & Carver, 2012). The next generation of research within the RDoC framework is examining these constructs and processes across diagnostic categories (e.g., Dillon et al., 2014) with the goal of identifying clearer treatment targets that will improve function in these domains, regardless of the symptom-based diagnostic category.

Although this is certainly an exciting time for transdiagnostic research, we note that it will be important to recognize that it is likely that some of our current symptom-based classifications may retain their clinical utility insofar as there may still be symptom domains that will benefit from distinct treatment approaches. For example, mindfulness meditation has become a more commonly employed intervention for mood and anxiety disorders. Yet, the mechanisms by which this treatment is effective appear to vary depending upon the symptom domain. Specifically, in one study worry mediated the relationship between mindfulness and anxiety symptoms, but reappraisal and rumination mediated the linkage between mindfulness and depression symptoms (Derosiers, Vine, Klemansky, & Nolen-Hoeksema, 2013). Similarly, Vine and Aldao (2014) found that the linkage between deficits in emotional clarity (i.e., awareness of emotional experience) and psychopathology symptoms is differentially mediated by different emotion regulation strategies (e.g., attention deployment, impulse control, acceptance) depending upon the symptom domain (i.e., anxiety, depression, alcohol, eating, personality).

Indeed, though the RDoC endeavor is transdiagnostic by design, it may not fully supplant our current diagnostic categories. For example, Shankman and colleagues (2013) examined whether physiological and self-report measures of two of the RDoC domains—threat (in negative valence systems) and reward sensitivity—cut across diagnostic boundaries of panic disorder and depression. The findings indicated specificity rather than unanimity. Specifically, people with panic disorder showed greater sensitivity to threat than people with depression, and people with depression showed less sensitivity to reward than people with panic disorder. Notably, this pattern of specificity was also observed for people who had both panic disorder and depression.

Furthermore, the current RDoC domains are not entirely distinct from one another, at least at the brain circuit unit of analysis. For example, positive valence systems and cognitive systems both involve circuits including frontal and striatal regions. Whether or not the RDoC constructs ought to be distinct across units of analyses is open for debate. However, if one of the goals of the RDoC is to reduce comorbidity, beginning with constructs that already overlap with one another will limit the achievability of this goal. However, it may not be possible to generate constructs with no overlap given what we know about brain circuits (e.g., Barrett & Satpute, 2013; Buckner & Carroll, 2007).

Nevertheless, with the advent of the RDoC, alongside the newer research on transdiagnostic processes, the promise of a transdiagnostic approach to emotion disturbances has already begun to be revealed. At the broadest level, a transdiagnostic approach can inform the ways in which different disorders are classified. In other words, examining emotion-related commonalities at the symptom level may help to account for the high levels of comorbidity in the current diagnostic system, and in turn may provide guidance on refining current clinical diagnostic categories. Second, a transdiagnostic approach can be informative with respect to identifying common emotion-related causal and/or maintaining processes across disorders. Third, a transdiagnostic approach can be useful for treatment development, with an emphasis on changing emotion processes. In the remaining sections of the chapter, we consider the relative merits of adopting a transdiagnostic approach to emotion disturbances in psychopathology across these three levels: descriptive phenomenology, etiology, and treatment.

Descriptive Psychopathology and Diagnosis

In an effort to spur the field toward greater attention to emotion and psychopathology, Berenbaum, Raghavan, Le, Vernon, and Gomez (2003) proposed a separate taxonomy of emotional disturbances as a companion to the current diagnostic system. Although this was not adopted in DSM-5, their articulation of three broad areas of emotion disturbances—"valence," "intensity/regulation," and "disconnections"—maps onto the newly conceived RDoC domains. For example, emotional valence disturbances can involve pleasant or unpleasant emotions (positive and negative valence systems in the RDoC), as well as too much or too little of these emotions. Emotional intensity/regulation disturbances are defined as over- or underregulation of both pleasant and unpleasant emotions. Emotion regulation difficulties can span nearly all of the RDoC domains. Disconnection disturbances reflect disconnections between the expressive component of emotion and other components, as in schizophrenia, where people experience strong feelings yet do not express them outwardly (see Kring & Elis, 2013, for a review). Disconnection disturbances also reflect a lack of conscious awareness of one's own emotional responses, and in the RDoC approach, this could reflect valence and cognitive systems difficulties.

Reconfiguring the current diagnostic categories based only on emotion-related disturbances would leave out much clinically relevant information. Indeed, mental disorders do not solely consist of emotion-related symptoms. Different symptoms reflect other, interrelated processes, including cognitive (e.g., inattention, thought disorder), behavioral (e.g., avoidance), and interpersonal (e.g., no close friends or confidants) processes. However, a transdiagnostic approach would not necessarily have to supplant the current diagnostic categories for it to inform our understanding of the symptoms of various disorders. Understanding the emotion-related symptoms that cut across disorders may help to refine the current diagnostic categories without necessarily reconfiguring them. At the level of descriptive psychopathology, a hybrid approach that combines transdiagnostic and disorder-specific approaches may be fruitful, at least in the short term until additional research more clearly illuminates the promise of a solely transdiagnostic approach.

This type of hybrid approach is consistent with some current neuroscience models of emotion that posit that emotion is not a "special case" with respect to its neural underpinnings. Instead, emotions are instantiated by the same neural networks that support perception, attention, cognition, and all other aspects of mental life (Barrett & Satpute, 2013; Lindquist & Barrett, 2012; Lindquist, Wager, Kober, Bliss-Moreau, & Barrett, 2012). Emotions may be supported by the same neural networks (e.g., salience, default mode, executive control networks) that support other mental processes, but this does not obviate the utility of considering emotions in their own right (Barrett, 2012). In this view, both mental disorders and emotions are conceptualized in a "top-down" fashion such that the neural correlates of these are more domain/process general and variations in manifestations of disorders or emotions are understood as reflecting differential strength or engagement of neural networks alongside genetic, environmental, prior learning, and cultural influences. Although this approach appears to be similar to the RDoC approach, as we noted earlier, the RDoC have not yet grappled with the notion of how the units of analysis, at least at the level of brain circuits, may cut across the different constructs.

Causal and Maintaining Processes

There have been several reviews of emotion disturbances in psychopathology (e.g., Kring & Sloan, 2009; Rottenberg & Johnson, 2007). Instead of duplicating these efforts, we focus here on candidate transdiagnostic emotion disturbances that may reflect causal or maintaining processes. There are many points along the temporal course of disorders at which a transdiagnostic perspective may be informative (Barnett & Gotlib, 1988; Harvey et al., 2004). Specifically, transdiagnostic emotion disturbances may be antecedents (i.e., predisposing or vulnerability factors), concomitants, or consequences (i.e., perpetuating or maintaining factors). For an emotion disturbance to be considered an antecedent transdiagnostic process, it must be shown to precede the onset of a disorder. Disturbances that are observed during active episodes of disorders may be more accurately construed as concomitant transdiagnostic processes, and disturbances that persist after active episodes have abated might be considered consequences or maintaining processes.

Much of the evidence to date regarding specific emotion disturbances in particular disorders is most readily interpreted as evidence for maintaining processes. There has been less theoretical, conceptual, and empirical work on possible transdiagnostic causal or maintaining emotion processes than in the domains of phenomenology and treatment. Indeed, the disorder-centric focus of research has been particularly dominant in studies of possible etiological emotion disturbances, though this is currently undergoing a significant shift with the RDoC. Although space constraints preclude us from considering many possible transdiagnostic emotion disturbances, we briefly consider four promising candidates: core affect, emotion awareness, emotion regulation, and emotion disconnections. These four constructs were developed in basic affective science research and have been meaningfully translated to the study of psychopathology. These constructs were also developed prior to the RDoC initiative, and some are embedded within the RDoC. For example, emotion awareness is embedded within the RDoC social processes construct (perception and understanding of the self). In our view, these four areas will retain promise and utility in psychopathology research even as the RDoC continues to develop and evolve.

Core Affect

Although the terms "affect" and "emotion" are often used interchangeably in the psychopathology literature, there are important conceptual and empirical distinctions between the terms. Generally speaking, affect is most often used in reference to feeling states, whereas emotion is used to reference instances that may include behavior (e.g., facial expression or shouting), feeling states and language (e.g., anger), and changes in the body (e.g., heightened skin conductance). Barrett and colleagues have distinguished "core affect" from the more generic term "affect." Core affect reflects neurophysiological states that are an omnipresent indicator of a person's relationship to his or her environment at any given time (Barrett, 2006a; Barrett, Mesquita, Ochsner, & Gross, 2007; Russell, 2003). Core affect is experienced as feelings of pleasure or displeasure, and to a lesser extent arousal or activation (Barrett, 2006a; Barrett et al., 2007). Although core affect is observed across cultures, there are nevertheless important individual and cultural differences (Barrett, 2006b; Mesquita & Karasawa, 2002) that may be important for understanding disturbances in core affect in psychopathology.

Findings from several studies that have measured reports of feeling states have indicated that the experience of excessive unpleasant affect (although it is not necessarily conceived of as core affect) is common across many different disorders, including depression (Bylsma, Morris, & Rottenberg, 2008), the anxiety disorders (Watson, 2005), eating disorders (e.g., Stice, 2001), schizophrenia (Kring & Moran, 2008), substance-related disorders (e.g., Kassel, Stroud, & Paronis, 2003), and a number of personality disorders (e.g., Berenbaum et al., 2006; Huperich, 2005; Putnam & Silk, 2005). Integrating findings across behavioral and brain imaging studies, Barrett et al. (2007) have suggested that disturbances in core affect may reflect an important emotion-related transdiagnostic process in psychopathology. Indeed, the RDoC domains of negative valence states and positive valence states would seem to encompass core affect, and the conceptual, theoretical, and empirical advances regarding core affect among healthy individuals are ripe for translation into the realm of psychopathology.

Emotion Awareness: Clarity and Differentiation

Barrett and Gross (2001) have argued that knowledge and awareness of one's emotions are necessary prerequisites to effective emotion regulation. However, simply having knowledge about emotion is not sufficient; rather, greater accessibility of that emotion knowledge is believed to promote effective emotion regulation (e.g., Sauer & Baer, 2009).

For example, people who describe their feelings in a more differentiated manner (e.g., "sad," "confused," "elated") rather than more globally (e.g., "good," "bad") have greater accessibility to and awareness of emotion knowledge, and use this knowledge when trying to regulate their feelings (Barrett, Gross, Christensen, & Benvenuto, 2001; Sauer & Baer, 2009).

Recent evidence suggests that emotion awareness can be meaningfully distinguished into two constructs: emotion clarity or the awareness of one's feelings, and emotion differentiation (granularity), or the ability to distinguish among different feeling states (Boden, Thompson, Dizén, Berenbaum, & Baker, 2013). Emotion differentiation has yet to be fully studied across diagnostic categories, but there is some evidence suggesting that people with schizophrenia do not differ from people without schizophrenia in their emotion knowledge, though people with schizophrenia differentiate less among emotional states, and thus may be less effective at emotion regulation (Kring, Barrett, & Gard, 2003). Clinical conceptualizations of borderline personality disorder include the notion that people with this disorder have difficulty distinguishing among different emotional states (e.g., Westen, 1991), but the empirical confirmation of this notion is needed.

By contrast, emotion clarity has been assessed across different diagnostic categories. Emotion clarity is partially captured by the concept of "alexithymia," as assessed by the Toronto Alexithymia Scale (Bagby, Parker, & Taylor, 1994) subscales of "difficulty in identifying feelings" and "difficulty in describing feelings." This measure has been widely used in correlational studies of anxiety disorders (e.g., Frewin, Pain, Dozois, & Lanius, 2006; Parker, Taylor, Bagby, & Acklin, 1993; Turk, Heimberg, Luterek, Mennin, & Fresco, 2005), eating disorders (e.g., Cochrane, Brewerton, Wilson, & Hodges, 1993), personality disorders (e.g., Berenbaum, 1996), substance use disorders (e.g., Speranza et al., 2004), and insomnia (e.g., Lundh & Broman, 2006). However, the linkages between alexithymia and the various disorders are not always replicated across studies, and the extent to which this captures a transdiagnostic construct has not been explicitly assessed.

Emotion clarity has also been measured using the Differential Emotion Regulation Scale (DERS; Gratz & Roemer, 2004). Correlational studies using the DERS have found emotion clarity to be correlated with anxiety disorders (e.g., Mennin, Holaway, Fresco, Moore, & Heimberg, 2007), depression (e.g., Flynn & Rudolph, 2010), borderline personality disorder (e.g., Gratz, Rosenthal, Tull, Lejuez, & Gunderson, 2006), and eating disorder symptoms (e.g., Gilboa-Schechtman, Avnon, Zubery, & Jeczmien, 2006). Furthermore, emotion clarity is independently related to symptoms including depression, anxiety, borderline personality, alcohol use, and disordered eating even when controlling for the widespread overlap in these symptoms (Vine & Aldao, 2014), suggesting that emotion clarity is indeed transdiagnostic.

Emotion Regulation

Emotion regulation problems have been at the forefront of discussions about emotion disturbances in psychopathology for more than a decade (e.g., Aldao, Nolen-Hoeksema, & Schweizer, 2010; Carl, Soskin, Kerns, & Barlow, 2013; Garland et al., 2010; Gross & Muñoz, 1995; Kring & Sloan, 2009; Linehan, 1993). Broadly, emotion regulation refers to processes that serve to modify what we feel, when we feel it, and how we use that feeling to guide behavior (e.g., Gross, 1998). Many current diagnostic criteria explicitly refer to emotion regulation difficulties (Fairholme et al., 2013). For example, the criteria "difficulty controlling anger" in borderline personality disorder, "efforts to avoid distressing feelings" in posttraumatic stress disorder (PTSD), and "rapidly shifting expressions of emotion" in histrionic personality disorder all point to difficulties in regulating emotions.

Despite the perceived importance of emotion regulation deficits in psychopathology, it is difficult to integrate the literatures across disorders, because of the myriad approaches to constraining the concept of emotion regulation across studies. For example, some researchers do not distinguish emotional responding from regulation, following from theory that suggests the processes are indistinguishable (e.g., Campos, Frankel, & Camras, 2004; Davidson, 2000). Other studies examine emotion regulation within the person, whereas still other studies examine emotion regulation from the outside (e.g., having others provide soothing to down-regulate negative emotion). Disentangling emotion from emotion regulation remains a critical challenge for the field (Rottenberg & Gross, 2003). To date, the vast majority of emotion regulation and psychopathology studies have been conducted within rather than across disorders (Aldao, 2013), but momentum toward greater transdiagnostic work is growing (Kring & Sloan, 2009). Importantly, recent theoretical and clinical conceptualizations have questioned whether emotion regulation is always adaptive in psychopathology, and instead distinguish change-based strategies such as emotion regulation from acceptance-based strategies (e.g., Sauer & Baer, 2009).

A close cousin to emotion regulation is the time course, or chronometry, of emotional responses (e.g., Davidson, 1998). Emotional responses are not wholly temporally constrained by the presence of an eliciting stimulus, but instead vary in their peak and duration in ways that may hold important information about the nature of emotion disturbances in psychopathology (Aldao, 2013; Kring & Elis, 2013). Two elements of the time course of an emotional response that have been studied in healthy populations are (1) the time from the onset to the peak intensity of the response; and (2) the recovery time, or the time it takes for the emotional response to resolve. This latter process, recovery time, is a probable transdiagnostic emotion disturbance that has been studied in individual disorders, such as schizophrenia (Kring, Germans Gard, & Gard, 2011; Ursu et al., 2011) and depression (e.g., Moran, Mehta, & Kring, 2012; Rottenberg, Kasch, Gross, & Gotlib, 2002), but remains a topic for future transdiagnostic research. For example, the prolonged experience of negative affect (NA) associated with depression, generalized anxiety disorder, and eating disorders, or the prolonged experience of positive affect (PA) associated with bipolar disorder, may reflect a difficulty in the recovery time of emotional responding (e.g., Tomarken & Keener, 1998).

Emotion Disconnections

Disconnection among emotion response components has not yet been studied across diagnostic categories. A good deal of evidence indicates that people with schizophrenia report experiencing strong emotions in response to a variety of emotionally evocative stimuli (films, pictures, social interactions), yet they do not often display these feelings outwardly (see Kring & Elis, 2013; Kring & Moran, 2008, for reviews). In other words, their outward displays of emotion are not often accurate reflections of their experienced emotion, indicating a disconnection between emotion response components. There is some evidence to suggest that this disconnection may be present prior to the onset of the illness. Walker, Grimes, Davis, and Smith (1993) analyzed home movies of adults with schizophrenia that were made before the adults developed schizophrenia. They found that girls displayed fewer joy expressions, and that both boys and girls displayed more negative facial expressions, compared with their healthy siblings.

Studies using the emotion-modulated startle paradigm (Lang et al., 1990) have observed a different disconnection among people with psychopathy. Compared with healthy controls, these people showed comparable startle inhibition during exposure to pleasant stimuli, but they did not show startle potentiation during exposure to aversive stimuli (e.g., Patrick, 1994; Patrick, Bradley, & Lang, 1993). However, the people with psychopathy did not differ from controls in their reported emotional experience to the aversive stimuli. Additional evidence for this disconnection has been found in imagery studies (Patrick, Cuthbert, & Lang, 1994) and incidental memory paradigms (Christianson et al., 1996). In both of these examples, the reports of emotional experience of people with psychopathy were indistinguishable from healthy controls, but their behavioral or psychophysiological responses differed. It may well be that such emotion disturbances are better construed as reflecting a relatively intact core affect system with corresponding behavioral system disturbances.

More broadly, situating these and other observations of emotion disconnections within recent conceptualizations of emotion that point to variability in connection (coherence) as the norm, not the exception (Barrett, 2006a; Barrett et al., 2015), remains to be done. In other words, understanding when emotion disconnections are instances of typical variability versus an indicator of an emotion disturbance remains an important direction for future research.

Treatment Development and Evaluation

Although medication is a common form of treatment for many different disorders, very few investigations have explicitly adopted a transdiagnostic approach to evaluating pharmacological treatment. Nevertheless, the evidence that particular medications may be effective for multiple disorders is hiding in plain sight. For example, studies have found that antidepressant medications are effective at reducing the symptoms of several other disorders, including specific and social phobias (e.g., Stein et al., 1998; Van Ameringen et al., 2001), panic disorder (White & Barlow, 2002), generalized anxiety disorder (Lydiard & Monnier, 2004), obsessive–compulsive disorder (OCD; Steketee & Barlow, 2002), PTSD (Brady et al., 2000), some of the personality disorders (e.g., Rinne, van den Brink, Wouters, & van Dyck, 2002), and eating disorders (e.g., Walsh et al., 2000). Following from such evidence, medications that were originally approved by the U.S. Food and Drug Administration (FDA) for the treatment of depression have since received approval (or an "indication," in FDA terminology) for the treatment of other disorders. For example, paroxetine (Paxil) was later approved for the treatment of OCD, panic disorder, generalized anxiety disorder, and social anxiety; fluoxetine (Prozac) was later approved for the treatment of OCD and bulimia nervosa; sertraline (Zoloft) was later approved for the treatment of OCD, panic disorder, social anxiety, and PTSD.

Although it may be the case that antidepressant medications are rather blunt instruments for targeting the general distress that is common across disorders, little research has directly examined the emotion-related mechanisms by which the medications might exert their transdiagnostic effects. However, we know that the selective serotonin reuptake inhibitors work on the neurotransmitter serotonin (as well as others, including dopamine; e.g., Svenningsson et al., 2002), functionally leaving more serotonin in the synapse, and that disruptions in serotonin have been implicated in depression (e.g., Thase, Jindal, & Howland, 2002), anxiety disorders (e.g., Stein et al., 1998), and eating disorders (e.g., Carrasco, Dyaz-Marsa, Hollander, Cesar, & Saiz-Ruiz, 2000; Kaye et al., 1998). We also know a good deal about how serotonin works throughout the brain, and perhaps not surprisingly, this neurotransmitter is heavily concentrated in areas of the brain linked with emotion (e.g., Barrett et al., 2007; Wrase, Reimold, Puls, Kienast, & Heinz, 2006). Finally, research has indicated that serotonin levels are associated with positive affect among healthy people (e.g., Duffy et al., 2006; Zald & Depue, 2001). The building blocks are thus available for constructing a transdiagnostic approach to medication treatment that explicitly links pharmacology, neuroscience, and emotion. Much of this integrative work remains to be done, but it is certainly a fruitful avenue for future research.

Historically, different forms of psychotherapy were conceived of as treatments that could be applied across disorders or clinical problems (e.g., psychoanalysis). Furthermore, despite the distinctly different theoretical traditions underpinning various types of psychotherapy (e.g., psychodynamic, interpersonal, gestalt, client centered, behavioral), each of these traditions has included some consideration of emotion (see Greenberg, 2002b; Greenberg & Safran, 1987, for reviews). One form of psychotherapy that is relevant to the focus of this chapter is emotion-focused therapy (EFT), which was developed by Leslie Greenberg (e.g., 2002a). Boiled down to its essence, EFT is based on the idea that some emotions are adaptive, whereas others are maladaptive. Maladaptive emotions are based on an underlying loneliness, abandonment, worthlessness, anger, or inadequacy, and they can interfere with a person's relationships and overall functioning. The primary therapeutic goal is for a client to become more aware of these maladaptive emotions, to understand the source of these feelings, and to learn emotion regulation skills. According to Greenberg (2002a), EFT is better suited to particular types of clinical conditions (including depression and generalized anxiety disorder) and less well suited to others (such as panic disorder). Unfortunately, data regarding the efficacy of this treatment are limited. No randomized controlled clinical trials have been conducted, although smaller studies examining the process of change within EFT indicate that the treatment is effective for some clinical problems (Greenberg, 2002a). The theoretical foundations of this treatment continue to be enhanced by research in emotion, emotion and psychopathology, and affective neuroscience (e.g., Greenberg, 2002b, 2004); a worthwhile endeavor for future research would be to examine whether this treatment is effective in targeting transdiagnostic emotion-related disturbances.

The shift to more disorder-specific psychotherapeutic approaches perhaps began in the late 1950s, with the pioneering work of Joseph Wolpe (1958), who developed systematic desensitization for the treatment of specific phobias. Additional disorder-specific psychotherapies were developed in the 1960s, as cognitive-behavioral therapies became more prominent. A number of other influences in the field since the 1970s have converged to solidify a disorder-specific approach to treatment development. These have included the greater demand to show that psychotherapy is effective; the development of the DSM-III, which was heavily influenced by the medical model (Wilson, 1993); the sophistication of research methods to evaluate treatment outcomes for specific disorders (e.g., Barlow, 2004; Westen, Novotny, & Thompson-Brenner, 2004); the emphasis on evidence-based practice (e.g., Barlow, 1996; Chambless & Hollon, 1998;

Kendall, 1998); the efforts to position psychology as a health care profession and thus in the larger health care context (e.g., Johnson, 2001); and the observation that psychological treatments tailored to specific disorders are as effective as, or more effective than, other types of interventions. Indeed, as Barlow (2004) has noted, "Few would argue that diversity in procedures to address specific aspects of pathology is not necessary" (p. 873).

The disorder-specific approach to treatment development, particularly in the context of empirically supported treatments (Chambless & Hollon, 1998), spawned a large number of individual treatment protocols and manuals. This proliferation of different treatment protocols has undoubtedly benefited countless people who have received these treatments, as they have been shown to be effective (Nathan & Gorman, 2002). However, the sheer magnitude of treatment protocols has become a bit overwhelming to treatment professionals, with respect to both learning the varied protocols and disseminating them to a broader range of treatment providers (e.g., Barlow, Allen, & Choate, 2004; Clark, 2009; Persons, 2005). Furthermore, the reality in clinical practice is that providers often select bits and pieces from a number of different protocols, in order to provide the best possible treatment for a given person (Persons, 2005).

Partly in reaction to this overwhelming number of treatment protocols, there has recently been a call for more unified treatments across treatment types (McEvoy, Nathan, & Norton, 2009; Mennin, Ellard, Fresco, & Gross, 2013) and, germane to this chapter, disorders. Most transdiagnostic treatments have been, to date, developed for anxiety disorders and depression, and some of these have been informed by research on emotion-related disturbances that are common across these disorders. A recent review of seven uncontrolled trials and three randomized controlled trials (RCTs) of unified treatments for anxiety and depression found that these treatments were effective in reducing both anxiety and mood symptoms (McEvoy et al., 2009), though given that the majority of these were uncontrolled trials, it remains to be determined how these treatments compare with other empirically supported treatments.

To illustrate a transdiagnostic treatment that was developed from affective science research on emotion regulation, we describe in a bit of detail the intervention of Barlow and colleagues who developed a unified protocol for anxiety and mood disorders (Barlow, Ellard, et al., 2011; Barlow, Farchione, et al., 2011). The focus of this intervention is on putative emotion-related mechanisms, particularly emotion regulation, that are common across mood and anxiety disorders. The treatment has five core skills modules derived from affective science that teach: (1) emotion awareness, (2) cognitive flexibility, (3) identification and prevention of emotion avoidance and maladaptive regulation strategies, (4) awareness of emotion-related interoceptive sensations, and (5) interceptive-based exposure. The treatment also includes education about emotions and their adaptive nature as well as relapse prevention skills. Two small open (i.e., uncontrolled; Ellard, Fairholme, Boisseau, Farchione, & Barlow, 2010) trials and one small RCT comparing the unified protocol with a wait-list control (Farchione et al., 2012) suggest that it is effective in reducing anxiety and depression symptoms as well as negative affect (and in the RCT, increasing positive affect) for people with different anxiety disorder diagnoses (social anxiety, generalized anxiety), OCD, PTSD, and depression. The unified protocol has been modified for adolescents (Ehrenreich, Goldstein, Wright, & Barlow, 2009) and children (Ehrenreich-May & Bliek, 2012) but these have not yet been tested. Though promising, additional study is needed with larger, more clinically diverse samples to determine whether this intervention is effective transdiagnostically. In addition, studies are only beginning to examine mechanisms of change for the unified protocol (Sauer-Zavala et al., 2012). Indeed, there has been a call for more treatments to target mechanisms rather than disorders per se. For example, Rosen and Davison (2003) have argued that we should be defining empirically supported principles of change rather than empirically supported treatments.

Other treatments have been designed to target emotional disturbances, such as Mennin and colleagues' emotion regulation treatment for generalized anxiety disorder (e.g., Mennin, 2004). Though this intervention was designed around the emotion regulation problems associated with generalized anxiety disorder, it seems probable that it would be useful for a number of disorders with similar difficulties in emotion regulation, such as an inability to down-regulate intense negative emotions and a lack of awareness of negative emotions (Mennin & Fresco, 2009). Furthermore, treatment development researchers have recently turned their attention toward developing interventions that focus on positive emotion (Carl et al., 2013; Garland et al., 2010), and these may also be effective across diagnostic categories, though this remains a topic for future research.

Summary and Conclusions

Advances in affective science have greatly contributed to our understanding of emotion disturbances in psychopathology. Indeed, methods, theories, and measures developed in these domains have allowed us to achieve greater clarity regarding the reach of emotion disturbances across many different disorders. With this clarity has come the realization that many of the observed emotion disturbances are common across disorders. Progress in understanding the reach of transdiagnostic emotion disturbances has begun to be achieved at the levels of descriptive phenomenology, etiology, and treatment. We have argued for the promise of four transdiagnostic emotion disturbances—core affect, emotion awareness, emotion regulation, and emotion disconnections—that are grounded in affective science research and meaningfully translated to the study of psychopathology. We also highlighted the potential of the NIMH RDoC initiative, which is by definition a transdiagnostic approach to classifying psychopathology and where emotion disturbances figure prominently. Future research will likely reveal important transdiagnostic casual and maintaining processes as well as meaningful treatment targets. Even with the promise of and current momentum toward transdiagnostic approaches to emotion disturbances in psychopathology, we also suggested that the manifestation of transdiagnostic disturbances may differ from disorder to disorder in consequential ways, thus supporting the clinical utility of (some) current diagnostic categories.

Note

1. The five current RDoC domains are not considered to be the only domains by the NIMH. Instead, they are viewed by the NIMH as a sample of possibly many such constructs or domains that will be useful for propelling research on psychopathology closer to effective treatment development.

CHAPTER 39

The Clinical Application of Emotion in Psychotherapy

Leslie S. Greenberg

This chapter addresses the emerging focus on emotion in psychotherapy. Given that emotion is now seen as information (i.e., as signaling the significance of a situation to a person's well-being), and that affect regulation is seen as a key human motivation, it has become clear that emotion needs to be focused on, validated, and worked with directly in therapy to promote emotional change (Greenberg, 2002; Samoilov & Goldfried, 2000; Fosha, 2000). The idea that accessing and exploring painful emotions, within the context of a secure therapeutic relationship, makes one feel better is currently widely held by several schools of psychotherapy but during the past it had been difficult to prove.

In the prior decades, influenced by the cognitive revolution in psychology, emotion in therapy was seen by cognitive therapy as postcognitive and often a function of error (Beck, 1976; Ellis, 1994) and by the behavioral therapies as needing to be modified or regulated to prevent being overwhelmed (Linehan, 1993). This often led to interventions involving reasoning to correct error and psychoeducation to teach ways of managing emotion. However, exposure to fear—which involved activating the emotion—was also used and was viewed as resulting in decreasing intensity or eliminating the emotion by desensitization, habituation, or extinction rather than by actually changing the emotion. Psychoanalytic theories initially viewed emotion as discharge and saw catharsis of blocked emotion as curative (Freud, 1915/1957). Psychoanalysts later saw reflection on and understanding the source of emotions and more recently mentalization of emotion (the ability to reflect on that one has emotion) as curative (Maroda, 2009; Bateman & Fonagy, 2004). However, another more interpersonal view sees emotions as needing to be evoked with the therapist to provide a corrective emotional experience that changes the emotion (Mitchell, 1988; Castonguay & Hill, 2012). Humanistic views saw emotions as basically healthy expressions of the self that needed to be brought to awareness, experienced, and reowned (Rogers, 1951; Perls, 1969). Very few tests of the different proposed mechanisms were done except for depth of experiencing, which was shown to relate to outcome in many studies (Elliott, Greenberg, & Lietaer, 2004). Thus, although cognitive-behavior therapy (CBT) has shown treatment outcome effects, no convincing evidence has shown that cognitive change is the actual mechanism of change. However, over the last decades, newer therapeutic approaches that treat emotion as a primary target of intervention and work on changing emotion within the context of an empathic relationship have been developed and tested.

This chapter begins with a brief review of the results of evidence-based studies of the efficacy of emotion-focused treatment of mood disorders, personality disorders, and trauma. Principles of emotion assessment and emotional change processes are discussed, and evidence on the change processes are reviewed. These principles provide a map for differential intervention with emotion by showing that different classes of emotions in therapy benefit from different types of interventions—ranging from awareness of adaptive emotions through regulation of dysregulated emotions to transformation of maladaptive emotions. The chapter concludes with a discussion of different methods of activating new emotional responses to change habitual problematic emotional responses.

Evidence-Based Treatment

A number of treatment approaches that focus on painful emotions have been demonstrated to be effective in randomized clinical trials (Elliott et al., 2004; Greenberg & Pascual-Leone, 2006; Whelton, 2004). Emotion-focused therapy (EFT) for depression (Greenberg & Watson, 2006) has been found to be highly effective in treating depression in three separate studies (Greenberg & Watson, 1998; Goldman, Greenberg, & Angus, 2006; Watson, Gordon, Stermac, Kalogerakos, & Steckley, 2003). In these studies, EFT was found to be as effective as, or more effective on some indices, than either a purely relational empathic treatment or CBT. Both the treatments with which EFT was compared were themselves also found to be highly effective in reducing depression, but EFT was found to be more effective in both reducing interpersonal problems and promoting change in symptoms than the purely relational treatment and more effective in preventing relapse (Greenberg & Watson, 1998; Goldman et al., 2006; Ellison, Greenberg, Goldman, & Angus, 2009). EFT was also found to be equally effective to CBT in symptom reduction and more effective in reducing interpersonal problems (Watson et al., 2003), which could have implications for relapse given the strong role of interpersonal factors in depression.

The objective of EFT is to access and restructure the habitual maladaptive emotional states that are seen as the source of dysfunctions such as the depression. This involves accessing feelings of shame-based worthlessness, anxious dependence, powerlessness, abandonment, and invalidation, and transforming these through accessing adaptive emotions (such as healthy grief and empowering anger), as well as reflecting on emotional experience to create new meaning and develop new narratives. This process of emotional change is aided by the use of specific therapeutic techniques that help stimulate both the arousal and processing of emotion. Various experiential interventions are used to engage patients in emotion processing in session. For example, in two-chair dialogue, two parts of the self—one the internal self-critical voice and the other the responding, experiencing self—are put into contact with each other in response to in-session statements of self-critical conflicts. In empty-chair dialogue, in response to in-session statements of unresolved feelings toward a significant other, the self expresses previously unexpressed feeling to the imagined other, and focuses attention on bodily felt meaning in response to an unclear felt sense

Short-term dynamic therapy, which works on overcoming defenses and treats affect phobia by exposure to dreaded emotion, has been found to be effective in treating personality disorders in two studies (Winston et al., 1994; Svartberg, Stiles, & Seltzer, 2004). EFT for adult survivors of childhood abuse, which uses empathy plus empty-chair work and involves the arousal and processing of painful emotions, has been found effective in treating abuse (Paivio & Nieuwenhuis, 2001). Emotionally focused couple therapy (Greenberg & Johnson, 1988; Johnson, 1996), which involves partners' revealing their underlying attachment- and identity-related vulnerable feelings to each other, has been found to be effective in treating couples' distress (Johnson, Hunsley, Greenberg, & Schindler, 1999). In addition, versions of CBT based on exposure to imaginal stimuli have been shown to be effective for posttraumatic stress disorder (PTSD) and other anxiety disorders (Borkovec, Alcaine, & Behar, 2004; Shapiro, 1999). Finally, therapy based on an avoidance theory in which worry is understood as a cognitive response that orients individuals to a threat, while insulating them from the immediacy of their emotional experience, has recently gained support (Borkovec et al., 2004).

A recent study examining the therapists' stance in interpersonal therapy (IPT) and CBT for depression showed the importance of focusing on emotion, regardless of orientation. This study (Coombs, Coleman, & Jones, 2002) found that collaborative emotional exploration (which occurred significantly more frequently in IPT) was found to relate positively to outcome in both forms of therapy, whereas educative/directive process (which was more frequent in CBT) had no relationship to outcome. Helping people overcome their avoidance of emotions, focusing collaboratively on emotions, and exploring them in therapy thus appears to be important in therapeutic change, whichever therapeutic orientation is employed. What is needed now is a more differentiated understanding of how to work with emotion. A differential approach to assessment and intervention has recently emerged.

Differential Emotion Assessment and Intervention

In assessing and working with emotion in therapy, it is helpful to make certain distinctions between different types of emotional experiences and expressions, which require different types of in-session interventions. This involves differentiating between "primary" emotions and "secondary" or "reactive" emotions, and between "adaptive" and "maladaptive" emotional experiences (Greenberg, 2002). Primary emotions are people's first, gut-level emotional responses to situations. These responses need to be accessed and assessed for whether they provide adaptive information and the capacity to organize action, or whether they are maladaptive. Maladaptive emotions are learned responses that are not appropriate to current situations and thus are no longer adaptive; these emotions need to be regulated and transformed. Secondary emotions are those responses that are secondary to other, more primary internal processes and may be defenses against these, such as feeling ashamed of one's sadness or hopeless when angry. Secondary maladaptive emotions need to be explored to access their more primary cognitive or emotional generators. These distinctions between different types of emotions thus provide clinicians with a map for differential intervention with emotions.

The Dualities of Emotion

Clinicians have had to recognize that to work with emotion therapeutically, they need to treat emotion processing not as singular phenomenon but to adopt, at least, dual views of emotional processing. The first duality is that emotions serve both *informational* and *hedonic* functions. Emotions are both carriers of knowledge and givers of pleasure/pain. A second duality lies in the difference between automatically activated amygdala-based, "low"-road emotions and "high"-road emotions that involve more deliberate prefrontal cortex processing (Le Doux, 1996).

Feelings in their informational aspect act as a form of knowing that provide us with immediate, intimate, personally meaningful information about ourselves and others in an unmediated and personally specific manner. They need *articulation*, as this sharpens and clarifies what is felt and promotes self-understanding. There comes a point, however, when feelings change their function. Given the powerful dimension of feelings as pleasure/pain, they can lose their meaning giving function and become overwhelming or destructive experiences. These are more like the passions the Stoics wanted to rid us of, although they seemed more concerned with freeing us from the appetitive functions of the passions than the pain itself. The hedonic aspects of feelings carry suffering and pain at intensities that cannot be tolerated (or feelings of pleasure beyond description), can produce intolerable experiences, be a danger to psychological existence, and can become a source of threat and trauma. In these cases, they need to be regulated to preserve a sense of self-coherence.

The second duality important in working with emotion stems from the different ways in which emotion is produced. Low-road emotional processing is automatic and holistic, and occurs out of our control like the passions of which we are the passive recipients. When functioning well, however, these emotions are a source of adaptive intelligence. They can be brought to awareness and help us orient to the environment. When dysfunctional, these emotions need to be accessed to change them. Low-road emotions, when dysfunctional, need to be worked by using principles of *emotional change* designed to deal with the automatic, prereflective, bodily felt nature of emotion (Greenberg, 2012).

On the other hand, emotion produced by high-road processing is far more cognitively derived and culturally influenced. Reason is involved in both its generation and change, and dysfunction in this system is based on cognitive error; change involves *cognitive change* principles designed to deal with errors in reasoning or learning. Those problems based on deliberate processes such as faulty thinking, or skill deficits, are more likely to benefit from efficient psychoeducational and rational methods. These forms of intervention are aimed at changing things under more deliberate control such as clients' thinking and learned behavior, and promoting the practice of new coping skills.

However, where reason cannot penetrate, cognitive and psychoeducative methods that appeal to reason and deliberate processing will not work, and emotional change processes will be needed. Change in the domain of amygdala-based emotion (Whalen & Phelps, 2009) involves both awareness of emotion and its transformation. Awareness is facilitated by approaching and attending to the emotion, tolerating it, symbolizing it—most often with words—and becoming aware of the "cues" that trigger it. Transformation occurs by activating problematic maladaptive emotions and both exposing them to new opposing emotions, and constructing new narrative meanings to create coherence and consolidate the felt change into a new account.

With the advent of the view of emotion as an adaptive resource and a meaning system—rather than as something that needs to be got rid of cathartically, modified, or corrected by reason—the understanding of emotion's role in human relationships and psychotherapy has changed. This "new look" has begun to set a new agenda for psychological research: to determine under what conditions emotions play a determining role in the human experience and how this occurs. The question especially relevant to psychotherapy is how can therapists best facilitate change in emotions themselves, treating emotion as independent variables that exist as such, rather than being secondary to cognition.

Principles of Working with Emotion

Outcome and process research findings point toward emotional processing as centrally important to good therapy, but what good processing is actually remains to be elucidated. Emotional insight, catharsis, awareness, and exposure have all been put forward as explanations of the role of emotion in change, but there is still not a comprehensive, empirically based understanding of how emotion and its processing lead to change. The following five principles provide an empirically based understanding of emotional change processes in clinical change: (1) increasing awareness of emotion, (2) expressing emotion, (3) enhancing emotion regulation, (4) reflecting on emotion, and (5) transforming emotion (Greenberg, 2002; Greenberg & Watson, 2006).

Emotion Awareness

The first and most general goal of emotional change is for clients to become aware of their emotions in general and their primary adaptive emotions in particular. Increased emotion awareness is therapeutic in a variety of ways. Becoming aware of core emotional experience and symbolizing it in words provides access to both the adaptive information and action tendency in the emotion. Labeling emotions is often a first step in problem definition. It is important to note that emotion awareness is not thinking about feeling; it involves feeling the feeling in awareness. Only once an emotion is felt does its articulation in language become an important component of its awareness.

The therapist thus needs to help clients approach, tolerate, and accept their emotions. Acceptance of emotional experience as opposed to its avoidance is the first step in awareness work. Once clients have accepted their emotions rather than avoided them, the therapist then helps the clients in the utilization of emotion to improve coping—that is, clients are helped to make sense of what each emotion is telling them and to identify the goal/need/concern that it is organizing them to attain. Emotion is thus used both to inform and to move.

A measure of levels of emotion awareness has been developed by Lane and Schwartz (1992). Five such levels can be measured. In ascending order, these are physical sensations, action tendencies, single emotions, blends of emotions, and blends of blends of emotional experience (the capacity to appreciate complexity in the experiences of self and other). The dynamic interactions among phenomenal experience, establishing a representation of it, elaborating that representation (e.g., identifying the source of the emotional response), and integrating it with other cognitive processes are the fundamental processes involved in the cognitive elaboration of emotion and addressed by the levels of this measure. Scores on the measure have been found to correlate significantly with self-reported self-restraint and impulse control. Individual differences in emotion awareness have also been found to predict recovery of positive mood and decrements in ruminative thoughts following a distressing stimulus (Salovey, Mayer, Golman, Turvey, & Palfai, 1995).

Awareness of emotion also involves overcoming the avoidance of emotional experience. There is a strong human tendency to avoid or interrupt painful emotions. Normal cognitive processes often deny, distort, or interrupt emotion and transform adaptive but unpleasant emotions into dysfunctional behaviors designed to avoid feeling. Leahy (2002) has defined "emotional schemas" as cognitive structures that frame the interpretation of emotional experience and guide the strategies used in coping with emotion. He has noted that there are two fundamental coping pathways for dealing with emotion. One involves attending to and labeling emotions in a manner that accepts and normalizes them; the other pathway pathologizes some emotional experiences, and this leads to attempts to distort or avoid them (initiating guilt, frantic efforts at control, obsessive rumination, etc.). To overcome emotion avoidance, clients must first be helped to approach emotions by attending to their emotional experience. This often involves changing the cognitions governing their avoidance. Then clients must allow and tolerate being in live contact with their emotions. These two steps are consistent with notions of exposure.

Emotional Arousal and Expression

Emotional expression has recently been shown to be a unique aspect of emotional processing that predicts adjustment to breast cancer (Stanton et al., 2000). Women who coped with cancer through expressing emotion had fewer medical appointments, enhanced physical health and vigor, and less distress than those low in emotional expression. Expressive coping was also related to increased quality of life for those who perceived their social environment to be highly receptive. Analyses further suggested that expressive coping enhanced the pursuit of goals, perhaps by helping clients attend to and clarify central concerns, but that this relationship was mediated by hope. Emotional arousal and its expression in therapeutic contexts thus appears to constitute a therapeutic aspect of emotional processing. Expressing emotion in therapy does not involve simply venting emotion, but rather overcoming avoidance of, strongly experiencing, and expressing previously constricted emotions.

There is a long line of evidence on the effectiveness of arousal of and exposure to previously avoided feelings as a mechanism of change. Results from a variety of studies indicate that emotional engagement (fear expression) with trauma memories during exposure in early sessions, and habituation (reduced distress) during exposure over the course of therapy, predict better outcome (Foa & Jaycox, 1999; Jaycox, Foa, & Morral, 1998). Emotional engagement with trauma memories early in therapy appears to be important in overcoming trauma. However, only a subgroup of individuals are able to engage in the exposure technique and therefore maximally benefit from therapy (Jaycox et al., 1998). Pretreatment severity of PTSD symptoms is also associated with engagement difficulties and poorer outcome. Foa, Zoellner, Feeny, Hembree, and Alvarez-Conrad (2002) have shown that although imaginal exposure, which arouses strong emotion, can exacerbate symptoms in some clients, it does this in relatively few cases, and even then this does not impede a long-term positive outcome. Overall, a chain of factors beginning with trauma symptom severity through initial engagement in imaginal exposure, activation of the fear structure, and repeated exposure while providing new information, appears to predict outcome (Jaycox et al., 1998).

However, studies on exposure and arousal do not take into account the importance to the client of the change in the therapeutic relationship. In a process–outcome study evaluating EFT for adult survivors of childhood abuse (Paivio, Hall, Holowaty, Jellis, & Tran, 2001), the therapeutic alliance, initial engagement in the primary imaginal confrontation intervention, the overall dosage of this intervention (quality × frequency), and client predisposing variables all contributed to reduced global and trauma-specific symptomatology and interpersonal problems. The effect of emotional arousal in therapy also depends on the quality of the working alliance. Beutler, Clarkin, and Bongar (2000) studied several therapies in an attempt to match patient variables with treatments. Across modalities, emotional intensity of sessions was a strong predictor of outcome, but this effect was mediated by the working alliance. Likewise, Iwakabe, Rogan, and Stalikas (2000) documented that high arousal predicted good session outcome only when there was a strong alliance.

Learning to contain and regulate strong emotions is central to adaptive emotional arousal and expression, and these skills are often lacking in people seeking therapy. The ability to regulate emotion is believed to emerge from early attachment experiences of validation, soothing, and safety, and involves attending to emotions and dampening or expressing them as appropriate. The emotional validation and empathy of the therapist seem to be particularly important in allowing clients with dysregulated emotions to learn to self-soothe and restore emotional equilibrium (Greenberg, 2002).

It is clear that emotional arousal and expression are not always helpful or appropriate in therapy or in life, and that for some clients, training in the capacity for emotion regulation (see the section "Emotion Regulation") must precede or accompany it (Greenberg, 2002). Any benefits believed to accrue from the intense expression of emotion are generally predicated on the client's overregulation (overcontrol) or suppression of emotion

(Gross, 1999), but it is apparent that for some individuals with certain psychological disorders or in particular situations, emotions are under- or dysregulated (Linehan, 1993; Gross, 1999). Some support has been found for the cathartic expression of feeling in therapy, but only with certain people under specified circumstantial conditions (Pierce, Nichols, & DuBrin, 1983). Catharsis is not helpful all the time for all people. Process–outcome research on EFT for depression, however, has shown that higher expressed emotional arousal at midtreatment predicted positive treatment outcomes (Warwar, 2003). This supports the importance of expressed arousal as a key change process in these treatments. It is important to also note that this study measured *expressed* as opposed to *experienced* emotion. A follow-up study examining in-session client reports of experienced emotional intensity (Warwar, Greenberg, & Perepeluk, 2003) found that client reports of in-session experienced emotion were not related to positive therapeutic change. A discrepancy was observed between clients' reports of in-session experienced emotions and the emotions that were actually expressed, based on arousal ratings of videotaped therapy segments. For example, one client reported that she had experienced intense emotional pain and anger in a session. Her level of expressed emotional arousal, however, was judged to be very low by observers who rated emotional arousal from videotaped therapy segments. The therapeutic outcome here validated the difference between expressed and reported experiences in that it was only expressed emotion that predicted outcome.

Exposure methods have established a basis for understanding the emotional processing required for therapeutic change in the treatment of fear and anxiety. Hunt (1998), however, looked at emotional processing of depressive events and found that although greater short-term attention to negative feelings induced short-term emotional pain, those who went through this pain felt better in the long run than individuals who engaged in problem solving or avoided processing their feelings after the depressive event. This benefit was mediated by degree of emotional arousal, suggesting again that emotions must be "up and running" and must be experienced for beneficial emotional processing to occur. Evidence has also been found supporting the specific effectiveness of arousing and expressing *anger* in the treatment of depression and traumatic sexual abuse (Beutler et al., 1991; Van Velsor & Cox, 2001). Anger can be a means for survivors of sexual abuse to develop self-efficacy, heal memories, and correctly attribute blame. In these studies, arousal and expression of anger was related to the development of agency, self-efficacy, and self-assertion. In a review of research literature related to the benefits and dangers of reexperiencing painful emotion in therapy, Littrell (1998) concluded that when therapy is designed to allow for the planned restructuring of painful memories, the reexperience of pain in therapy has been demonstrated to be beneficial and therapeutic.

Pierce et al. (1983) found that catharsis was therapeutically useful only under very specific circumstances and only for certain people. There can be no universal rule about the effectiveness of arousing emotion or evoking emotional expression. The role of arousal and the degree to which it may be useful in therapy depend on what emotion is expressed and about what issue; how it is expressed, by whom, to whom, when, and under what conditions; and in what way the emotional expression is followed by other experiences of affect and meaning (Whelton, 2004). Nonetheless, the evidence suggests that emotional processing is mediated by arousal, so that for emotion processing to occur, the distressing affective experience must be activated and viscerally experienced by the client. Arousal is necessary but not sufficient for therapeutic progress. Recently we (Greenberg, Auszra, & Herrmann, 2007; Auszra, Greenberg, & Herrmann, 2013) found that the productivity of processing of aroused emotions, rather than arousal alone, distinguished good from poor outcomes.

Emotion Regulation

The third principle of emotional processing involves the regulation of emotion. Important issues in any treatment are what emotions are to be regulated and how. Undercontrolled secondary emotions and maladaptive emotions are what need to be regulated. Clients with these types of underregulated affect have been shown to benefit both from validation and from the learning of specific emotion regulation and distress tolerance skills (Linehan, 1993).

The provision of a safe, validating, supportive, and empathic environment is the first level of intervention for automatically generated underregulated distress (Bohart & Greenberg, 1997). Linehan et al. (2002) found evidence for the effectiveness of emotional validation and soothing as part of the treatment for borderline personality disorder. Empathy from another person seems to be particularly important in learning to self-soothe, restore emotional equilibrium, and strengthen the self.

Emotion regulation skills—including such things as identifying and labeling emotions, allowing and tolerating emotions, establishing a working distance, increasing positive emotions, reducing vulnerability to negative emotions, self-soothing, breathing, and distraction—have also been found to help with high distress (Linehan, 1993). Particularly important among these skills are getting some distance from overwhelming shame, despair, hopelessness, and/or shaky vulnerability, and developing self-soothing capacities to calm and comfort core anxieties and humiliation. Forms of meditative practice and self-acceptance are often most helpful in achieving a working distance from overwhelming core emotions. The ability to regulate breathing, and to observe one's emotions and let them come and go, are important processes to help regulate emotional distress. Mindfulness treatments have been shown to be effective in treating generalized anxiety disorder and panic (Kabat-Zinn et al., 1992), treating chronic pain (Kabat-Zinn, Lipworth, Burney, & Sellers, 1986), and preventing relapse in depression (Teasdale et al., 2000).

Another important aspect of regulation, however, is developing clients' abilities to tolerate emotion and to self-soothe *automatically*. Such abilities can be developed at various levels of processing. Physiological soothing involves teaching clients to activate the parasympathetic nervous system to regulate heart rate, breathing, and other sympathetic functions that speed up under stress. At the more deliberate behavioral and cognitive levels, promoting clients' abilities to receive and be compassionate to their emerging painful emotional experience is the first step toward helping them develop automatic emotion tolerance and self-soothing. This form of self-soothing involves, among other things, diaphragmatic breathing, relaxation, and the development of self-empathy and self-compassion.

Soothing also comes interpersonally in the form of another's empathic attunement to one's affect and through acceptance and validation by another person. Internal security develops from feeling that one exists in the mind and heart of another, and the security of being able to soothe the self develops through internalizing the soothing functions of the protective other (Sroufe, 1996). It is also important to make a distinction in emotion work between intensity of emotion per se and the depth of processing of the emotion. It is the latter that is the aim in EFT, not the former, and the regulation of overwhelming emotional intensity is vital in promoting the required depth of processing of emotion.

Reflecting on Emotion

The fourth principle of emotional change is related to the first principle, emotion awareness, in that it involves making meaning of emotion. Reflection on emotion helps people make sense of their experience and promotes its assimilation into their ongoing self-narratives. What we make of our emotional experience makes us all who we are. In addition to the informational value of emotion awareness, symbolizing emotion in awareness promotes reflection on experience to create new meaning, and this helps people develop new narratives to explain their experience (Pennebaker, 1995; Greenberg & Angus, 2004). Understanding an emotional experience always involves putting it into narrative form. In therapy as well as in literature, all emotions occur in the context of significant stories, and all stories involve significant emotions (Greenberg & Angus, 2004). Therapy thus involves both change in emotional experiences and change in the narratives in which they are embedded.

In particular, symbolizing traumatic emotion memories in words helps promote their assimilation into people's ongoing self-narratives (van der Kolk, 1995). This process of verbalization allows *previously unsymbolized* experience in emotion memory to be assimilated into people's conscious, conceptual understandings of self and world, where it can be organized into a coherent story. Once such emotions are in words, they allow people to reflect on what they are feeling, create new meanings, and evaluate their own emotional experience. For example, reflecting on interpersonal difficulties and understanding that one is prone to get angry at one's partner because one is feeling abandoned, and that this relates to one's own history of abandonment rather than to the withholding nature of the partner, can be most therapeutic.

Pennebaker (1995) and colleagues have shown the positive effects of writing about emotional experience on autonomic nervous system activity, immune functioning, and physical and emotional health. Pennebaker (1995) concludes that through language, individuals are able to organize, structure, and ultimately assimilate both their emotional experiences and the events that may have provoked the emotions. Both insight and reframing of emotional experience have long been viewed as ways to change emotion. The role in psychotherapy of humans' capacity for conscious awareness of the processes and contents of their own minds, and for reason and insight to shed light on unconscious motivations, has been substantial—from the beginnings of psychoanalysis right up to the present day. In addition, many therapists have written on the importance of changing people's assumptive frameworks in therapy (see, e.g., Frank, 1961).

In a study of events in which problematic issues were resolved in session, Watson (1996) found that vivid descriptions, emotional arousal, and cognitive meaning making interacted in complex yet orderly stages to produce therapeutic change. Theses stages allowed for clients to reflect on the emotions they were experiencing. Similarly, Stalikas and Fitzpatrick (1995) did an intensive analysis of "good client moments" and showed that in-session change was related to the combination of strength of feeling and higher-order levels of reflection. In addition, computer-assisted studies of verbal patterns in psychodynamic and other therapies have shown that in the key moments in therapy in which substantial shifts happened, there was a frequent co-occurrence of high emotion tone (emotional arousal) and high abstraction (a reflection on this emotional process)—a beneficial co-occurrence that was called "making a connection" (Mergenthaler, 1996). It seems to be the timely conjunction of emotional arousal and a thoughtful exploration of the emotion's meaning that generates change.

Thus, as well as having emotions, we also live in a constant process of making sense of our emotions. A dialectical–constructivist view of human functioning has been offered to explain this process (Greenberg & Pascual-Leone, 1995, 2001; Neimeyer & Mahoney, 1995). In this view, personal meaning emerges from the self-organization and explication of one's own emotional experience, and optimal adaptation involves an integration of reason and emotion. This integration is achieved by an ongoing circular process of making sense of experience by symbolizing bodily felt sensations in awareness and articulating them in language, thereby constructing new ones.

In this dialectical–constructivist view, symbol and bodily felt referents are viewed as interacting to carry meaning forward, and newly symbolized experience is organized in different ways to construct new views. Attending to and discovering preconceptual elements of emotional experience influence the process of meaning construction. New experiential elements from many sources from within, and sometimes from without, can be integrated into this process. People are then viewed as constantly striving toward making sense of their preconceptual emotional experience by symbolizing it, explaining it, and putting it into narrative form. Preconceptual tacit meaning carries implications and acts to constrain, but does not fully determine, meaning. Rather, it is synthesized with conceptual, explicit meaning to form explanations constrained by experiencing (Greenberg & Pascual-Leone, 1995, 2001). This provides the ongoing narrative of a person's life.

Thus, although the recipe for emotional processing from the perspective of behavioral therapies and CBT is that arousal plus habituation to the distressing stimulus produces change, approach, arousal, acceptance, and tolerance of emotional experience are necessary but not sufficient from an EFT perspective. Optimum emotional processing involves in addition the integration of cognition and affect and the creation of new meaning (Greenberg, 2002; Greenberg & Pascual-Leone, 1995; Pos, Greenberg, Goldman, & Korman, 2003). Once contact with emotional experience is achieved, clients must also cognitively orient to that experience as information, and explore, reflect on, and make sense of it.

EFT appears to work by enhancing emotional processing, and this involves helping people both accept their emotions and make sense of them (Pos et al., 2003; Goldman, Greenberg, & Pos, 2005). Deepening of experience over therapy as measured by the Experiencing Scales (Klein, Mathieu-Coughlan, & Kiesler, 1986), which measure clients' ability to focus on feelings and use them to solve problems and create new meaning, has been shown to be a specific change process that predicts outcome over and above the change predicted by the therapeutic alliance. Past studies also show a strong relationship between in-session emotional experiencing and therapeutic gain in dynamic, cognitive, and experiential therapies (Castonguay, Goldfried, Wiser, Raue, & Hayes, 1996; Silberschatz, Fretter, & Curtis, 1986). This suggests that this variable may be a common factor that helps explain change across approaches.

In addition, it has been shown that therapists' depth of experiential focus influenced clients' depth of experiencing in the next moment, and that this predicted outcome. Moreover, the effect of early emotional processing on outcome was found to be mediated by late emotional processing, where "emotional processing" was defined as depth of experiencing emotion episodes (Pos et al., 2003). Early capacity for emotional processing alone thus did not guarantee good outcome; nor did entering therapy without this capacity guarantee poor outcome. Therefore, although early emotional processing skill was probably an advantage, it appeared not as critical as the ability to acquire and/or increase depth of experiencing throughout therapy. In this study, late emotional processing independently added 21% to the explained variance in reduction in symptoms over and above early alliance and early emotional processing level.

In another study (Warwar, 2003), not only did midtherapy-expressed emotional arousal predict outcome, a client's ability to use internal experience to make meaning and solve problems as measured by the Experiencing Scales, particularly in the late phase of treatment, added to the outcome variance over and above middle-phase emotional arousal. This study thus showed that a combination of emotional arousal and reflection was a better predictor of outcome than either index alone. Reflection on aroused emotion thus appears to be an important change process (Missirlian, Toukmanian, Warwar, & Greenberg, 2005).

Emotion Transformation

The final and probably most fundamental principle of emotional change is the transformation of one emotion into another. This applies most specifically to transforming primary maladaptive emotions—those old familiar bad feelings that occur repeatedly but do not change by contact with more adaptive emotions. Although the more traditional ways of transforming emotions (either exposure through experience, expression, and completion, or reflection on them) can occur with primary maladaptive emotions, another process appears to be more important. This is a process of *changing emotion with emotion* (Greenberg, 2002). In other words, a maladaptive emotional state can be transformed best by undoing it with another, more adaptive emotion. In time, the activation of the more adaptive emotion along with or in response to the maladaptive emotion helps transform the maladaptive emotion. While thinking usually changes thoughts, only feeling can change emotions.

Spinoza (1677/1967) was the first to note that emotion is needed to change emotion; he proposed that "An emotion cannot be restrained nor removed unless by an opposed and stronger emotion" (p. 195). Reason clearly is seldom sufficient to change automatic emergency-based emotional responses. Darwin (1872/1998), on jumping back from the strike of a glassed-in snake, noted that despite his having approached it with the determination not to start back, his will and reason were powerless against the imagination of a danger that he had never even experienced. Rather than reasoning with an emotion, one needs to transform the emotion by accessing another emotion.

In an interesting line of investigation, positive emotions have been found to undo lingering negative emotions (Frederickson, 2001). The basic observation is that key components of positive emotions are incompatible with negative emotions. Frederickson (2001) suggests that by broadening a person's momentary thought–action repertoire, a positive emotion may loosen the hold that a negative emotion has on the person's mind. The experiences of joy and contentment were found to produce faster cardiovascular recovery from negative emotions than a neutral experience. Frederickson, Mancuso, Branigan, and Tugade (2000) also found that resilient individuals coped by recruiting positive emotions to regulate negative emotional experiences. They found that these individuals manifested a physiological "bounce back" that helped them to return to cardiovascular baseline more quickly.

It thus seems possible to replace bad feelings with happy feelings, not in a simple manner, by trying to look on the bright side, but by evoking meaningfully embodied alternative experiences to undo the negative feelings. For example, in grief, laughter has been found to be a predictor of recovery; thus being able to remember the happy times, to experience joy, serves as an antidote to sadness (Bonanno & Keltner, 1997). Similarly, warmth and affection are often antidotes to anxiety. In depression, a protest-filled, submissive sense of worthlessness can be transformed therapeutically by guiding people to the desire that drives their protest—a desire to be free of their cages and to access their feelings of joy and excitement for life. Isen (1999) notes that at least some of the positive effects of happy feelings have been hypothesized to depend on the effects of the neurotransmitters involved in the emotion of joy on specific parts of the brain that influence purposive thinking. Mild positive affect has been found to facilitate problem solving.

In a study of self-criticism, Whelton and Greenberg (2005) found that people who were more vulnerable to depression showed more contempt but also less resilience in response to self-criticism than people less vulnerable to depression. The less vulnerable people were able to recruit positive emotional resources, such as self-assertive pride and anger, to combat the depressogenic contempt and negative cognitions. In other words, after a distressing experience, resilient people appear to generate a positive feeling (often through imagery or memory) in order to soothe themselves, and they can combat negative feelings and views of self in this more resilient state. Accessing a positive emotional state therefore helps them counteract the effect of a negative emotional state. These studies together indicate that positive affect can be used to regulate negative feelings.

Davidson (2000) suggests that the right-hemispheric, withdrawal-related negative affect system can be transformed by activation of the approach-related system in the left prefrontal cortex. He defines "resilience" as the maintenance of high levels of positive affect and well-being in the face of adversity; he highlights that it is not that resilient people do net feel negative affect, but that their negative affect does not persist. Levenson (1992) has reviewed research indicating that specific emotions are associated with specific patterns of autonomic nervous system activity, providing evidence that different emotions change one's physiology differentially. Emotion has also been shown to be differentially transformed by people's differing capacity to self-generate imagery to replace unwanted, automatically generated emotions with more desirable imagery scripts (Derryberry & Reed, 1996); this finding suggests the importance of individual differences in this domain.

It is important to note that the process of changing emotion with emotion goes beyond ideas of catharsis, completion, exposure, extinction, or habituation, in that the maladaptive feeling is not purged, nor is it simply attenuated by the person feeling it. Rather, another feeling is used to transform or undo it. Although exposure to emotion at times may be helpful to overcome affect phobia in many situations in therapy, change also occurs because one emotion is transformed by another emotion rather than simply attenuated. In these instances, emotional change occurs by the activation of an incompatible, more adaptive experience that undoes or reverses the old response.

Clinical observation and research suggest that emotional transformation occurs through a process of dialectical synthesis of opposing schemes. When opposing schemes are coactivated, they synthesize compatible elements from the coactivated schemes to form new higher-level schemes, just as in development when schemes for standing and falling, in a toddler, are dynamically synthesized into a higher-level scheme for walking (Greenberg & Pascual-Leone, 1995; Pascual-Leone, 1991). Schemes of different emotional states are similarly synthesized to form new higher-level states. Thus, in therapy, maladaptive fear, once aroused, can be transformed into security by evoking the more boundary-establishing emotions of adaptive anger or disgust, or the softer feelings of compassion or forgiveness. Similarly, maladaptive anger can be undone by adaptive sadness. Maladaptive shame can be transformed by accessing anger at violation, self-comforting feelings, and pride and self-worth. For example, the tendency to shrink into the ground in shame is transformed by the thrusting-forward tendency in newly accessed anger at violation. Withdrawal emotions from one side of the brain are replaced with approach emotions from another part of the brain, or vice versa (Davidson, 2000). Once the alternative emotion has been accessed, it transforms or undoes the original state, and a new state is forged.

Given the importance of accessing new, more adaptive emotions to transform old maladaptive emotions, this question arises: "How then are new emotions accessed?" How does a therapist help people in the midst of maladaptive experiences access emotions that will help them transform their maladaptive feelings and beliefs? Some different ways are listed below (Greenberg, 2002, 2010; Greenberg & Watson, 2006):

1. *The therapeutic relationship.* A good therapeutic relationship provides an ongoing source of new emotions by providing a secure empathic environment that soothes and calms.

2. *Shifting attention.* Shifting people's focus of attention so that they pay attention to a background feeling is a key method of helping them change their emotional states. On the edge of awareness or in the background, behind their current dominant emotion, often lies a subdominant emotion that can be found if attended to or searched for. Another feeling is there, but not yet in focal awareness. Behind anger is sadness, love, or forgiveness; at the edge of sadness is anger; within hurt or fear is anger; behind shame are pride and self-esteem. The subdominant emotion is often present in the room nonverbally, in tone of voice or manner of expression.

3. *Accessing needs/goals.* A more process-directive way in which a therapist can help clients access their healthy healing emotions and internal resources is by asking them when they are in a maladaptive state, such as shame, what they

need to resolve their pain. People usually know what they need when they are suffering their pain. Once they know what they need in a situation, they often begin to feel as if they have some control over it. Raising a need or a goal to a self-organizing system has a number of effects. At the conscious, intentional level, it opens a problem space to search for a solution. At an affective level, it conjures up a feeling of what it is like to reach the goal, and opens up neural pathways to both the feeling and the goal. Most important, raising a need that is unmet helps a new feeling such as anger or sadness to emerge.

4. *Positive imagery.* Another way to activate alternative feelings is to use imagery. Imagination is a means of bringing about an emotional response. This involves helping clients use their conscious capacities to generate new experience. People can use their imaginations to create scenes that they know will help them feel an emotion, and can use this emotion as an antidote to a maladaptive feeling they want to change. They can change what they feel, not by changing feelings with reason, but by using imagination to evoke new emotions. With practice, people can learn how to generate opposing emotions through imagery and use these as antidotes to negative emotions.

5. *Expressive enactment of the emotion.* Yet another way to access alternate emotions is to have people enact a feeling that is not currently being experienced. This goes back to William James's (1890) idea that we feel afraid because we run. The therapist asks clients to adopt certain emotional stances, and helps them to deliberately assume the expressive posture of that feeling and then to intensify it. Thus, a therapist might use a psychodramatic enactment and instruct a client, "Try telling him, 'I'm angry.' Say it again—yes, louder. Can you put your feet on the floor and sit up straight? Yes, do it some more." Here the therapist coaches the person in expressing an emotion until the emotion actually begins to be experienced. This is not encouraging phony expression, but trying to facilitate access to a suppressed, disallowed experience. Instructions to take on expressive postures are always balanced by asking people what they experience after doing this.

6. *Remembering another emotion.* Remembering a situation in which an emotion occurred can bring the emotion memory alive in the present. This technique is related to the imaging process described above. Remembering past emotional scenes clearly produces emotion. To help people change what they feel, a therapist has to help them access and restructure their emotion memories. One important way of changing emotion memories involves accessing the emotion memory to be changed and then transforming it with another emotion memory. Once another emotion memory is evoked, either the new memory dominates and the old one recedes into the background and becomes less accessible, or the new one eventually transforms the old memory.

7. *Cognitive change.* A therapist can also help people access a new emotion by talking with them about the more desirable emotion. This is using cognitive meaning to generate new feelings. Talking about an emotional episode helps people reexperience the feelings they had in that episode.

8. *Expressing the emotion for the client.* A therapist might express outrage or sadness for a client that the client is not yet able to express. This gives the client permission to begin experiencing this emotion. We all often see ourselves in the reflections of ourselves that we get back from others. Seeing that our stories have an impact on others and that they are moved can also move us.

9. *Using the therapy relationship to generate a new emotion.* A new emotion can be evoked in response to a new interaction with a therapist. The therapist can evoke a particular emotion in a client by taking a particular position in the interaction. For example, a therapist who is comforting will evoke soft feelings; one who is confrontive will evoke anger.

Emotion Coaching

A view of the therapist as an "emotion coach"—a view that encompasses the importance of both the therapeutic relationship and emotional processing—has been proposed as a model of the therapist's role and function in working with emotion. Emotion coaching (Gottman, 1997; Greenberg, 2002) is essentially aimed at helping people become aware of and make sense of their emotional experience. The effects of a good therapeutic relationship on outcome is widely recognized (Norcross, 2002), and there is good reason to believe that a good alliance is also a prerequisite to productive emotional processing, as noted throughout this chapter. An accepting, empathic relational environment provides people with the experience of emotional soothing and support they need to pay attention to their bodily felt experience. This type of relational environment helps people to sort out their feelings, develop self-empathy, and find alternative inner resources from which new responses can be constructed. Within this relational context, emotion coaching aims to help clients be informed by their emotions, regulate them, transform them, and use them intelligently to solve problems in living.

In addition to following where the client is moment by moment, the therapist acting as an emotion coach guides the client in new ways of processing experiential information. Emotion coaching thus involves a style that combines leading and following, and embodies the idea that it is possible to influence the construction of people's subjective experience. Change and novelty can be introduced in the emotional domain by training people to become aware of their emotional processes, and by guiding their attention and meaning construction processes.

Based on a major principle that one cannot leave an emotional place until one has arrived, two phases of emotion coaching—the "arriving" phase and the "leaving" phase—have been proposed. Each phase includes four steps designed to help people experience their emotions more skillfully. The first phase, focused on awareness of emotion, is designed to help people arrive at what they feel and involves the following steps:

1. The coach helps people attend to their emotions.
2. The coach encourages people to welcome their emotional experience and allow it (this does not necessarily mean they must express everything they feel to other people; rather, they must acknowledge it themselves). People also need to be coached in skills of emotion regulation if these are needed.
3. The coach helps people to describe their feelings in words, in order to aid them in solving problems.
4. The coach guides people to become aware of whether their emotional reactions are their primary feelings in this situation. If not, they need help in discovering what their primary feelings are.

The second phase focuses on emotion utilization or transformation and is designed to help clients leave the place where they have arrived. This stage involves moving on and transforming core feelings when necessary. It is here that the coaching aspect is more central.

5. When a person has been helped to experience a primary emotion, the coach and person together need to evaluate whether the emotion is a healthy, adaptive emotion or an unhealthy, maladaptive response to the current situation. If it is healthy, it should be used as a guide to action. If it is unhealthy, it needs to be changed.
6. If the accessed primary emotion is unhealthy, the person has to be helped to identify the negative cognition associated with this emotion.
7. Alternative, adaptive emotional responses and needs are now processed and developed.
8. People are coached to challenge the destructive thoughts in their maladaptive emotions from their new inner voice, based on their adaptive primary emotions and needs, and to regulate maladaptive emotions when necessary.

Coaching in the emotional domain thus involves helping clients verbally label each emotion they are feeling, accept the emotion, talk about what it is like to experience the emotion, develop new ways of processing the emotion, and learn ways of soothing or regulating the emotion. It is important to note that people often cannot simply be explicitly taught new strategies for dealing with difficult emotions; they have to be assisted to engage in the new process experientially, and only later explicitly taught what to do. For example, accessing a need or goal may be very helpful in overcoming a sense of passivity or defeat or to help a painful feeling. However, explicitly teaching people that this is what they should do is not nearly as helpful as interpersonally facilitating this by asking them at the right time what it is they need. For example, it is through experiencing a process of shifting from negative to more positive emotional states that the experiential links between states are best forged. This then is consolidated only later by explicit knowledge of the process.

Conclusion

EFT emphasizes becoming aware of and reflecting on primary emotions, as well as regulating and transforming maladaptive emotions. Both the utilization and the transformation of emotion are seen as therapeutic. A two-step therapeutic process is recommended when the core emotion accessed is adaptive. First, the symptomatic secondary emotion (such as feeling upset, despairing, or hopeless) is evoked in therapy; then the core primary adaptive emotion that is being interrupted (such as sadness, grief, or empowering anger) is accessed, validated, and utilized to promote adaptive action. A three-step sequence is required to transform a core maladaptive emotion. In this sequence, the secondary emotion is first evoked; then the core maladaptive emotion being avoided (such as shame, fear, or anger) is accessed. This latter emotion is then transformed by accessing a more adaptive emotion (such as anger, sadness, or compassion). When adaptive emotions finally are evoked, they are incorporated into new views of self and used to transform personal narratives.

CHAPTER 40

Eat, Drink, and Be Sedentary

A Review of Health Behaviors' Effects on Emotions and Affective States, and Implications for Interventions

Elissa Epel, Aric A. Prather, Eli Puterman, and A. Janet Tomiyama

There is a large body of work showing that emotions and emotion regulation shape health behaviors (DeSteno, Gross, & Kubzansky, 2013; see Chapter 36, "Emotions and Health," this volume). In turn, many health behaviors have potent effects on how we feel. When feeling emotional, many people often turn to unhealthy behaviors to modulate or dampen their emotions. It is not surprising then that health behaviors are often conceptualized as a way to cope with stress. Standard coping scales include, in addition to emotional and problem-focused coping responses, the common behavioral responses to stress such as eating, drug use, drinking, watching television, or sleeping more than usual. Behavioral responses such as these are a form of passive coping or mental disengagement, reflected in our cultural idioms "drown your sorrows," "numbing out," using "food as therapy," or "sleeping it off." While the more common behavioral responses to "negative" emotions, like sadness and anxiety, tend to be "negative" health behaviors, some people lean toward exercise to feel better. Positive health behaviors such as exercising and sufficient sleep may also impact affective states, both dampening negative but also increasing positive affect and related specific emotions. Clearly, then, this relationship is bidirectional, although much less attention is on the path from health behaviors to affect.

Why should one care about the transient emotional responses to a bout of exercise, for example? It may be that within such phenomena lie the critical levers to promoting positive habits. The link between how health behaviors shape emotional responses is sorely underexamined. Emotional responses that are induced by health behaviors predict a wide range of outcomes that can then feed back to further shape decision making and other health behaviors. New initiatives to understand behavior change, such as the National Institutes of Health Science of Behavior Change (SOBC) initiative's attempt to find commonalities in mechanisms of behavioral change across types of behaviors, in order to promote more effective in-

All authors contributed equally; authors are listed in alphabetical order.

terventions (National Institutes of Health, 2015). Promoting adherence to health behaviors is one of the toughest issues in public health, and the role of emotional responses may provide one window into understanding individuals' choices to engage or terminate health behaviors.

Here we review the primary health behaviors that are relevant to most people as they age, regardless of health status, including positive behaviors—*exercise* and *good sleep*—and consummatory behaviors—*overeating* and *drinking alcohol*—and what is known about their effects on emotion and affective states, and stress-related processes, including physiological responses to stress. We touch upon emotion regulation when there is research directly assessing regulation (see the section "Eating"). Health behaviors can affect default or basal emotional states, anticipation of stressors, and then appraisal and evaluation. They also impact neurobiological processes that maintain or modulate affective states and discrete emotional experiences *after* a stressor has occurred. Further, the affective and emotional responses during and immediately after engaging in a health behavior may affect a person's decision to continue to engage in or maintain the behavior, although this is less studied.

This chapter lays initial groundwork for a better understanding of the behavior–affect link. In addition, we pose the question of whether health behaviors at the right dose and intensity can promote more positive emotional responses, which may predict better adherence to the healthy behavior (Figure 40.1). This is a nascent area of research, applied mainly to exercise so far.

Acute versus Chronic Effects

One obstacle to understanding health behavior's effects on emotions is that there is not a programmatic literature with a common language and conceptual paradigm. How can we best learn from the studies that have been done thus far? Here we organize studies based on the exposure (chronic/regular or acute health behavior). If an individual is regularly engaging in a health behavior, we can consider *chronic effects* of the health behavior on emotion and emotion regulation processes. We review how emotional experiences differ in people who vary on physical activity, sleeping habits, eating patterns, and alcohol consumption. To varied extents, each behavior has been studied in its chronic form and how it impacts discrete emotions and affective states, in psychiatric conditions, general emotional experiences of everyday life, and in the laboratory in response to stress induction. We also review the small but important experimental literature on the impact of acute health behaviors on emotions. *Acute effects* of a health behavior can be studied through one-time or short-term repeated manipulations of the health behavior, by using either standardized conditions, such as in the lab, or by using more naturalistic examination in daily life, with repeated ecologically valid measurements, such as those afforded by ecological momentary

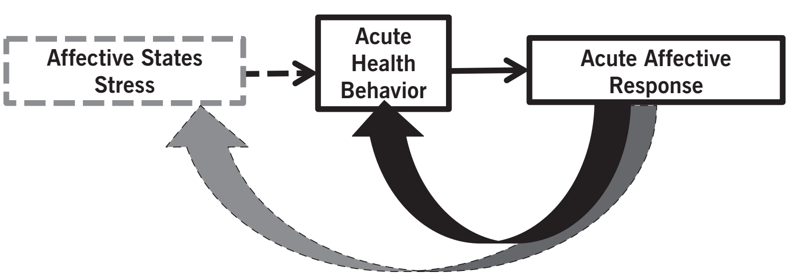

FIGURE 40.1. Health behaviors can acutely alter affective experience—emotions (valence, arousal), emotion regulation, and stress appraisal. This can affect both longer-term affective states, and we propose may affect frequency of the health behavior. Using the example of exercise, a positive emotional response to a bout of exercise can predict better adherence (Williams et al., 2008). This may extend to other health behaviors where changes in negative and positive emotional balance could be critical determinants of future adherence or abstinence from that behavior, and predict treatment success.

assessment (EMA). And while each behavior has been studied in a vacuum, we present suggestions for a more programmatic focus on health behaviors and their impact on emotions that envelops common strategies and language to uncover common, underlying neurobiological mechanisms situated within a broader conceptual model.

Physical Activity

First, it is important to be specific about definitions of activity, since they may work differently. Physical activity, exercise, and sedentary behavior are typically used interchangeably, yet incorrectly (Caspersen, Powell, & Christenson, 1985). *"Physical activity" is defined as any skeletal muscle movement that results in energy expenditure.* Physical activity can occur at home during household activities, at work, during leisure time, and sports, for example. Exercise, on the other hand, is structured, deliberate, and repetitive physical activity that has the planned outcome of improving physical fitness. Researchers also differentiate between type, duration, and intensity (light, moderate, and vigorous) of physical activity. Activity in the moderate and vigorous intensity zones is typically considered an "exercise bout" since these levels of intensity are typically only reached during structured and deliberate exercise. Recent research also differentiates between physical activity and sedentary behaviors (television watching, sitting at work, spending time at a computer), as there is growing evidence that they independently predict health and disease (Chomistek et al., 2013; Katzmarzyk, 2010).

It is apparent from the literature that depression and physical activity are intimately connected. Depressed and anxious individuals are less likely to be physically active (Camacho, Roberts, Lazarus, Kaplan, & Cohen, 1991; Goodwin, 2003; Stroehle, 2009) and remain more sedentary (Teychenne, Ball, & Salmon, 2010). Prospectively, physical inactivity appears to increase the risk of developing depression (Farmer et al., 1988; Lampinen, Heikkinen, & Ruoppila, 2000; Motl, Birnbaum, Kubik, & Dishman, 2004). Several meta-analyses and reviews suggest that exercise interventions promote reductions in depressive and anxious symptoms in healthy and clinical populations (Blumenthal et al., 2007; Brosse, Sheets, Lett, & Blumenthal, 2002; Conn, 2010a, 2010b; Rethorst, Wipfli, & Landers, 2009; Wipfli, Rethorst, & Landers, 2008). Randomized trials demonstrate that exercise interventions considerably benefit depressed individuals, with similar effects to pharmacotherapy (Barbour, Edenfield, & Blumenthal, 2007; Blumenthal et al., 2007; Brosse et al., 2002), and that depressed individuals who start an intervention and maintain regular exercise over the long term also maintain the therapeutic affective effects of exercise up to 1 year later (Babyak et al., 2000; Hoffman et al., 2011). Physical activity, thus, appears to have antidepressant effects.

Here we examine research that assesses the emotion- and affect-altering effects of physical activity by examining how physical activity and exercise can help people "feel less worse" and "feel better." Much of the work to date rests in the area of affective states, general states of positive affect or negative affect, or pleasure and displeasure. We highlight evidence from observational and experimental studies that examines differences in affective states that occur naturally and in the laboratory between physically active people and those who are less active. We also highlight the work on affective states from naturalistic and experimental studies that occur after a bout of exercise in everyday life and in response to a standard exercise bout in the laboratory. We complete the section with a focus on the potential neurobiological mediators of these effects.

Regular Physical Activity

Regular Physical Activity, Emotions, and Affect

From a broad emotions perspective, it has been of considerable interest to examine whether becoming physically active makes people feel better (i.e., boost positive affect) or makes people feel less worse (i.e., reduce negative affect). Reviews and meta-analyses abound addressing these studies. A review of the literature indicates that physical activity is more likely to be related to changes in positive affect than to negative affect. For example, the long-term benefit of an exercise intervention on older adults' quality of life is mediated by positive affect alone, not negative affect (Elavsky et al., 2005). In fact, a meta-analysis (Reed & Buck, 2009) suggests that participants who are randomized to an exercise program increase in positive affect, with a Cohen's d effect size of 0.57. Importantly, those who start preintervention with lower positive affect scores or who exercise more than three times a week are especially more likely to increase in their positive affect ratings. However, it is unclear which discrete emotions are altered or whether the impact of exercise is more general.

Regular Physical Activity and Emotional and Stress Reactivity

Studies in the laboratory have, however, examined the response of discrete emotions to novel stressors in active individuals compared with those less active. Physical activity buffers individuals' emotional responses to acute and novel stressors. Active individuals are less likely to experience psychological stress or increased negative emotions after a laboratory-induced stressor than inactive individuals. For example, Rimmele and colleagues (2007, 2009) demonstrated that while all individuals experience heightened state anxiety and decreased calmness in response to stress induction in the laboratory, athletes are seemingly less emotionally responsive to stressors than sedentary, untrained individuals. Similarly, individuals with high levels of regular physical activity have smaller neuroendocrine and autonomic responses to a stressor compared with those who are sedentary (Puterman et al., 2011; Rimmele et al., 2007, 2009; Traustadóttir, Bosch, Cantu, & Matt, 2004).

Acute Physical Activity

Acute Physical Activity, Emotions, and Affect

While regular physical activity is psychologically beneficial, perhaps via alterations in positive affect, less is known about how an acute bout of exercise impacts trajectories of positive and negative affect or discrete emotions. Diary studies, including EMAs, have opened the door to understanding the relationships between acute episodes of physical activity and positive and negative affective states on a daily basis. Giacobbi, Hausenblas, and Frye (2005) examined the relationships between self-reported physical activity and affect on a daily basis in 106 college students utilizing end-of-day 24-hour recall self-reports. They demonstrated that on days that students were physically active, reported positive affect was higher whereas negative affect was lower, compared with the days these students were inactive. However, to eliminate the effects of random events that occurred, Giacobbi and colleagues (2005) covaried actual positive and negative events that the participants' experienced on each day and found only positive affect was related to reporting being active, whereas negative affect was no longer related. These findings corroborate previous research on daily activity and positive affect (Steptoe, Kimbell, & Basford, 1998), although there are also null findings with similar methods (Ready, Marquez, & Akerstedt, 2009).

To better assess acute effects of activity naturalistically, it is necessary to examine repeated assessments of mood in order to get at changes before and after activity. Using such an exemplary study method as EMAs, Wichers and colleagues (2012) examined the lagged relationships between physical activity and affect in over 500 female twins by measuring self-reported physical activity and negative and positive affect at 10 time points throughout the day for 5 consecutive days. Fluctuations in negative affect within individuals were not related to engaging in physical activity on a daily basis nor did physical activity decrease negative affect after an increase in activity. On the other hand, positive affect increased immediately after a bout of activity for as long as 180 minutes in women with no history of depression, and for 90 minutes in women with a history of depression.

The question of whether a bout of exercise makes people "feel better" (i.e., increase in positive affect) or "feel less worse" (i.e., decrease in negative affect) has received wide attention beyond daily experiences, and has a longer history in laboratory experiments. Wichers and colleagues' (2012) study suggests that activity makes people feel better, but experimental studies suggest that this might be the case because people in their daily lives self-select types of activities at intensity and duration levels that *make* them feel better. In a series of studies that span the past decade, Ekkekakis, Hall, and Petruzzello (2008), as well as others, have demonstrated that while most people feel better *after* exercising (typically when affect is measured in EMA studies), not everyone feels better *during* exercise—in fact, many people feel worse.

One might wonder why exercise seems pleasant for some people and torturous for others. One's fitness level and the intensity of a bout of activity seem to play crucial roles in this equation (Reed & Ones, 2006). One's physiological fitness states, including ventilatory and lactate thresholds, are key to understanding when physical activity switches from a positively to negatively valenced effect on emotional state. The ventilatory threshold is the point at which breathing becomes disproportionately high in comparison to how much oxygen is actually being consumed. The lactate threshold is the point at which lactic acid starts to accumulate in the blood, forcing the organism to switch to anaerobic respiration (Caiozzo et al., 1982). While these thresholds are reached at slightly different intensities, based on nutrition and overall fitness of the individual, a wide range of studies suggest that below these thresholds, physical activity is widely experienced as pleasurable, with some interindividual variability. Above these thresholds, exercising switches from an experience of positive affect to negative affect (Ekkekakis et al., 2008; Ekkekakis & Petruzzello, 1999; Hall, Ekkekakis, & Petruzzello, 2002; Welch, Hulley, & Beauchamp, 2010). Furthermore, in those who remain subthreshold, positive affect seems to peak at 30 minutes and starts declining soon after (Woo, Kim, Kim, Petruzzello, & Hatfield, 2009). Last, during recovery from exercise, there is another burst of positive affect (Woo et al., 2009).

This trajectory—positive affect subthreshold, negative affect above threshold, and positive affect after a bout of exercise—may differ for individuals based on factors such as how active individuals are in their daily lives. For example, some evidence suggests that *inactive* women tip toward negative affect even before the ventilatory threshold is reached, and bounce back toward a positively valenced experience after around 10 minutes after a bout of exercise (Welch, Hulley, Ferguson, & Beauchamp, 2007). In contrast, active women typically bounce back immediately after a bout of exercise that surpasses the ventilator threshold.

Temperament also seems to influence the experience of affect during exercise. Individuals who tend toward reward seeking or high arousal states experience greater positive affect during exercise than those who are more driven toward low arousal states or avoiding pain (Legrand, Bertucci, & Thatcher, 2009; Schneider & Graham, 2009). Additionally, those who feel higher levels of mastery during activity (Hu, Motl, McAuley, & Konopack, 2007; Jerome et al., 2002) and autonomy over the choice of intensity (Lind, Ekkekakis, & Vazou, 2008; Parfitt, Blisset, Rose, & Eston, 2012; Parfitt & Hughes, 2009) seem to receive greater boosts in positive affect during a bout of exercise. For example, overweight and obese women *forced* to exercise 10% greater than their preferred or self-selected intensity level are more likely to experience negative affect during a 20-minute bout of exercise than normal-weight women (Ekkekakis & Lind, 2006).

These studies may be of critical importance in understanding adherence to—versus dropping out—from exercise programs. In one study, greater positive affective response to one acute bout of moderate intensity exercise predicted maintenance of a fitness regimen up to 1 year after assessment (Williams et al., 2008). As a result of these findings, clinical researchers are increasingly recommending that individuals without current fitness routines base their new activities on what feels good to them, and less on their maximum heart rate target zones. Target zones might surpass the thresholds in unfit individuals, in turn promoting negative affect sooner into a bout of exercise (Welch et al., 2010) and thus, an increased likelihood to drop out of an exercise routine (Ekkekakis, 2009b). A recent study increased expectations of a positive mood after exercise in one group of volunteers. Both groups exercised for 10 minutes, and the group with the positive expectation induction indeed had significantly higher positive affect and greater behavioral intentions to exercise again (Helfer, Elhai, & Geers, 2015). Manipulating positive expectations, in order to promote more positive affect, may be yet one more important lever that can be used in promoting better adherence.

Acute Physical Activity and Affective and Stress Reactivity

The affect-moderating effects of activity in response to stressors are not limited to only those who are active versus inactive but extend to a single bout of exercise as well (Anshel, 1996; Mata, Hogan, Joormann, Waugh, & Gotlib, 2013; Smith, 2013). In a study of nondepressed and previously depressed individuals, Mata and colleagues (2013) induced a sad mood twice in a 20-minute period and monitored mood states continuously. Prior to the sad mood induction, however, half of the participants exercised for 15 minutes at self-selected intensities while the other half rested comfortably. All increased in negative affect after the first mood induction; however, only those with histories of depression who did not exercise for 15 minutes prior to the mood-induction task continued to increase in their negative affect after the second induction, whereas all the other participants did not. Thus, those with tendencies toward depression may be sensitive to the positive effect of exercise on negative emotional processing.

Neural Mechanisms of Physical Activity and Affective Experience

Research from animal and human studies has identified neurobiological underpinnings that may partially mediate the affective responses experienced during a bout of exercise. One of a rodent's favorite pastimes is to run on a wheel. Fortunately for the rodent, wheel running appears to be mood enhancing and stress buffering. Rodents provided a running wheel have amplified expression of several neurotransmitters (e.g., serotonin, brain-derived neurotrophic factor [BDNF], galanin) that increase cognitive flexibility and learning and reduce arousal of the endocrine and autonomic nervous activity, systems that play a role in the experience of affect and stress (Dishman et al., 2006; Matta Mello Portugal et al., 2013; Sciolino, Dishman, & Holmes, 2012; Sciolino & Holmes, 2012). In a recent mouse study, immersing mice in a cold-water swim stress task—much more of a stressor than an exercise opportunity—provoked a large stress response and neurogenesis in the region of the hippocampus that plays a role in heightened emotion processing (ventral hippocampus). However, mice that were provided free access to running wheels for several weeks prior to immersion in the cold-water swim stress task calmed much sooner. These exercise related effects on reducing behavioral signs of anxiety were accounted for by increased gamma-aminobutyric acid (GABA)-releasing neurons in the ventral hippocampus that inhibited the excitatory neurons (Schoenfeld, Rada, Pieruzzini, Hsueh, & Gould, 2013).

In humans, such detailed examinations of the neurobiological effects of chronically exercising are either not explored as of yet or currently impossible to test. However, physical activity in humans changes brain activity in ways that may affect stress appraisal and emotion regulation processes, and possibly underlie antidepressant responses. Recent advances in cerebral hemodynamics support previous studies of electroencephalogram (EEG) research demonstrating differential activation of the frontal and prefrontal areas of the brain at increasing levels of exercise intensity. Many of these changes correlate with the experience of pleasure or displeasure during exercise, and the transition from the former to the latter at the ventilatory threshold (Ekkekakis, 2009a; Fumoto et al., 2010; Hall, Ekkekakis, & Petruzzello, 2010; Kop et al., 2011; S. Schneider et al., 2009; Tempest, Eston, & Parfitt, 2014; Woo, Kim, Kim, Petruzzello, & Hatfield, 2010). In individuals not pushed to their ventilatory threshold, however, it is believed that the required neural activity for movement and balance during exercise, coupled with the finite metabolic resources of the brain that limit neural activity in nonmovement essential areas, allows for the decreased stimulation of the prefrontal and limbic regions. These regions are typically overly active in anxiety and depressive disorders, and, in part, these alterations in the brain that occur during exercise may partly underlie some of the benefits of physical activity to those suffering mood disorders (Dietrich & Audiffren, 2011).

Summary and Future Directions

Regular physical activity is associated with less major depression, anxiety disorders, and greater positive affect in general. Acute exercise is associated with a trajectory of affective responses—more positive emotional response in the low and moderate intensity zones—and if it reaches the ventilator threshold and an anaerobic state, a short-lived negative affective tone until the exercise bout ends.

In recovery from exercise, EMA studies suggest that a positive affective state is induced that can last for up to 3 hours. If this type of quantification of standard affective effects was performed reliably across studies and types of health behaviors, we could better examine how affective responses predict future health behaviors and modifiers of these effects. As shown in Figure 40.1, the dynamics of the affective response may be critical for understanding individual differences in new exercisers—or any new health behavior for that matter—who take to their new lifestyle and those who drop out quickly. There are hints that a positive affective response to a bout of exercise predicts long-term adherence to a program. Thus, making exercise pleasurable by, in part, keeping people in a subthreshold zone is key to long-term maintenance in new exercisers. Past depression, temperament, and fitness level are important moderators of affective response.

It is clear from previous research that being physically active has affect-altering effects, and that perhaps, the immediate effects of a single bout of exercise build over time to secure a general better mood for individuals. Much less is known about discrete emotional experiences, whether experienced naturalistically, in the laboratory after a bout of exercise, or in response to a laboratory stressor. Whether the affect-altering effects are universal remains unknown. For example, the physical activity-depressive symptomatology association was apparent only in adolescent girls with the met-allele BDNF polymorphism (not val/val polymorphism) in a prior study (Mata, Thompson, & Gotlib, 2010). Future research directed toward the genetic, social, or life history underpinnings of who benefits affectively from interventions is thus of particular interest. To date, few exercise-based intervention studies combine daily process methods and laboratory evaluations of affect and emotion pre- and postintervention, so it is unclear exactly how affect experience is altered in naturalistic and experimental conditions.

Sleep

The link between sleep and emotion is intuitive. One only needs to pull an all-nighter, either in the service of extending fun or by necessity, and then reflect on how one's mood was disrupted the next day to appreciate that sleep loss can dramatically affect the emotional system, including one's expression and regulation of emotions. Taken to its extreme, chronic sleep disturbances, such as prolonged difficulties in falling or staying asleep, can constitute psychiatric conditions in their own right (e.g., primary insomnia) and co-occur with many other psychiatric conditions (e.g., mood and anxiety disorders; Baglioni, Spiegelhalder, Lombardo, & Riemann, 2010). This co-occurrence is so common that sleep disturbance has been proposed as a potential transdiagnostic factor in psychiatric illness (Harvey, Murray, Chandler, & Soehner, 2011). The relation between sleep and emotion is complex and bidirectional, and accruing evidence suggests that sleep and emotion are in "obligate symbiosis" (Walker & Harvey, 2010). Here we focus primarily on one direction of this dynamic system, namely, on how the quantity and quality of sleep serves to modulate emotional health, by studying affect in people with chronic sleep conditions, and by examining how acute sleep deprivation influences affective experience.

Chronic Sleep Disturbances

Chronic sleep disturbance is a significant predictor of onset and recurrence of several psychiatric conditions, especially major depressive disorder (MDD; Baglioni et al., 2010, 2011; Tsuno, Besset, & Ritchie, 2005). Further, sleep complaints often remain after the MDD remits (Iovieno, van Nieuwenhuizen, Clain, Baer, & Nierenberg, 2011). Accordingly, sleep interventions have emerged as promising treatment strategies in mitigating affective disorders. Chronic sleep problems also negatively affect emotional functioning in nonclinical samples. For instance, rotating shift workers, who by the nature of their jobs have disrupted sleep, show elevated rates of emotional exhaustion as well as mood disorders compared with nonrotating night-shift workers and day-shift workers (Drake, Roehrs, Richardson, Walsh, & Roth, 2004; Jamal, 2004). Similarly, police officers who screened positive for a sleep disorder, including obstructive sleep apnea and insomnia, were at significantly greater risk of making cognitive errors on the job, falling asleep while driving, and missing work. However, what was particularly alarming was that these officers were also significantly more likely than non-sleep-disordered officers to display uncontrolled anger toward a citizen or suspect and receive citizen complaints (Rajaratnam et al., 2011). The impact of sleep on emotion generation and regulation is complex. To get a better handle on the link between sleep and emotion, researchers have turned to more experimental paradigms.

Acute Sleep Disturbances

Acute Sleep Disturbance, Emotions, and Affect

The effects of sleep disturbance on emotions can be large, and in some cases more robust than sleep-induced decrements in cognition (Pilcher & Huffcutt, 1996). Experimental paradigms employing sleep deprivation serve as useful tools for elucidating these effects (Hall, Levenson, & Hasler, 2012; Kahn, Sheppes, & Sadeh, 2013; Vandekerckhove & Cluydts, 2010). In general, findings from this literature demonstrate that experimental acute sleep deprivation is associated with increases in a bevy of negative emotions. For instance, participants subjected to 1 week of partial sleep deprivation (5 hours of sleep per night) reported increases in daily emotional difficulties and negative mood states (Dinges et al., 1997). Elevations in reports of anxiety and depression have been observed in several other studies employing sleep deprivation in otherwise healthy adults (Babson, Trainor, Feldner, & Blumenthal, 2010; Franzen, Siegle, & Buysse, 2008; Sagaspe et al., 2006). These sleep-related impairments in emotion are thought to be particularly salient to adolescents, who as a group are experiencing developmental brain changes that affect sleep and emotional processes (Dahl, 2004). For example, 1 week of partial sleep restriction (6.5 hours in bed per night for five nights) produced greater reports of anxiety, anger/hostility, fatigue, and confusion in adolescents, and increased parental reports of oppositional behavior by their adolescent child as compared with the same young adults (ages 14 to 17) under a week of "healthy sleep duration" (10 hours in bed per night for five nights; Baum et al., 2014).

There is also growing evidence that positive affect is tied to sleep (Ong et al., 2013; Steptoe, O'Donnell, Marmot, & Wardle, 2008), a relationship that is often independent of negative affect. In a recent naturalistic study of 100 midlife adults who underwent eight consecutive end-of-day telephone interviews and 7 consecutive days of actigraphy to measure sleep, greater trait levels of positive affect were associated with feeling more rested and overall better-quality sleep. However, greater positive affect reactivity in response to daily events was related to overall poorer self-reported sleep efficiency (Ong et al., 2013). While this study cannot determine the directionality of the relationship between positive emotions and sleep, a recent report found that acute sleep loss modulates the neural processing of positive stimuli. In this regard, Gujar, Yoo, Hu, and Walker (2011) demonstrated that acute sleep deprivation led to interpreting emotional stimuli as more positive, which in turn was correlated with exaggerated activity in the mesolimbic circuitry.

Positive affective responses may be partly dependent on the stimulus. For instance, in a longitudinal study of medical residents, researchers employing EMA found that sleep loss intensified negative affect from a disruptive daily event, while sleep loss attenuated positive affective responses to goal-enhancing events (Zohar, Tzischinsky, Epstein, & Lavie, 2005). This study stresses the importance of context when considering the effects of sleep on affect. In another recent study, adolescents undergoing a 2-night partial sleep-deprivation protocol showed a decrease in the ratio of positive to negative affect—but this was solely due to a decrease in positive affect alone, and no significant change in negative affect following sleep deprivation (Dagys et al., 2012). Endogenous diurnal sleep rhythms may also matter—those who had an evening chronotype (went to bed much later) had a lower positive to negative ratio even when rested.

Chronotype also appears to modulate diurnal patterns of positive affect, and has been implicated in the onset of mood disorders such as depression (Hasler, Allen, Sbarra, Bootzin, & Bernert, 2010). In a recent analysis, participants with an evening chronotype displayed lower amplitude and delayed peak in daily levels of positive affect as compared with other chronotypes (Miller et al., 2014). This underscores the importance of accounting for circadian factors when investigating links between sleep and affect.

Acute Sleep Loss and Affective Reactivity to Stress

Sleep disturbance may lower one's threshold for emotional reactivity, enhancing one's emotional sensitivity to stressors. In this regard, Minkel and colleagues (2012) showed that following a night of total sleep deprivation participants reported greater subjective distress, anxiety, and anger in response to a low-stress cognitive task compared with normal sleepers; however, no differences in affect were observed between groups following a high-stress task (Minkel et al., 2012). This suggests that sleep-deprived individuals may have a lower threshold for what they perceive as stressful. Concordant with the line of thinking, participants under a night of sleep deprivation showed enhanced systolic blood pressure reactivity following an acute laboratory stressor (Franzen et al., 2011). In terms of chronic effects, poorer global subjective sleep quality enhanced the effects of acute stress exposure on proinflammatory cytokines (Heffner et al., 2012; Prather, Puterman, Epel, & Dhabhar, 2013).

Neural Mechanisms of Sleep and Affective Experience

Studies of sleep restriction have also demonstrated changes in several objective markers of emotional functioning, which further strengthens the argument that sleep is intimately related to the processing and production of affective experience. Franzen, Buysse, Dahl, Thompson, and Siegle (2009) employed pupillography as an indicator of affective processing and found that sleep-deprived participants showed greater pupil dilation to negative emotional stimuli compared with normal sleepers. Advances in neuroimaging have further illuminated the effects of sleep on the emotional brain. In a seminal study, Yoo, Hu, Gujar, Jolesz, and Walker (2007) showed that 1 night of sleep deprivation resulted in a 60% increase in reactivity of the amygdala to negative emotional stimuli compared with a rested control group. Moreover, sleep-deprived participants showed less functional connectivity between the amygdala and medial prefrontal cortex, a brain region important in exerting top-down regulatory control of the amygdala. This is consistent with a recent study that found similar decrements in functional connectivity between these brain regions and that the declines were associated with higher reports of state anxiety (Motomura et al., 2013). Habitual sleep quality has been significantly related to stronger links between amygdala reactivity and negative affect (Prather, Bogdan, & Hariri, 2013), while longer durations were associated with stronger resting state connectivity between the medial prefrontal cortex and the amygdala (Killgore, 2013). Taken together, these data suggest that sleep loss results in greater threat reactivity, possibly due to impaired emotion regulation. Consistent with this, a recent study found that poorer overall sleep quality was related to greater difficulty utilizing cognitive reappraisal strategies in response to a sadness-inducing film clip (Mauss, Troy, & LeBourgeois, 2013).

There is also mechanistic understanding of why sufficient sleep enhances emotional functioning (Goldstein & Walker, 2014), focused on the role of rapid eye movement (REM) sleep. In this regard, REM sleep has been shown to be central to emotional memory consolidation (see Walker & van der Helm, 2009, for a review). Additionally, REM sleep is proposed to aid in resolving the strong emotions associated with challenging memories, serving as a sort of "overnight therapy" (Walker & van der Helm, 2009). REM sleep has also been implicated in recalibrating the emotional brain before the next-day emotional events, thus restoring appropriate emotional reactivity (Goldstein & Walker, 2014). The centrality of REM sleep in emotional functioning is consistent with the observed REM abnormalities associated with daily affect (Vandekerckhove & Cluydts, 2010) and REM alterations commonly observed in psychiatric samples, particularly MDD and posttraumatic stress disorder (PTSD; Baglioni et al., 2010).

Summary and Future Directions

There continues to be disagreement over the purpose of sleep and why it is conserved across species despite drastically varied predatory environments. However, it is clear that one function may be to maintain adaptive emotional functioning—by resetting the limbic machinery each night for greater connectivity between aspects critical to emotion regulation, such as the medial prefrontal cortex and amygdala. Chronically disrupted sleep leads to greater negative mood, less positive mood, and in the extreme, affective disorders. In some cases, acute and chronically disturbed sleep predicts greater reactivity to an acute lab stressor, such as in terms of blood pressure and proinflammatory responsiveness. Acute sleep deprivation appears to shape affective experience as well, although few studies have actually assessed the dynamics of emotional experience across the day. Therefore, it remains unclear whether acute sleep loss affects the diurnal rhythmicity of positive and negative mood, which tends to change significantly from waking to bedtime. There is some evidence to suggest that circadian rhythms play a role, particularly with regard to positive affect. Research methods using both standardized lab stimuli, employing state-of-the-art emotional probes, and EMA to examine the architecture of affective experience of a day would shed light on the complex dynamics between sleep and affect. Sleep can vary across several distinct dimensions, including type (REM, non-REM), ability (initiation, maintenance), form (amount, structure), and occurrence (timing, variability; Walker & Harvey, 2010). The extent to which each dimension contributes to the generation and regulation of emotion remains to be discovered.

Another open question in sleep research is whether improvements in sleep can promote long-term changes in emotion. Indeed, behavioral sleep interventions are remarkably effective in improving sleep quality among individuals with clinical sleep disorders (e.g., insomnia; Edinger & Means, 2005), and while affective processes are not primary outcomes in trials testing the efficacy of sleep interventions, there is accruing evidence that improvements in symptoms of depression, anxiety, and overall quality of life often co-occur with resolving sleep (e.g., Thorndike et al., 2013). Unfortunately, a sophisticated exploration of the affective processes that may underlie some of these findings, as well as identification of individual differences that may contribute to success of the sleep treatment for some but not others, has been lacking. Accordingly, there is unique space for affective and sleep scientists to work together to explore these processes and improve health and well-being.

Eating

Culturally speaking, the power of food to comfort us has been assumed across many centuries, as early as 1615 in the first modern novel *Don Quixote*, in which Cervantes penned the line "All sorrows are less with bread" (p. 537). The rigorous study of how eating behavior affects emotions is, however, sparse. The effects of emotions—in particular, negative emotional states or stress—on eating are summarized in several reviews (Adam & Epel, 2007; Greeno & Wing, 1994; Sinha & Jastreboff, 2013; Wardle, Chida, Gibson, Whitaker, & Steptoe, 2011), and several of the most commonly used scales to measure eating behavior contain emotional eating subscales (Stunkard & Waterland, 1997; Van Strien, Frijters, Bergers, & Defares, 1986). Emotion is clearly important in triggering eating behavior, but does this eating behavior have consistent effects on changing emotional experience? If so, for who, and for how long? What are the long-term consequences?

Chronic Eating Behaviors

Chronically Disordered Eating, Emotions, and Affect

Individuals with eating disorders (anorexia nervosa and bulimia nervosa) report higher emotion regulation difficulties and have attentional biases toward negative emotional stimuli (Harrison, Sullivan, Tchanturia, & Treasure, 2010). Emotion regulation is particularly relevant to binge-eating disorder, with negative affect being the most commonly reported triggers for binge episodes (Polivy & Herman, 1993). In a clinical sample of treatment-seeking patients with binge-eating disorder, for example, emotional eating was related to fewer emotion regulation strategies, lack of emotional clarity, and difficulty accepting emotions (Gianini, White, & Masheb, 2013). Although studies of emotion regulation in eating-disordered populations are often framed as emotion regulation failure causing the disordered eating, many of these studies are cross-sectional, and therefore the converse—that eating disorders yield negative emotion regulation strategies—should also be considered.

Chronic Dietary Restraint and Dieting

Dieting is a common health behavior that can affect emotional states as well. Here we review studies on (1) diet interventions, which lower caloric intake; (2) self-reported dieting status (e.g., "Are you currently on a diet?"); and (3) chronic *dietary restraint*, which is not necessarily associated with lower caloric intake.

The negative emotional sequelae of severe caloric deprivation itself have been documented since the 1950s, beginning with Ansel Keys's seminal Minnesota Starvation Experiment using conscientious war objectors (Keys, Brozek, Henschel, Mickelson, & Taylor, 1950). In that study and others, negative emotional symptoms following dieting interventions included depressive symptomatology, anxiety, nervousness, weakness, and irritability (Stunkard & Rush, 1974; Stunkard, 1957). In experimental studies, dieting can cause depressive symptomatology in both animals (Chandler-Laney et al., 2007; Jahng et al., 2007) and humans (Wadden et al., 2004). Other human experimental data has indicated that dieting causes negative emotion after eating (Hetherington & MacDiarmid, 1993), as well as self-blame and negative views of one's character (Jeffery, French, & Schmid, 1990). In one of the few studies designed to examine the stress of dieting, in a randomized, controlled experiment, participants assigned to a 1,200-kilocalorie diet for just 3 weeks increased in both perceived stress and diurnal salivary cortisol levels, thereby providing causal evidence of dieting as an elicitor of the stress response (Tomiyama et al., 2010).

However, many intervention studies also find positive emotion effects of dieting. A paper that reviewed 10 studies of the mood effects of behavioral weight loss therapies found six out of 10 studies (separate from those above) showed an improvement in mood posttreatment while the other four showed no significant change in mood (Wing, Epstein, Marcus, & Kupfer, 1984). One short-term experimental study also observed improvements in depressive symptomatology (Bryan & Tiggemann, 2001).

In terms of self-reported dieting, depressive symptomatology appears to be one of the most common correlates of dieting in cross-sectional human studies (Ackard, Croll, & Kearney-Cooke, 2002; Cachelin & Regan, 2006; Crow, Eisenberg, Story, & Neumark-Sztainer, 2006; Gillen, Markey, & Markey, 2012; Isomaa, Isomaa, Marttunen, Kaltiala-Heino, & Bjorkqvist, 2010; Wadden, Stunkard, & Smoller, 1986). Other correlates of self-reported dieting status include anxiety symptoms (Isomaa et al., 2010). Similarly, higher dietary restraint is associated with greater depression (Cachelin & Regan, 2006), higher perceived psychological stress (McLean & Barr, 2003), and higher urinary levels of the stress hormone cortisol (McLean, Barr, & Prior, 2001).

Acute Eating Behavior

In terms of acute/experimental effects of eating on emotion and emotion regulation, several studies have examined effects of acute stress reactivity and negative mood on eating during recovery from stress. While some studies have shown that acute high cortisol reactivity predicts greater snacking after stress (Epel, Lapidus, McEwen, & Brownell, 2001; Newman, O'Connor, & Conner, 2007), other studies have found important moderators that suggest people with more stress eating may have underlying profiles of cortisol hyporeactivity. One study found that emotional eating moderated the relationship between cortisol responses to a standardized laboratory stressor (Trier Social Stress Test) and subsequent food intake, such that high-emotional eaters with a blunted cortisol response to the stressor ate more food (van Strien, Roelofs, & de Weerth, 2013). Tryon, DeCant, and Laugero (2013) found that chronically high-stress women with low cortisol reactivity ate more food in response to the stressor and had higher total fat percentage. It is unclear whether blunted stress response is a marker for vulnerability to emotional eating, or if emotional overeating dampens stress reactivity chronically, or both. In rodent research, chronic access to palatable food leads rats to develop abdominal fat, which then functions to dampen physiological stress responses at every level of the hypothalamic–pituitary–adrenal (HPA) axis (Dallman et al., 2003)—a phenomenon termed the "chronic stress response network" (Dallman, 2010; Dallman et al., 2003, 2004). Human research on this phenomenon is sparser, but one cross-sectional study found positive correlations among high chronic stress, emotional eating, and abdominal obesity, where high-stress women demonstrated dampened HPA axis activity (lower cortisol responses to a standardized stressor as well as lower daily cortisol levels; Tomiyama, Dallman, & Epel, 2011).

A small number of studies have examined food's effect on affect, rather than on stress response. Macht and Mueller (2007) found that compared with water, chocolate (but only palatable chocolate) ameliorated negative mood, although the effects were short-lived on the order of 3 minutes. In a different study by this group (Macht & Dettmer, 2006), however, both chocolate and apple consumption showed positive mood effects as long as 90 minutes after consumption. Interestingly, these positive mood effects were concurrent with guilt effects, particularly in the case of chocolate. Hetherington and MacDiarmid (1993) observed that positive mood effects of food occur only during the moment of eating, with negative emotions returning soon thereafter. Bongers, Jansen, Havermans, Roefs, and Nederkoorn (2013) found a positive correlation between calories consumed and mood improvement on a visual analog scale, regardless of whether the eating was induced by a negative, neutral, or positive mood-eliciting film clip. Finally, a study of adolescent young adult females found that the relationship between stressful life events and perceived stress was attenuated in self-reported emotional eaters (Finch & Tomiyama, 2015). However, this attenuation was not observed in those high in depressive symptoms, pointing to the complexity of the effect of eating behavior along the many different dimensions of affect.

Clearly, emotions must be measured frequently to capture acute effects of eating, and palatability of food may matter. Across three well-controlled lab studies, Wagner and colleagues (2014) sought to determine whether "comfort" food had comforting properties. Participants in these studies watched negative emotion-inducing film clips and were fed their top-ranked comfort food (including their desired brand and flavor) or a control food (a low-ranked noncomfort food), a neutral food (granola bars), or no food in respective studies. Comfort foods did indeed lead to significant improved mood, but no more so than any of the control conditions (which included no food at all), prompting the authors to determine that comfort food was a "myth." It is possible that for some people, when facing naturalistic life stressors that cause larger affective responses than the lab-based stressor, comfort eating might promote quicker recovery from negative affect through distraction or neural mechanisms of reward. It may also be that eating motives shape emotional response. Parker, Parker, and Brotchie (2006), based on their literature review, conclude that eating to feel better prolongs dysphoric mood, whereas eating to satisfy cravings provides hedonistic reward and improvements in mood.

Nutritional scientists have come at this question with a different lens by identifying chemical properties of food that might have psychoactive properties. Food contains substances such as carbohydrates, protein, fat, caffeine, tryptophan (the precursor to serotonin), and theobromine (a stimulant that is relatively high in chocolate), all of which can affect emotions (Rogers, 1995). These emotion effects are sometimes observed only when the relative ratio of one substance to another is altered. For example, food that is high in carbohydrates but low in protein can increase the ratio of tryptophan to other large neutral amino acids and therefore affects central serotonergic function (Markus et al., 1998; Wurtman, Hefti, & Melamed, 1980). Beyond chemical substances, the orosensory properties of food (i.e., sweetness as opposed to sucrose content) can also have emotion effects. Administering sugar (vs. water) to infants reduces crying (Ramenghi et al., 2002; Smith, Fillion, & Blass, 1990), and these effects can be seen with nutritionally insignificant amounts of sucrose, implicating orosensory effects. These effects are likely mediated through opioid peptides (Kirkham & Cooper, 1988). Rogers's (1995) review of the chemical properties of food highlight other notable inconsistencies in the literature, such as the fact that mood-altering chemicals in chocolate occur at much higher levels in foods not often used for mood effects (Rogers & Smit, 2000), and note the importance of culture, learned preferences, and moderators such as dietary restraint. Examining key mediators and moderators, as well as nutritional and orosensory components, may provide a fuller picture of the effects of eating on emotions.

Neural Mechanisms of Eating and Affective Experience

The neural mechanisms that govern eating are complex and deeply intertwined with affective and emotional experience, and beyond the scope of this chapter. Here we highlight a few key models that specifically address affective and emotional *responses* to eating behavior, as that is the focus of this chapter. The aforementioned chronic stress response network as put forth by Dallman and colleagues (Dallman, 2010; Dallman et al., 2003) describes decreased basal corticotropin-releasing factor (CRF) in the hypothalamus of rodents that have consumed "comfort foods" under conditions of chronic stress. In this model, comfort foods also lessen chronic stress-induced dopamine inhibition (by preventing inhibition of dopamine output and increasing dopamine transporter activity) in the nucleus accumbens seen under chronic stress. Furthermore, comfort-eating behavior promotes intra-abdominal fat stores, which go on to act as a surrogate negative feedback signal, suppressing hypothalamic CRF expression (Dallman et al., 2004). These neural mechanisms, however, have yet to be confirmed in humans. In their reward-based stress eating model, Adam and Epel (2007) describe the ability of palatable foods to stimulate endogenous opioid release in the brain, which in turn function to attenuate the HPA stress response. Stress further sensitizes the brain to the rewarding value of palatable food, leading to a chronic drive for palatable food, and chronic suppression of the stress response. In our unpublished data from a large weight loss trial, we find that women with a blunted cortisol response to a stressor have both a greater drive to eat and a significantly greater likelihood to regain weight earlier, underscoring the tight links between eating and reactivity. Causality is unknown but the rodent studies suggest that palatable food consumption can precede the blunted reactivity.

Summary and Future Directions

Eating is a complex behavior, with many factors to consider such as overeating versus dieting, nutrient content versus orosensory properties of food, and time course of emotion effects due to eating behavior—the latter particularly in the context of acute eating given the conflicting literature. Furthermore, the potential negative emotional consequences of dieting, which is typically considered "healthy," should not be overlooked. Conversely, the positive emotional effects of being on a diet should be better understood. We must understand how dieting can promote both positive and negative emotion. What type of restricted eating behavior promotes positive emotion, and for what type of person? Can we tailor interventions so that people have positive emotion as a reinforcement and less of the "stress of dieting," and are thus more likely to adhere?

Alcohol

"Drown your sorrows" is an adage that captures the emotion-dampening role of alcohol. For centuries, humans have turned to alcohol in response to emotions (Sayette, 1993). How does imbibing alcohol, in turn, affect emotion? Of the health behaviors discussed in this chapter, the theory and literature on alcohol's effect on emotions is the most long-standing. The dampening effect of alcohol on negative emotion is one of the key examples of Hull's (1943) drive reduction theory of motivation from the 1940s. An often-cited study from this decade showed, for example, that cats provided ethanol demonstrated reduced tension and cat neurosis (Masserman & Yum, 1946). Conger (1956) then formally characterized the tension reduction hypothesis of alcohol in the 1950s, which has spawned nearly 70 years of research on what the literature has termed "stress-response dampening" (SRD; Levenson, Sher, Grossman, Newman, & Newlin, 1980; Sher & Walitzer, 1986) resulting from alcohol consumption (Sayette, 1993).

Chronic Alcohol Use

The effects of chronic alcohol use and alcoholism on emotion have been studied during use and in response to withdrawal. Anxiety and depression are often comorbid with alcoholism, although in some cases a pathological absence of anxiety (externalizing psychopathology) is also observed (Heilig, Egli, Crabbe, & Becker, 2010). Increased anxiety is a hallmark of alcohol withdrawal, and poses a risk for relapse during treatment (Heilig et al., 2010). In later stages of alcohol withdrawal, heightened stress sensitivity (Lovallo, Dickensheets, Myers, Thomas, & Nixon, 2000) and upregulated HPA axis responsivity (Heilig & Koob, 2007) are observed. In recently abstinent alcohol-dependent individuals, however, hyporesponsivity of the HPA axis is observed (see Adinoff, Junghanns, Kiefer, & Krishnan-Sarin, 2005).

Acute Alcohol Use

The acute effects of alcohol use on stress reactivity have been widely studied in the SRD literature. Stress has been operationalized using a variety of measures. Rat models demonstrate a direct SRD effect, wherein ethanol administration dampens basal corticosterone levels (Brick & Pohorecky, 1985) as well as corticosterone responses to foot shock, restraint, and tail pinch stress (Brick & Pohorecky, 1982). In humans, acute alcohol consumption has been shown to dampen self-report measures of anxiety and distress, such as the State/Trait Anxiety Inventory (Spielberger, 2005) and physiological measures such as galvanic skin response and cardiovascular reactivity as measured by heart rate (Sayette, 1993). Despite these and other empirical studies, notable inconsistencies in the literature are evident (Wilson, 1988). For example, researchers have observed a "crying-in-your-beer" effect, wherein alcohol consumption can exacerbate negative emotions (Steele & Josephs, 1988). Indeed, for every paper indicating SRD effects in self-report, physiological, and behavioral stress, roughly equal numbers of studies fail to find effects in these very outcomes (Sayette, 1993). Even within studies examining physiological outcomes, alcohol effects can diverge, with significant findings for some measures and not others (Stritzke, Lang, & Patrick, 1996). A number of theoretical approaches have been advanced to reconcile these conflicting findings. Most notable are the Steele and Josephs's (1988, 1990) attention allocation model (later renamed the alcohol myopia model), Sayette's (1993) appraisal disruption model, and Hull's (1981) self-awareness model.

Noting that none of the existing models of alcohol and emotion was able to account for the many divergent findings, Stritzke and colleagues (1996) outlined several methodological issues to consider, including lack of consistent operationalization of "stress," both in terms of experimental manipulations and outcome measures, variation in time sampling, and variation in data analytic procedures. They called for multilevel, multidimensional models of emotion/affect that simultaneously take into account, for example, appetitive versus withdrawal motivations, positive and negative valence, and primary motivational systems versus higher cognitive functions. They also called for experimental designs that do not confound the physiological effects of alcohol with the outcome measures. For example, alcohol pharmacologically increases heart rate, and therefore using heart rate to index emotional arousal would be unproductive (Stritzke et al., 1996).

The phrase "drown your sorrows" suggests that dampening negative emotion is the predominant reason for alcohol use, but individuals also use alcohol to experience positive emotion. Among recovering alcoholics, the reasons cited for relapse are not only reducing negative emotions but also actively seeking euphoria (Marlatt & Gordon, 1980). Individuals also use alcohol acutely to increase positive emotions, particularly when fatigued or underaroused (Wills & Shiffman, 1985), or when drinking with social motives (Cooper, Frone, Russell, & Mudar, 1995).

Neural Mechanisms of Emotional Response to Alcohol Consumption

Alcohol, unlike food, is processed centrally by the central nervous system (CNS). The stimulant/depression hypothesis of alcohol accounts for both the positive and negative emotions that arise out of alcohol consumption (Tucker, Vuchinich, & Sobell, 1982). At low to moderate levels, alcohol is presumed to act as an emotional stimulant and euphoriant (or "elatant"), whereas at higher levels, alcohol acts as an emotional depressant (Stritzke et al., 1996). Another conceptualization that takes into account the arc of CNS metabolism of alcohol is the slope of intake; rather than simple blood alcohol levels, the "rising limb" of the blood alcohol content curve is presumed to be stimulating and elating, whereas the "falling limb" of intoxication acts as an emotional depressant (Newlin & Thomson, 1990; Stritzke et al., 1996). In support of this, euphoria ratings and EEG alpha activity were closely tied to the rising blood alcohol curve in one study, but only at moderate (not low) doses (Lukas, Mendelson, Benedikt, & Jones, 1986).

Summary and Future Directions

Taken together, substantial research supports the existence of a relationship between alcohol and changes in emotional experience. However, the literature is extremely conflicted, pointing to the existence of many dispositional and situational moderators (summarized in Sayette, 1999). Regardless of whether drinking actually elicits positive or negative emotion, it is clear that individuals *expect* changes in emotional states—and these expectations may be the most fruitful area for intervention. In the validation sample of the widely used Alcohol Expectancies Scale (Brown, Christiansen, & Goldman, 1987), "physical and social pleasure" and "relaxation and tension reduction" were among the subscales with the highest endorsement (Brown, Goldman, Inn, & Anderson, 1980). Indeed, interventions that target these expectancies have had success in the short term (Darkes & Goldman, 1993; Scott-Sheldon, Terry, Carey, Garey, & Carey, 2012).

Future research should identify individual differences that govern differential responses to alcohol, with careful calibration of blood alcohol content given the physiological actions of alcohol. Do emotional effects on a person predict vulnerability to addiction, or treatment response? For example, those who evidence subjective sensitivity to the stimulating properties of alcohol (e.g., those who feel "elated" and "excited"; Martin, Earleywine, Musty, Perrine, & Swift, 1993) relative to the sedating properties of alcohol (e.g., those who feel "down") are at greater risk of developing alcoholism (Ray, Mackillop, & Monti, 2010). Finally, as alcohol contains calories, the fields of eating behavior and alcohol consumption should intersect, and future studies should also examine the two behaviors in tandem as they relate to emotional experience.

General Conclusions and Future Research Directions

Our emotional life, starting early in life, shapes our pattern of health behaviors in ways that are difficult to change. While the transactional process between emotions and health behaviors has been a focus of some scientific inquiry, one angle that has received little attention is whether engagement in health behaviors shapes emotional processes, and if this, in turn, has consequences for future health behaviors. This review shows that health behaviors have potent effects on immediate affective and emotional responses, longer-term mood states, appraisal of stressful situations, and stress reactivity.

While our review also highlights specific areas in the brain that play a role in modulating emotional states and affective responses to stress in response to each specific behavior, it is important to move beyond the idea that there is any type of one-to-one mapping of brain region and function. While each has been studied in isolation, recent reviews highlight common underlying brain regions for many health behaviors and emotions (Barrett & Simmons, under review; Lenard & Berthoud, 2008). Barrett and Simmons (under review) and Lenard and Berthoud (2008) highlight the key role of the limbic region to gauge and modulate glucose storage and usage in the body, and to promote behavioral modifications (e.g., increased or decreased food intake, exercise, sleep) accordingly to access more or use fewer nutrients (or vice versa). Emotions are the interoceptive experiences of the incongruence between the nutrient needs and usage of the body and memories from previous experiences. Emotions can thus result from or promote/hinder behavioral engagement. Within this context, for example, the findings that exercising beyond our physiological thresholds stimulates negative affective states (Ekkekakis et al., 2008; Ekkekakis & Petruzzello, 1999; Hall et al., 2002; Welch et al., 2010) makes biological sense. The negative affective state that is reached when one surpasses his or her threshold is perhaps the interoceptive experience resulting from a physiological imbalance that attempts to provoke disengagement of the activity.

We propose that a deeper understanding of the behavior–affect trajectory, in part by adopting a transdisciplinary framework, may lead to powerful insights into how to tailor interventions for better adherence and ultimately mobilize this information for health promotion at the individual and population level (Figure 40.1). We further propose that the study of chronic health behavior effects would be best performed through long-term interventions that examine the process of change, as well as an examination of dose–response effects, and a closer examination of affect valence and arousal dynamics (Kuppens, Tuerlinckx, Russell, & Barrett, 2013).

There is tremendous potential to learn about the development and maintenance of health behaviors by applying an emotion research lens. Emotion research provides a fresh perspective on the old but important questions such as Why do some people adopt and adhere to health behaviors, both salutary (sufficient exercise and sleep) and damaging (overeating and alcohol abuse)? It also raises new questions at the heart of the emotion–health behavior processes, such as How can we capitalize on the finding that, in many cases, doing what is good for us feels good? Further, how do we reconcile that harmful appetitive behaviors, like overeating, make us feel good in the moment but often promote more negative affect than positive in the long term? Using the methodology of emotion research for a more mechanistic view of how health behaviors affect emotional and affective experiences and regulation will provide a large step forward in this field. Such information might be applied to promote more effective interventions.

We call for a new generation of research that takes on understanding the health behavior–emotion relationship with greater granularity. Specifically, we believe that it is critical that research investigate the emotional antecedents and consequences that bookend both salubrious and deleterious health behaviors, with attention to both valence and arousal, and their interrelationship (Kuppens et al., 2013; see Figure 40.1). Factors that increase postbehavior positive affect or reduce postbehavior negative affect should be identified and capitalized on. For example, manipulating positive expectations appears to have at least a short-term effect on positive affect and intentions to engage in the behavior again.

The first steps in laying a foundation in this area would be a fuller examination of emotional experience throughout the health behavior process—before onset of health behavior, during, in recovery, and long-term effects. For people who do not have the habit of a behavior (e.g., not a regular exerciser) what is the valence, arousal, and duration of positive and negative emotions arising from a bout of a new health behavior (e.g., a bout of exercise)? Do emotional effects last across a day or spill into subsequent days, and what determines duration? Does the health behavior impact the balance of positive and negative valence, evoke specific types of emotions, and/or alter appraisal processes? Such studies will require both laboratory experiments, EMA methods in naturalistic environments, and randomized behavioral interventions. **Without a within-person examination of behavior and affect dynamics, intervention data will be of limited utility in explaining individual differences in uptake and adherence of new behaviors.**

There is also a need to identify important individual differences in the behavior–emotion relationship, which may be behavior dependent. As noted above, both fitness level and dietary restraint appear to matter for exercise and for eating, respectively. Genetic propensities, personality, or emotional differences are likely important as well. It will also be important to more closely examine the mechanisms through which the health behavior modulates and improves emotional responses. For instance, the specific emotion regulation processes underlying exaggerated stress sensitivity and how they shift after behavioral interventions are key to our understanding of the emotional benefits of behavior change.

The science of emotion and behavior change hold great promise for improving individual and population health. It is clear that investigations of chronic and acute effects of specific health behaviors provide important information about emotions, affective states and regulatory processes, and their underlying neurobiology. Innovations in physiological assessment, including neuroimaging, and in sampling daily experience, provide windows into health behavior–emotion processes once hidden from view. Future research focused on teasing apart and carefully tracking the dynamic and recursive processes linking emotion and health behaviors will, without question, advance our science of both, and thus our ability to promote lifelong health at its roots.

CHAPTER 41

STRESS AND EMOTION

Embodied, in Context, and across the Lifespan

Barbara Ganzel, Jason R. D. Rarick, and Pamela A. Morris

In this chapter, we examine the relationship between stress and emotion within the context of a novel bioecological model, *triple-network allostasis* (Ganzel & Morris, 2016). Triple-network allostasis is the result of integrating a developmentally informed model of allostasis (Ganzel, Morris, & Wethington, 2010; Ganzel & Morris, 2011) with new findings about the large-scale functional architecture of the brain. We initially presented triple-network allostasis as a lifespan diathesis-stress model (Ganzel & Morris, 2016); this allowed us to more closely examine mechanisms through which life stress interacts with an individual's accumulating physiological predispositions to impact the large-scale neural networks of the brain, thus driving psychopathology onset and the course of mental illness. Here, we expand this model to include nonclinical populations, using it to examine long-term developmental and stress-related changes in core affect and emotional response in individuals who do not have a clinical disorder. In doing so, we raise novel questions about the relationships among stress, distress, core affect, and emotion across the lifespan. These, in turn, have implications for interventions to promote social-emotional well-being at all ages. We conclude by arguing that allostatic models need not and should not be limited to representation of the stress process, but rather may serve as a more general framework for modeling an organism's biopsychosocial functioning in a changing, challenging environment, over time and across the lifespan.

We write this chapter from our perspective as developmental psychosocial stress researchers. Taken together, our own published work spans multiple levels of analysis from neurons to national policy, and from infancy to the end of life. From this stance, it is a short step to embracing the human brain as developing, embodied, and intrinsically embedded in a dynamic social and physical environment. The core tenets of our argument may appear obvious: stress impacts health and behavior; brain function links a psychosocial stressor to stress-related behavior and changes in health; the brain exists in a body; the body exists in context; age-related brain/body change doesn't stop until brain/body function stops. We have found, however, that careful analysis of these associations leads to unexpected insights, as well as novel and interesting questions for future research (Ganzel et al., 2010; Ganzel & Morris, 2011; Ganzel & Morris, 2016). Our goal for this chapter is to expand this work to include a consideration of core affect and emotional response, and to examine the implications of this new model for theory and intervention.

Based on our prior work, we consider the entire stress process to be *relational* in that there are profound reciprocal influences among a given stressor, the individual (body, brain, and mind) in which the stress process occurs/manifests, and the broader physical and social environment in which the individual is embedded. As such, *the stress process itself* can be expected to change as a function of events or chronic conditions in the physical and social environment. We have examined mechanisms and supporting evidence for this phenomenon, concluding with a bioecological model of the stress process based in the concepts of allostasis and allostatic load (Ganzel et al., 2010). The theory of allostasis places the brain at the center of this interplay over time among a stressor (in its context), stress-related changes in physiology and mental state, and stress-related behavioral and health outcomes (Bronfenbrenner & Morris, 1998; McEwen & Stellar, 1993; Sterling, 2004; Sterling & Eyer, 1981).

The stress process is also *embodied*, in that it occurs within the body and as a function of bodily physiology. As noted, allostasis requires that the stress process be mediated by the brain (Ganzel et al., 2010; Sterling & Eyer, 1981; Sterling, 2004). Because of this central mediation, we have argued that *the stress process itself changes continuously across the lifespan* as a function of ongoing age-related physiological change (particularly in the brain). Thus, stress outcomes would be expected to vary systematically as a function of age across the lifespan. We have examined evidence for these effects in prior work, concluding with a developmentally informed allostatic model of the stress process (Ganzel & Morris, 2011, 2016).

At the heart of the present chapter are the relationships between stress processing and emotion processing in the brain and body. These processing streams have outcomes variously termed "distress," "core affect" and/or "emotion," and "emotion regulation," depending on the field of research. These concepts and terms are not often considered together in the literature. We argue here that these are related, often overlapping constructs that are united by their common neurobiology within the framework of *salience processing*, described below. The implications of these relationships are potentially far-reaching, as we discuss throughout and especially in our section "Future Directions."

In the section that follows, we review the relationship between *stress* and *distress* as these constructs developed in biology, sociology, and psychosocial stress research. We follow that with a discussion of the neural mechanisms of stress processing and introduce triple-network allostasis in more detail. In the process, we also introduce the concept of salience, along with salience processing, the salience network, and the other canonical large-scale neural networks of the brain. We next discuss the extensive overlaps in the function and neurobiology of stress-related distress, core affect, and indeed emotion itself. We then extend this to a discussion of emotion regulation, a highly related concept with direct applications to intervention. The implications of these associations are addressed, and we present a lifespan model of triple-network allostasis that includes these outcomes. We end our chapter with "Future Directions," where we discuss the next stages of work that might follow from this new model, with relevance for intervention as well as for a future research agenda to test the opportunities and constraints of our new model. We conclude briefly in the final section.

Stress and Distress

The General Adaptation Syndrome

"Stress" and "distress" are terms used in sociological, biological, and psychosocial stress research (e.g., Lagner & Michael, 1963; Ward et al., 2008). These domains of inquiry have their roots in the mid-20th century, when Hans Selye (e.g., 1956) described a general-purpose multistage physiological syndrome that occurs in response to threats to the integrity of the organism; he called this the general adaptation syndrome (GAS). The lynchpin of Selye's (1950, 1956) GAS is activation of the hypothalamic–pituitary–adrenal (HPA) axis, resulting in the production of corticosteroids (cortisol, in humans and other primates). Corticosteroids, in turn, act globally but relatively slowly to mobilize the body's energy resources to help resist the precipitating threat.

Selye (1956) redefined the colloquial term "stress" to mean "that which stimulates the GAS response" (p. 54). Using rodents as his laboratory models, Selye (1950) tested the uniformity (a.k.a. the *nonspecificity*) of the GAS across a very broad range of physical threats. He concluded that threats to the biological integrity of the organism invariably activated the stress response (1956). Selye's work prompted literally thousands of articles across the fields of medicine, biology, psychology, and sociology (Goldstein, 1995b; Mason, 1975a). In many of these discussions, stress (more properly, the *stressor*) came to mean any stimulus that prompts HPA axis activation and increases production of cortisol, which in turn became synonymous with a generalized, nonspecific *stress process*.

The GAS was thus conceptualized as the process linking stress and *distress* (i.e., negative mental states; Wheaton & Montazer, 2010) and it was often considered to be the physiological link between stressor exposure and adverse mental and physical health.

Over time, it became clear that Selye's (1950, 1956) GAS incompletely describes the human stress process. The GAS does not, for example, explain the importance of cognitive and emotional responses to a stressor (anticipation, appraisal, coping, learning) in determining health outcomes (e.g., Foa & Kozak, 1986; Lazarus, 1991; Siegel & Allan, 1998; Sterling & Eyer, 1988; Stone, 1995; Toates, 1995; Tolin & Foa, 2002; Wheaton, 1985). Nor does the GAS account for the critical contributions of past and current stressor context, such as socioeconomic status or social support (e.g., Baltes & Baltes, 1990; Furstenberg, Brooks-Gunn, & Morgan, 1987; Lazarus, 1993, 1999; Masten et al., 1988; McEwen & Gianaros, 2010; Rutter, 1979; Sameroff, Seifer, Barocas, Zax, & Greenspan, 1987; Taylor, Karlamangla, Friedman, & Seeman, 2011). Moreover, the "nonspecificity" of the GAS has come under challenge because the valence and type of stressor often lend substantial variance to stress–health associations (e.g., Mason, 1971, 1975a; Pacák & Palkovits, 2001; Schulkin, 2003). In short, psychological aspects of stressor exposure often play a pivotal role in the human stress response.

Apropos of this point, John W. Mason (1971), an early stress researcher, noted that whenever it is possible to substantially reduce or remove the psychologically "noxious" nature of the stressor, then there *is* no GAS response (p. 326; 1975b). He (1975a) commented that "the knowledge that the psyche is superimposed upon the humoral machinery for endocrine regulation drastically complicates our whole view" (p. 177).

Homeostasis versus the Psyche

Other major theories of physiological regulation have run afoul of the psyche. There has been an ongoing struggle to modernize the core principles of homeostasis (Cannon, 1920, 1932, 1935) in response to concerns similar to Mason's (1975a, 1975b) above. Homeostasis was developed to describe well-defined disturbances to key elements of regulatory physiology that maintain life, such as body temperature and blood oxygen (Ramsay & Woods, 2014). With the application of cybernetics and engineering control theory, homeostasis became synonymous with self-regulation via interrelated negative feedback loops with fixed "set points" (Langley, 1973; Mrosovsky, 1990; Wiener, 1948). Over time, however, there has been growing dissatisfaction regarding the mismatch between the classic homeostatic model and observations of physiological regulation in functioning organisms as they navigate their environments (e.g., Chrousos & Gold, 1992; Goldstein, 1995a, 1995b; Hammel, 1988; Levine & Ursin, 1991; Moore-Ede, 1986; Mrosovsky, 1990; Schultz, 1996; Sterling & Eyer, 1988; Waddington, 1957, 1968). It has been argued that an understanding of integrated, high-level whole-animal physiological regulation is unlikely to come from applications of homeostatic control theory at the molecular level (Woods & Ramsay, 2007; see also von Bertalanffy, 1952, on general systems theory as applied to biology). Furthermore, Ramsay and Woods (2014, p. 236) argue that there is "no indication" that homeostasis as initially conceived was intended to "address the effect of complex psychosocial stressors on physiological processes relevant to health and illness" (see also Woods & Ramsay, 2007).

But what is and is not a "complex psychosocial stressor" in the alert individual with a functioning brain (as compared with an organism that is, for eample, dissected and *in vitro*)? Sensory input from all types of stressors is channeled through the brain before affecting any other physiological regulatory response, and this input is modified by expectation and evaluation. Levine and Ursin (1991) argued that this is true even for stressors that do not appear overtly "psychological," such as cold exposure and tissue damage; this is because novelty, expectation, and efforts to avoid noxious stimuli will all activate memory and cognitive-emotional response (e.g., Pessoa, 2015). Any two individuals have unique biologies, life experiences, and contexts, so that their memories and cognitive-emotional responses will differ, even to a stressor held in common. In fact, it is argued that virtually *no* type of life event is uniformly viewed as negative or positive (Hardy, Concanto, & Gill, 2002; Hughes, George, & Blazer, 1988), which suggests that there is a critical psychosocial component to all occasions of stressor exposure.

Allostasis

These and similar questions prompted Sterling and Eyer (1988) to introduce *allostasis*, a replacement (Sterling, 2004) or update (e.g., McEwen, 2004) of classical homeostasis in which the brain exerts control over internal regulation in order to match physiological and behavioral response to environmental demand (Schulkin, 2003). Under allostasis, the brain is the central mediator of physiological and behavioral regulation in the alert and functioning organism. As such, it is the primary point of interface between a given stressor (in its physical and social context) and stress-related changes in health and behavior. To this theory, McEwen and Stellar (1993) added the concept of *allostatic load*, wherein adaptive changes to achieve the regulatory goals of allostasis create physiological wear and tear (the accumulating cost of allostatic adaptation). In this theory, allostasis provides adaptive regulation and reduces distress in the short run—but accumulating allostatic load may result in increased distress, dysregulation, and ill health if the individual lives long enough to experience the long-term costs of adaptation (e.g., Repetti, Robles, & Reynolds, 2011). The broad dissemination and application of allostatic theory has given it the status of "a new conceptual framework" for the study of stress (Schulkin, Gold, & McEwen, 1998, p. 220), with applications in both the social and life sciences (e.g., Koob & Le Moal, 1997, 2001, 2005; McEwen, 1998, 2000, 2003a, 2003b, 2003c; McEwen & Gianaros, 2010; McEwen & Seeman, 1999, 2003; McEwen & Stellar, 1993; Ramsay & Woods, 2014; Schulkin et al., 1998; Schulkin, McEwen, & Gold, 1994; Schulkin, 2003, 2004; Singer, Ryff, & Seeman, 2004).

Stress and Salience

Our exercise here is to extend theories of allostasis beyond the stress process; to do so, we draw now on the concept of salience and salience processing. This allows us to move toward our discussion of emotion, which we link to concepts of stress in the section "Stress and Emotion."

A Consideration of Salience and Two Propositions

A salient stimulus stands out. It attracts attention and is motivating because of its innate or learned biological relevance (e.g., Phan et al., 2004). A charging tiger and a delectable dessert are both salient, as is a winning lottery ticket or an angry manager at your workplace. Human and nonhuman primates can learn about a stimulus's salience vicariously (e.g., by social observation; Öhman & Mineka, 2001), and humans have the added advantage of being able to learn about the salience of a stimulus through instruction (Hugdahl & Öhman, 1977; Olsson & Phelps, 2004). For humans, salience-related processing can be triggered by even mild experimental stimuli, such as losing an intangible representation of money during a computer game (e.g., De Martino, Kumaran, Seymour, & Dolan, 2006; De Martino, Camerer, & Adolphs, 2010).

Proposition 1: Bridging salience and stress. *Stressors are intrinsically salient. Moreover, any salient stimulus can be defined as a stressor if it has the quality of being undesirable (i.e., aversive or "noxious").*

Proposition 1 is plausible because stressors and aversive salient stimuli are both defined as having innate or learned "biological relevance" (Phan et al., 2004). They are both intrinsically motivational because of their significance to reducing threat and preserving the safety, health, and/or the "operating integrity of the organism" (Wheaton & Montazer, 2010, p. 173). We argue, in addition, that these constructs are functionally interchangeable—an aversive salient stimulus functions as a stressor and a stressor constitutes an aversive salient stimulus. Stressors must, at their root, have the quality of being aversive in order to engender distress and have negative effects on mental and physical health (Elder, George, & Shanahan, 1996).

Notably, this proposition does not imply that salient events that are typically viewed as positive or desirable may not trigger a stress response. The stress literature initially included many positive life events within the category of stressors (e.g., weddings, promotions; Holmes & Rahe, 1967). This was under the assumption that the important factor was "life change" (i.e., the need for readjustment). However, the weight of research since then has suggested that *undesirability* is the key factor that links stressor exposure, distress, and negative mental and physical health outcomes (e.g., Mueller, Edwards, & Yarvis, 1977; Vinokur & Selzer, 1975). And, of course, we recognize that characteristics of the individual such as self-esteem (Brown & McGill, 1989) or role strain (Thoits, 1992) can make some positive events function as stressors. Proposition 1 leads directly to Proposition 2, in which we adopt the neurobiology of salience processing of aversive stimuli as the core neural mechanism of the stress process—and the central mediator of allostasis.

Proposition 2: Bridging stress processing and salience processing in the brain. *The neurobiology of salience processing (for aversive stimuli) is functionally identical to the neural substrates of the stress process, and thus it constitutes the central mediator of allostasis.*

Substantial gains have been made in recent years in delineating the neurobiology of salience processing. Below, we briefly review this work, with emphasis on the mechanisms and role of salience processing within the large-scale functional architecture of the brain. We then outline the key features of our current model of allostasis, which has salience processing at its core.

Salience Processing in the Human Brain

From this point in the chapter, we use the term "salience" to refer to the negatively valenced salience associated with aversive, threat-related stimuli. The needs of survival require that these stimuli have a privileged status in the brain, even relative to salient stimuli with a positive valence (e.g., Ito, Larsen, Smith, & Cacioppo, 1998; Smith, Cacioppo, Larsen, & Chartrand, 2003). Aversive stimuli co-opt attention and are prioritized in the competition for neural processing resources (e.g., Anderson, 2005; Corbetta, Patel, & Shulman, 2008; Öhman, Flykt, & Esteves, 2001; Vuilleumier, Armony, Driver, & Dolan, 2001; see also Schneider & Shiffrin, 1977). Salient stimuli trigger bottom-up, norepinephrine-driven activation of a large-scale array of coactivating neurons referred to as the *salience network* (Seeley et al., 2007), which is also called the *ventral attention network* (Corbetta et al., 2008; Yeo et al., 2011). This is a rapid and robust (usually temporary) reorganization of neural function that serves to maximize rapid behavioral response (Hermans et al., 2011).

Synchronous neural firing within the salience network generates oscillatory activity across a broad neuronal assembly that has anchoring nodes in the right anterior insula (right AI) and dorsal anterior cingulate cortex (dACC; Seeley et al., 2007; although see Yarkoni, Poldrack, Nichols, Van Essen, & Wager, 2011), as well as the right temporoparietal junction (right TPJ) and right inferotemporal regions (right IFG). Activation of the salience network diverts neural processing resources to reorient attention and foster rapid information processing in network nodes involved in autonomic and neuroendocrine "emergency response" systems (Hermans et al., 2011). Within this network, the right AI plays a prominent role in monitoring and subjective evaluation of personally salient information from outside and inside the body, regardless of whether the precipitating stimulus is cognitive, affective, or homeostatic (e.g., Borsook, Edwards, Elman, Becerra, & Levine, 2013; Downar, Mikulis, & Davis, 2003; Seeley et al., 2007; Uddin, Supekar, Ryali, & Menon, 2011: see Touroutoglou, Hollenbeck, Dickerson, & Feldman Barrett, 2012, for finer-grained distinctions within this system). The dACC has been implicated in both physical and social pain (rejection) detection, as well as in modulation of responses in the sensory cortex, motor cortex (e.g., motor planning), and association cortex (e.g., executive function; Bush, Luu, & Posner, 2000; Eisenberger, Lieberman, & Williams, 2003; Kempermann, Kuhn, & Gage, 1998). The right AI and dACC, in turn, prompt activation in the medial frontal, IFG, and TPJ regions, which underlie the reorienting of attention (e.g., Corbetta et al., 2008) that is necessary to implement behavioral response to a new or unexpected salient stimulus. This functionally integrative network shows heightened activity to negatively valenced stimuli, including uncertainty, pain, empathy for pain, social pain/rejection, metabolic stress, temperature variation, and hunger (Büchel, Morris, Dolan, & Friston, 1998; Craig, 2003, 2008; Critchley, 2004; Critchley et al., 2003; Critchley, Weins, Rotshtein, Öhman, & Dolan, 2004; Downar, Crawley, Mikulis, & Davis, 2002; Downar et al., 2003; Eisenberger et al., 2003; Rainville, Duncan, Price, Carrier, & Bushnell, 1997; Singer et al., 2004; Taylor, Seminowicz, & Davis, 2009; Touroutoglou et al., 2012). The salience network is also responsive to a lesser degree to positive stimuli, such as pleasant touch and seeing the faces of loved ones or friends (Bartels & Zeki, 2004; Craig, 2003).

Studies of the large-scale functional architecture of the human brain have isolated a number of other stable neural[1] networks that are fundamental to the organization of information processing (e.g., Fox & Raichle, 2007; Yeo et al., 2011). For this chapter, we briefly discuss two additional networks, the *central executive network* and the *default network* (Sridharan, Levitan, & Menon, 2008). Together with the salience network, these comprise the primary large-scale neurocognitive networks that underlie attention, memory, and information processing (also called the canonical large-scale networks of the brain; see Plate 41.1a in color insert).

In brief, the central executive network (CEN) shows synchronous activity at its nodes during top-down processing (i.e., in situations that require information maintenance and manipulation in order to generate task-specific, goal-directed behavior; e.g., Anderson, Fincham, Qin, & Stocco, 2008; Koechlin & Summerfield, 2007; Miller & Cohen, 2001; Seeley et al., 2007; Spreng, Sepulcre, Turner, Stevens, & Schacter, 2013). The primary nodes in this network are the dorsolateral prefrontal cortex (PFC) and lateral posterior parietal cortex (PPC), with multiple additional nodes making up this extended neural network (e.g., Habas et al., 2009; Seeley et al., 2007; Tomasi & Volkow, 2011).

In contrast to the CEN, the default network was initially characterized as having synchronous regional activity at rest, rather than during task-specific behavior (Raichle, 2001). Its primary nodes are located in the medial PFC, posterior cingulate cortex, and the posterior inferior parietal lobules (Binder et al., 1999; Fox et al., 2005; Greicius, Srivastava, Reiss, & Menon, 2004; Greicius, Krasnow, Reiss, & Menon, 2003; McKiernan, D'Angelo, Kaufman, & Binder, 2006; Raichle, 2001), with additional nodes in the superior/inferior frontal gyri and the medial/lateral temporal lobes (Buckner, Andrews-Hanna, & Schacter, 2008; Spreng et al., 2013). Previously, default network activation was thought to reflect the internal, intrinsic consideration of one's own experience (thoughts, feelings, memories, goals, and mental "time traveling"; Gusnard & Raichle, 2001; Kelley et al., 2002; Northoff & Bermpohl, 2004; Whitfield-Gabrieli et al., 2011). More recent thinking places the default network in a more dynamic role, in which it actively interacts with elements of the CEN to direct self-generated thought (Andrews-Hannah, Smallwood, & Spreng, 2014; Spreng, 2012). Activity and connectivity in this network have been associated with tasks that involve memory retrieval, reasoning about moral dilemmas, theory of mind, self-reflection, and planning for/thinking about the future (Andrews-Hannah et al., 2014), as well as social cognition (Spunt & Lieberman, 2013), monitoring of the surrounding environment (Gusnard & Raichle, 2001), and the integration of cognition and emotion (Greicius et al., 2003).

Importantly for our models, research indicates that the salience network plays a "critical and causal role" in toggling between the CEN and the default network, thus serving as *a critical hub for internetwork neural switching* (Sridharan et al., 2008). In this role, the salience network detects biologically salient[2] events and has executive control in directing processing resources among the large-scale neural networks to access memory resources, plan goal-directed action, and modulate autonomic response (Kempermann et al., 1998). Central to this role are the right AI and the dACC, which appear to be the key players in salience detection (e.g., Critchley et al., 2004; Critchley, 2005).

This large-scale salience network serves as a "general-purpose" modulatory system for input from multiple overlapping subcortical salience subnetworks ("survival" circuits; LeDoux, 2012). Each of these subnetworks detects a particular class of trigger stimulus that has intrinsic biological value or learned personal value (e.g., avoidance/defense, approach/reward, fluid balance, thermoregulation; LeDoux, 2012). Upon detecting its particular trigger, a salience subnetwork then integrates relevant sensory and motor information to drive appropriate adaptive behavior (e.g., Jennings et al., 2013; Kim et al., 2013; see also Hermans et al., 2011; Seeley et al., 2007). These specific subnetworks, combined with modulation by the large-scale salience network, form an integrated and flexible neural array that serves to represent salient stimuli and produce and regulate behavioral response. We argue that this *extended salience network* underlies an individual's motivational mental state and behavioral response to stressor exposure (Ganzel & Morris, 2016; see also Barrett, Mesquita, Ochsner, & Gross, 2007; Bechara, Damasio, Damasio, & Anderson, 1994; Damasio, 1999; LeDoux, 2012; Rosen & Schulkin, 1998).

Triple-Network Allostasis

We identify this extended salience network as the primary neural mediator of allostasis (Ganzel & Morris, 2016). This concept is at the heart of our triple-network model of allostasis, which is an integration of our prior brain-based models of lifespan allostasis (Ganzel et al., 2010; Ganzel & Morris, 2011) with Menon's (2011) triple-network model of psychopathology (see Ganzel & Morris, 2016, for a full discussion). Here, though, we expand this model to include normative populations.

The extended salience network serves as the central mediator of allostasis because it is the key player in detecting the "biological" significance of external stimuli and/or internal events, and because of its executive role in switching between default network and CEN activity (see previous discussion). The salience network is positioned to integrate information from the salience subnetworks (Cameron, Woolley, McEwen, & Gould,

1993) with interoceptive information (e.g., Damasio, 2003; Rakic, 2009) to facilitate threat evaluation, selection of motor and homeostatic response, and modulation of behavioral response (Touroutoglou et al., 2012). Moreover, the ability of the AI/dACC hub to switch among canonical networks (Kempermann et al., 1998; Sridharan et al., 2008) provides flexible access to autobiographical memory, prospection, and semantic memory via the default network, and to executive control and goal-directed planning via the CEN. Thus, the survival/salience network is the most current and precise representation of an organizing force linking salient stimuli with behavioral and physiological outcome. As such, we argue that the extended salience network necessarily constitutes the primary regulator of allostasis, to which all other physiological and behavioral allostatic accommodation is secondary.

Simplified/No Load. In Plate 41.1b, we present a stress model in standard form: *stressor* → stress response → distress (Wheaton & Montazer, 2010). The *stressor* is the current challenge to the organism, detected via aggregated interoceptive and exteroceptive sensory information (including that from current contextual risks and resources). The *stress response* refers to the perturbation and reestablishment of physiological equilibrium following this challenge. Under allostasis, this may include the resetting of homeostatic set points to establish a *new* physiological equilibrium that is more appropriate to the organism's circumstances (e.g., Sterling & Eyer, 1988; Sterling, 2004). Model outcomes may include mental and physical health (Ganzel et al., 2010; Ganzel & Morris, 2011) or mental and physical state (Ganzel & Morris, 2016). In keeping with our stressor–stress–distress format, above, we elect here to designate our outcome simply *distress*. Stress-related distress is usually defined as a "negative mental state" (e.g., Wheaton & Montazer, 2010) that is associated with broad stress-related changes in physiology and/or health (see Ganzel et al., 2010, for a review).

Starting on the right-hand side of the model in Plate 41.1b, we show how information about the current environmental stressor (in combination with current contextual risks/resources) is processed via the sensory systems to impact the expanded salience network. This network does the work of *central allostasis*, and it serves as the central mediator of physiological and behavioral response to a current stressor. Brain-based central allostasis drives *peripheral allostasis* in stress-responsive systems outside the central nervous system (see Ganzel et al., 2010, for a full discussion). These peripheral processes, in turn, feed back on the brain via interoceptive, hormonal, catecholamine, and immune signals (e.g., Damasio, 2003; Davidson, Maxwell, & Shackman, 2004; Sapolsky, 1998) and generate reverberating psychophysiological effects over time in response to the initial stressor.

Note that this version of triple-network allostasis does not include allostatic load (an omission we correct very soon; see below). In this simplified model, we assume that the individual has no prior experience and thus has acquired no physiological "wear and tear" (load) from accommodating to stress, and also none of the cognitive/emotional associations created by prior stressful experiences. Moreover, we assume here that there are no initial individual differences in physiology and no systematic stress-related changes in physiology over time. In short, we are modeling only the immediate effects of a stressor event, with no effects of prior experience, trait/genetic differences, or lifespan development.

Full Model. Exposure to a significant current stressor stimulates allostasis (as above). In addition, our full model (Plate 41.1c) includes the impact of allostatic load from prior stressor exposure.

Allostatic load accumulates due to chronic, intense, and/or repeated stressor exposure, during which the adaptive gains of allostasis may be reduced and previously helpful adaptations may become problematic (e.g., McEwen, 1998; McEwen & Stellar, 1993; Sterling & Eyer, 1988). We have argued that the extended salience network is the neural locus of allostatic regulation (above). If so, then the subnetworks and primary nodes of the salience network would be expected to accumulate allostatic load at a faster pace than surrounding tissue (see Ganzel et al., 2010; Ganzel & Morris, 2016, for a full discussion and accumulating evidence). Said differently, the function and structure of the salience network is likely to be critically influenced by individual differences in life experience. This, in turn, would impact the mechanisms of allostasis and the future accumulation of central and peripheral allostatic load.

To the left of Plate 41.1c, we show how central and peripheral allostatic load may accrue within the physiological mechanisms of allostasis, affecting an individual's ability to adapt to subsequent stressors (e.g., Ganzel, Kim, Glover, & Temple, 2008; Geronimus, Hicken, Keene, & Bound, 2006). In other words, the stress process itself can be expected to change as a function of prior stressor exposure (Ganzel et al., 2010). In this way, an individual's life history is written into his or her physiology to influence his or her responses to future events. An understanding of these processes is critical to the understanding and prediction of the physiological and behavioral consequences of adversity. This will, in turn, allow more precision in intervention strategies to aid populations at risk.

Stress and Emotion

Affect, Core Affect, and Emotion

Here, we consider the concepts of *emotion*, *affect*, and *core affect*, and their instantiation in the brain. These are identified as "central motive states" or "states of the brain" that underlie behavioral adaptation to the environment (Rosen & Schulkin, 1998; Russell, 1980, 2003). Our next steps in examining the relationship between stress and emotion will be to distinguish these concepts in the context of key theoretical models associating motivated behavior with brain structure and function, including the large-scale functional architecture of the brain.

Emotion

Models of the neural basis of the central motive states associated with emotion have increased in complexity over time and with advances in technologies that allow measurement of emotions "at their source" (Wager et al., 2009). In all of these models, neurotransmitters and neurohormones participate in system regulation, which in turn impacts—and is impacted by—peripheral physiology and behavioral response (see Gunnar & Quevedo, 2007; Schulkin, 2003; Salamone & Correa, 2002, for reviews). Early single-system models of emotion processing (e.g., MacLean, 1949, 1952) have been supplanted by dual- and multisystem models (e.g., Cacioppo & Berntson, 1994; Davidson, 1984; Fodor, 1983; Panksepp, 1998). These latter approaches, in turn, have been increasingly sharing the floor with models of large-scale functional neural networks that interact to produce emotion and cognition (e.g., Barrett & Satpute, 2013; Duncan & Barrett, 2007; Pessoa, 2015).

MacLean (1949, 1952, 1993), for example, developed one of the best-known early single-system models (see also Papez, 1937). In this approach, a unitary subsystem of specialized brain regions (the limbic system) mediates the processing of all types of emotion. This and other single-system models (e.g., single-hemisphere models; Sackeim, Gur, & Saucy, 1978; Schwartz, Davidson, & Maer, 1975) were challenged for reasons of theory (Calder, Lawrence & Young, 2001; Ekman, 1999; Russell, 1980; Watson, Wiese, Vaiya, & Tellegen, 1999) and anatomy (e.g., LeDoux, 1996, Panksepp, 2000).

Critics of single-system models argued for a limited number of discrete state or emotion programs (*affect programs*), each of which is associated with one specialized neural circuit and one complex emotional response, such as fear or happiness (Ekman, 1999; LeDoux, 1991, 2000; Öhman & Mineka, 2001; Panksepp, 1998; Panksepp & Miller, 1996; Rosen & Schulkin, 1998). In this view, discrete emotions are generated within a limited number of emotion-related brain circuits that are interconnected but functionally independent from one another and from dedicated cognitive systems.

These multisystem models arose in parallel with dual-system models. In dual-system models, emotional experience and/or emotion expression is argued to map onto dichotomous dimensions that represent constructs such as arousal (high vs. low), pleasure (pleasant vs. unpleasant), or valence (positive vs. negative; see Buck, 1999; Gainotti, Caltagirone, & Zoccolotti, 1993; Murphy, Nimmo-Smith, & Lawrence, 2003, for reviews). For example, Davidson and colleagues have argued for a valence asymmetry model. In this model, activity in the left hemisphere (especially the prefrontal and anterior temporal cortices) is associated with approach-related emotional expression such as happiness; activity in similar regions in the right hemisphere is associated with withdrawal-related emotions such as disgust (Davidson, 1984; Davidson, Ekman, Saron, Senulis, & Friesen, 1990).

Recently, increasing attention has focused on dual-system models of approach- and avoidance-related emotional expression that are mediated by highly evolved subcortical structures (Barton & Aggleton, 2000; Gerfen, 1992). The neural hubs within this dual-system model are identified as the amygdala/extended amygdala and the ventral striatum (e.g., Lang & Bradley, 2010). In general, activity in the ventral striatum and orbitofrontal cortex is associated with approach behavior, motivation, and positive incentive (e.g., Haber, Kim, Mailly, & Calzavara, 2006; Knutson, Adams, Fong, & Hommer, 2001). In contrast, the amygdala and extended amygdala have been associated with fearful, anxious, and avoidance-related behavior (e.g., Davis, Walker, & Lee, 1997; LeDoux, 1996; Phelps, 2004, 2006). Notably, these neural functions have been increasingly seen as distributed throughout the brain (e.g., Liu, Hairston, Schrier, & Fan, 2011), as research shows these brain structures to be interconnected with one another and with key neural systems underlying perception, cognition, bodily representation, homeostasis, and behavior (e.g., Gottfried, O'Doherty, & Dolan, 2003; Phillips, Ahn, & Howland, 2003; Pessoa, 2008).

The introduction of meta-analytic techniques appropriate to neuroimaging has provided a new lens through which to view all of these models (Kober & Wager, 2010). In general, meta-analyses of neuroimaging studies of emotion have not found strong support for multisystem models (i.e., one-to-one relationships between discrete brain circuits and discrete emotional states of happiness, fear, anger, surprise, etc.; e.g., Phan, Wager, Taylor, & Liberzon, 2002; Wager, Phan, Liberzon, & Taylor, 2003; Murphy et al., 2003). Instead, this meta-analytic work has largely supported the view that the brain regions central to emotion act in a coordinated way to process stimuli that have threat or reward value (e.g., Phan et al., 2002). While this might appear to support a dual-system model, the amygdala and striatum have been observed to be multifunctional in that they are each involved in the processing of *both* reward and threat (Wager et al., 2008). Within each of these superordinate structures there are subgroups of neurons that are dedicated to processing aspects of threat and other subgroups dedicated to processing aspects of reward. Moreover, meta-analyses suggest that these regions act in concert with other similarly multifunctional regions (e.g., orbitofrontal cortex, AI; Lindquist, Wager, Kober, Bliss-Moreau, & Barrett, 2012) to generate the full array of emotional experience (Wager et al., 2009; Wilson-Mendenhall, Barrett, & Barsalou, 2013; see also Hamann, 2012). Consideration of multifunctional circuitry that might give rise to *all* emotional states set the stage for new approaches to modeling emotion processing.

Increased awareness of the functional architecture of the human brain has drawn attention to the relationship between emotion processing and the large-scale neural networks previously discussed (see the section "Stress and Salience"). For example, when an individual experiences emotions of different categories, peaks in neural activity typically occur within these networks of intrinsic functional connectivity—particularly in the salience network and the default network (Touroutoglou, Lindquist, Dickerson, & Barrett, 2015). Negative emotionality (fear, anger, sadness, disgust) is especially likely to generate activity in nodes of the salience network (Touroutoglou et al., 2015). This is consistent with the hypothesis that the salience network acts to orient attention and neural processing resources from internal events toward biologically relevant external information, such as threat or loss (Barrett & Satpute, 2013; Lindquist & Barrett, 2012; see also the section "Stress and Salience" concerning the salience network's sensitivity to negative stimuli). Cross-category emotion processing also generates activity in the nodes of the default network (e.g., Lindquist, Satpute, Wager, Weber, & Barrett, 2015; Touroutoglou et al., 2015). The role of the default network in memory retrieval, self-reflection, and planning (again, see the section "Stress and Salience") has led to the hypothesis that this network serves to create "mental models" of biologically relevant exteroceptive and interoceptive information provided by the salience network; these are argued to be experienced by the individual as mental states, such as emotion and/or cognition (Barrett & Satpute, 2013; Lindquist & Barrett, 2012; see also Barrett, Wilson-Mendenhall, & Barsalou, 2014). All of the large-scale functional networks of the brain are thought to flexibly combine to generate the full range of human experience. However, the salience network is conceptualized as the critical link between a stimulus and the associated "states of the brain" that are interpreted by the individual as emotion (e.g., Barrett & Satpute, 2013).

Core Affect

The terms "affect" and "emotion" are often used interchangeably to describe unpleasant or pleasant "states of the brain" associated with biologically salient stimuli (Batson, Shaw, & Oleson, 1992; Wager et al., 2008), although *affect* is argued to apply specifically to the feeling or mental counterpart of emotion (e.g., Barrett, 2013). "Core affect," however, is a stronger term that refers to the "simplest raw (nonreflective) feelings evident in moods and emotions" (Russell, 2003, p. 148). This is conceived as a "psychological primitive" that is irreducible, a fundamental element of emotion. Core affect is experienced as varying states of *pleasantness* and *unpleasantness* (e.g., Cunningham, Dunfield, & Stillman, 2013; Russell, 2003) imbued with varying degrees of *arousal* (e.g., Barrett & Russell, 1999; Russell, 1980; Schachter & Singer, 1962).

Core affect is argued to underlie the experience of emotions, such as fear, happiness, or anger (the nature of this association is a source of disagreement in emotion research; see Lindquist et al., 2012, plus associated commentary). A parsimonious interpretation of the human imaging literature suggests that core affect represents the *embodiment of* intrinsic motivation and its most primitive mental representation.

A salient stimulus is registered in the brain via the sensory systems and the mechanisms of central allostasis. This information stimulates activation of a very broad array of peripheral/visceral systems via the sympathetic arm of the autonomic nervous system (rapid response) and the HPA axis (which works more slowly). Core affect is argued to derive, in part or in whole, from feedback from visceral (proprioceptive, kinesthetic, somatovisceral, neurochemical) systems that signal the body's valuation of biologically salient stimuli (e.g., Barrett, 2013; Lindquist et al., 2012). This interoceptive information is detected via the AI (e.g., Craig, 2002, 2009) and represented in the brain as mental states of varying degrees of approach/desire and avoidance/aversion (e.g., Barrett & Satpute, 2013; Lindquist et al., 2012; see also Damasio, 1999; 2003; Damasio & Carvalho, 2013). This is consistent with our allostatic model (see previous sections), in which top-down insemination and regulation is heavily influenced by interoceptive feedback from the physiological periphery, generating an iterative response that reverberates between central and peripheral allostasis (see Plates 41.1b and 41.1c).

To summarize, core affect indicates the motivational salience of a stimulus to the individual (Lindquist et al., 2012, p. 125). Put differently, the outcome of salience processing is change in core affect, which is experienced as mental states of approach/desire and avoidance/aversion with varying degrees of arousal (as discussed above). For example, if the initial stimulus is perceived as negatively valenced (undesirable), then the outcome of salience processing will be increased aversion/avoidance (i.e., an upswing in negatively valenced core affect).

Recall that Proposition 1 identifies stressors with salient stimuli, and Proposition 2 identifies the neurobiology of the stress process with the neurobiology of salience processing. Recall also that *stress* predicts *distress*, so that distress is the motivational mental state associated with the stress process. Taken together, this suggests the following third and fourth propositions, stated below:

Proposition 3: Bridging distress, salience, and core affect. *The construct of stress-related distress is functionally identical to salience-related aversion/avoidance and with negatively valenced core affect.*

Our second proposition not only equated the neurobiology of salience processing with the neurobiology of the stress process, it also identified salience processing as the neural keystone of central allostasis. This, combined with our third proposition, suggests the following:

Proposition 4: Bridging allostasis and core affect. *Negative core affect is a primary outcome of central allostasis.*

Core affect has been described as a "homeostatic barometer" (Lindquist et al., 2012) in that it reflects the physiological indicators of a cue's salience. As such, we argue here that it is a central outcome of the allostatic process. If core affect is a basic building block of emotion, as previously discussed, then discreet emotions will likewise arise as emergent properties of a complex allostatic system.

Stress and Emotion Regulation across the Lifespan

Emotion regulation is defined as the processes, whether automatic or controlled, that individuals use to influence which, how, and when emotions are experienced; as such, it is ideally suited to serve as an example of the psychobiological interplay between life stress and emotion, in context and across the lifespan (Thompson, 1994; Gross, 1998; John & Gross, 2004). Establishing healthy emotion regulation skills (e.g., the ability to recognize and label emotional states accurately, the ability to control which emotion is displayed, and coping with affective arousal) enable people across the lifespan to adaptively modulate the interaction between environmental stimuli and personal affect (Izard et al., 2001). Because of this, emotion regulation is a frequent target of interventions to improve social-emotional functioning and mental health in individuals of all ages.

Next, we present a brief overview of the literature on emotion regulation in the context of stress, with particular attention to the implications for psychobiological development at critical windows of vulnerability across the lifespan.

Prenatal Maternal Stress and Infant Emotion Regulation

Stressor exposure within early sensitive periods may be especially important for the healthy development of emotion regulatory systems, with one or more critical windows occurring before birth. Maternal exposure to stressors, reports of distress, and maternal biomarkers of stress during pregnancy have all been linked to emotional and behavioral problems for their children (Glover, 2011; Bolten et al., 2013; Davis, Sandman, Buss, Wing, & Head, 2013). A recent study of low-income Mexican American families demonstrated an inverse relationship between maternal prenatal stress and infant regulatory processes, offering early evidence of the influence of stress *in utero* (Lin, Crnic, Luecken, & Gonzales, 2014). In another study, maternal levels of cortisol were associated with plasma and amniotic fluid cortisol concentration in the womb, which was in turn associated with lower birth weights and emotion regulation difficulties for fear and distress for 3-month-old infants (Baibazarova et al., 2013). In another study, higher levels of maternal cortisol in the second and third trimesters were associated with larger infant cortisol and behavioral responses to a heel-stick blood draw done 24 hours after birth, suggesting that maternal psychosocial stress programs the child's stress regulation systems (Davis, Glynn, Waffarn, & Sandman, 2011). Additionally, fetal exposure to glucocorticoids was inversely associated with bilateral cortical thinning in preadolescents ages 6–10 years old, with the largest group differences detected in the rostral ACC (Davis et al., 2013). This has direct implications for stress and emotion regulation, since reduced anterior cingulate cortical activity has been associated with reduced emotion regulation and impaired top-down attentional control in an array of anxiety disorders in later stages of development (Blair & Raver, 2012).

These studies provide the psychobiological undergirding for research showing an association between self-reported stress measures and biomarkers of stress. For example, Gutteling and colleagues (2005) showed that maternal anxiety during pregnancy predicted elevated reactivity to stimulation and irritability in their 27-month-old toddlers. Perceived distress and anxiety in expectant mothers is similarly associated with increased irritability and crying behavior in their 6-month-old babies (Bolten, Fink, & Stadler, 2012). However, other studies have incongruent findings, such as higher levels of maternal prenatal emotional distress associated with their children's lowered affective reactivity and less crying in new and challenging situations (Rothenberger, Resch, Doszpod, & Moehler, 2011; Möhler, Parzer, Brunner, Wiebel, & Resch, 2006).

These inconsistencies suggest the importance of differential stress susceptibility as a factor for prenatal programming of emotion regulation. Specifically, many of the factors associated with more stressful prenatal environments, such as neonatal stress reactivity or low birth weight, can be considered physiological susceptibility factors that moderate how children interact "for better or worse" with their environment across time (Pluess & Belsky, 2011). For example, a recent study of prenatal development has shown that reactivity to stimulation at 6 months of age was associated with maternal basal and reactive cortisol during pregnancy, adjusting for child's temperament as determined in the neonatal period (Bolten et al., 2013). Children with high neonatal stress reactivity demonstrated deficits in emotion regulation if the mother's cortisol levels were high during pregnancy, whereas children with high neonatal reactivity and low maternal cortisol during pregnancy demonstrated positive emotion regulation. Thus, neonatal temperament moderated the relationship between maternal prenatal stress and later infant emotion regulation, which is consistent with the differential susceptibility hypothesis.

Genetics can present another susceptibility factor linking environment to infant negative emotionality. For example, the relationship between a mother's prenatal anxiety and her infant's negative emotionality appears to be moderated by a common polymorphism of the serotonin transporter gene, such that having a short allele predicts increased infant negatively valenced emotionality (Pluess et al., 2011).

Early Childhood Stress and Emotion Regulation

Early childhood stressor exposure represents another important developmental window. For example, early childhood life stress has been associated with diminished emotional and cognitive capacity, which in turn lessens the ability to delay gratification, manage conflict, and engage in goal-oriented and sustained learning efforts (Carlson & Wang, 2007; Denham & Burton, 2003; Trentacosta & Izard, 2007). Stressor exposure in early childhood is associated with alterations in the neural mechanisms that underlie emotion regulation. For example, in a neuroimaging study of children who were institutionalized in infancy (orphanage care), children who were in institutions longer tended to have larger amygdala volumes and these, in turn, were associated with increased difficulty in emotion regulation (Tottenham et al., 2010). Similarly, dysregulated patterns of connectivity between medial prefrontal cortex (mPFC) and amygdala have been observed in youth with a history of early maternal deprivation (e.g., orphanage care). When viewing emotional faces, these youth showed amygdala hyperactivity and a hypermature pattern of amygdala–prefrontal connectivity (Gee, Gabard-Durnam, et al., 2013; Gee, Humphreys, et al., 2013). This research is consistent with animal studies of maternal separation that show accelerated emergence of adult-like fear and extinction learning in young rats (Callaghan & Richardson, 2011; Muhammad, Carroll, & Kolb, 2012).

Early childhood stressor exposure has also been shown to have effects that endure into adulthood. Specifically, healthy adults who grew up in risky families (i.e., family environments that are harsh, neglectful, highly chaotic, and/or conflict ridden; Repetti, Taylor, Seeman, 2002) showed evidence of alterations in the neural mechanisms underlying emotion regulation and threat detection (Taylor, Eisenberger, Saxbe, Lehman, & Lieberman, 2006). Adult offspring of risky families showed a blunted amygdala response to the presentation of standardized emotional facial stimuli (negative vs. neutral faces). These individuals also had an atypical relationship between prefrontal activation and amygdala activation, suggesting a long-term alteration in response to emotional stimuli (Taylor et al., 2006).

Adolescent Stress and Emotion Regulation

Adolescence presents another developmental period in which allostasis is likely to be qualitatively or quantitatively different from other stages of development. The emergence of adolescence brings heightened significance of identity and social relationships that generate new and additional environmental stressors. Changes in the social environment typically result in adolescents spending more time with peers than adults, as well as increased conflict with parents regarding issues of autonomy and individuating identity (Steinberg & Morris, 2001; Baumrind, 2005). In parallel, adolescents are experiencing heightened amygdala activity in response to emotional stimuli, relative to younger children and to adults (Hare et al., 2008). The amygdala functions as a critical "salience detector" in the brain (Cunningham & Brosch, 2012), so that heightened activity here will prompt increased activity within the large-scale salience network that we have placed at the heart of allostatic regulation (see the section "Stress and Salience").

Other changes in the neural circuitry of emotion regulation are taking place during adolescence. By this stage, the neural underpinnings of complex motor skills are nearly matured (e.g., Kurth et al., 2012), as are the striatal regions, which are heavily implicated in reward-related behavior (e.g., Galvan et al., 2006) and positive core affect (Hermes, Hagemann, Naumann, & Walter, 2011). However, the superior and lateral prefrontal regions that underlie complex cognition and planning are not fully developed until well into early adulthood (e.g., Kurth et al., 2012). The maximum imbalance in the maturity of these systems occurs during adolescence, and evidence suggests that this underlies at least some of the increase in risk-taking behavior observed during this developmental period (Casey, Getz, & Galvan, 2008; Casey, Jones, & Hare, 2008; Steinberg, 2008). Neuroimaging studies of adolescents demonstrate the extensive functional and structural reorganization of brain regions that underlie response inhibition, affect modulation, and discrimination of emotional cues; these, in turn, are argued to contribute to the developmental changes in emotion regulation seen in adolescence and young adulthood (Yurgelun-Todd, 2007).

Stress and Emotion Regulation in Adulthood

While the above evidence supports the hypothesis that life stress impacts emotion regulation uniquely during different development periods, evidence also supports the importance of their interactions across the lifespan (see Ganzel & Morris, 2016, for a detailed discussion). In adults, chronic stress interferes with several important regulatory systems necessary for healthy lifespan development—such as working memory, attention, inhibitory control, and planning—all of which are necessary for healthy coping and self-regulation (Evans, Kim, Ting, Tesher, & Shannis, 2007; Blair & Raver, 2012). Acute stress, such as trauma exposure, predicts persistent increases in amygdala reactivity in healthy adults; not only to trauma reminders (Admon et al., 2009; Sharot, Martorella, Delgado, & Phelps, 2007) but also to standardized affective stimuli (images of emotional faces; Ganzel, Casey, Glover, Voss, & Temple, 2007; Ganzel et al., 2008). Evidence for these effects persists years after exposure to the target trauma, which is consistent with a model of heightened amygdala reactivity following psychological trauma exposure, with recovery on the order of decades (even in the absence of clinical disorder; Ganzel et al., 2007). As noted above, heightened amygdala activity will prompt increased activity within the salience network and alter the central mechanisms of allostatic regulation.

There are also significant differences across adulthood in how stress affects emotion processing and emotion regulation. Older adults show increased sensitivity to stress relative to young adults, as demonstrated by increased stress-related dysregulation of the cardiovascular and immune systems (e.g., Ong, Rothstein, & Uchino, 2012; Uchino, Birmingham, & Berg, 2010). Along with heightened stress vulnerability, older adult humans show a strong goal-directed decrease in attention to negative stimuli (a *positivity bias*), which is believed to be motivated by an increased interest in preserving positive emotionality and well-being (e.g., Carstensen, Gross, & Fung, 1997; Fischer et al., 2005; Gross et al., 1997; Mather et al., 2004; Mather & Carstensen, 2003; St. Jacques, Dolcos, & Cabeza, 2010; Tessitore et al., 2005; Urry et al., 2006). Despite this positivity bias, increased stress sensitivity in older adults combines with increased exposure to stressors (a normal hazard of aging) to predict age-related declines in health (e.g., Cohen & Williamson, 1991; Kiecolt-Glaser & Glaser, 2001). This synergy of sensitivity and exposure is exacerbated by contextual factors, such as increased loneliness (Cole et al., 2007; Ong et al., 2012).

There is also emerging evidence that prior trauma exposure carries unique risks for older adults. Older adults with a history of trauma exposure in adulthood have a higher likelihood of dementia than older adults with no history of adult trauma (Burri, Maercker, Krammer, & Simmen-Janevska, 2013; Tsolaki et al., 2010; Yaffe et al., 2010). Notably, older adults with a history of *childhood* trauma do not appear to share this increased risk of dementia (e.g., Burri et al., 2013; Ravona-Springer, Beeri, & Goldbourt, 2011), but they are more at risk for geriatric depression (Kuhlman, Maercker, Bachem, Simmen, & Burri, 2013). Thus, the developmental timing of stress and trauma continues to be an important modulating factor in emotion regulation, even into old age.

Implications

We have argued that allostasis is relational, in that there are profound reciprocal influences between a given stressor, an individual, and his or her broader physical and social environment. As noted in the beginning of this chapter, the stress process itself can be expected to change as a function of life experience (e.g., traumatic events or chronically stressful conditions), even in individuals who do not have a mental disorder. Thus, it follows from Proposition 4 that when central allostasis varies as a function of life experience, then so will negative core affect. This concept is pivotal in our use of triple-network allostasis as a diathesis-stress model predicting psychopathology onset and the course of mental illness (Ganzel & Morris, 2016). Here, we expand this concept to include individuals with and *without* mental disorder (i.e., everybody).

We have also argued that the stress process is embodied and thus changes continuously across the lifespan as a function of ongoing age-related neurophysiological change (Ganzel & Morris, 2011, 2016). Thus, it follows from Proposition 4 that systematic age-related change in central allostasis can be expected to drive age-related change in negative core affect. These effects may be observed as changes in baseline negative core affect, changes in affective reactivity to negative stimuli, or both (e.g., Rosen & Schulkin, 1998). Moreover, we have argued here that these systematic developmental changes in core affect are typical of normal development. Figure 41.1 includes both of these effects in depicting stress-related changes in allostasis over the lifespan. In this model, ongoing allostasis and accumulating allostatic load exert long-term influences on baseline core affect and/or reactivity to aversive stimuli.

There is considerable evidence that stressor exposure during a particular stress-sensitive period can have reverberating consequences for the magnitude, duration, and intensity of the stress response (e.g., Caldji, Diorio, & Meaney, 2000; Pryce et al., 2005; Sanchez, Ladd, & Plotsky, 2001). We have argued that the stress response itself is different within these time windows and thus produces different stress-related physiological and behavioral outcomes (see the beginning

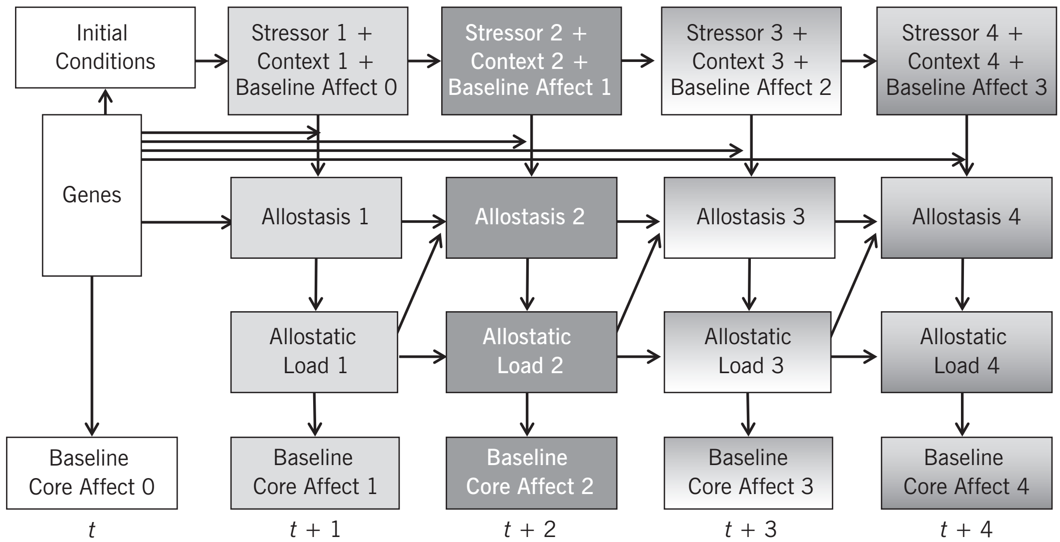

FIGURE 41.1. *Modulated allostasis predicting negative core affect.* Here we model ongoing allostasis in response to current stressors (columns at each time point: $t + n$) and ongoing accumulation of allostatic load over time (horizontal axis). In this model, both processes are modulated by developmental timing; the different shading in each column indicates varying stress sensitivity across the lifespan. Stressors that occur at different developmental periods are expected to have different long-term consequences for baseline core affect and/or reactivity to aversive stimuli. Not drawn: genes → stressor + context (all); baseline affect ($t + n$) = → stressor + context ($t + n$). Based on Ganzel and Morris, 2011.

of the chapter). Put differently, there are certain points in development in which the *mechanisms of allostasis* are uniquely constrained or expanded, or qualitatively changed. These changes may be temporary (a window) or long term (a stage). A stressor that occurs during this time period will have a qualitatively or quantitatively different impact on the processing of negative core affect, as compared with a stressor that occurs before this window opened or this stage began (see Ganzel & Morris, 2011, for a discussion). Moreover, a stressor that occurs during this time period will also generate a characteristic pattern of physiological "wear and tear" within the mechanisms of allostasis, and this will uniquely constrain future attempts at allostasis. The additional allostatic load from this stressor will be unique to this stressor *and* to this developmental period, with distinctive long-term consequences for baseline core affect and/or reactivity to aversive/negative stimuli.

As discussed in the previous sections, discrete emotions are argued to be constructed from the basic building blocks of core affect. If so, then any discrete emotion based in negative core affect will also *be expected to change systematically with life experience and age*. At present, these conclusions apply only to negative core affect, although see the section "Future Directions" for a discussion of the ways in which positive core affect may enter this model. Next, we consider the translational implications of this model.

Future Directions

Based on the models presented here, we urge future research to address questions of developmental timing in emotion processing by including developmental comparison groups. Ideally, these studies would compare across small-enough age intervals to build, over time, a detailed developmental time line of negative and positive core affect and affective reactivity across the lifespan.

We also urge research into how life stress influences these effects, namely, developmental timing of emotion processing. We discussed one example (above) in which early maternal deprivation was associated with amygdala hyperactivity and early maturation of amygdala-PFC connectivity (Gee, Gabard-Durnam, et al., 2013). This raises the question of the effects of attachment disruptions at other points in development. In general, it will be important to know the effects of similar stressors on core affect, affective reactivity, and emotion regulation in different developmental periods (in early childhood, middle childhood, and adolescence, etc.). And how would attachment disruptions differ with other types of social stressors, or from physical threats? There is growing evidence that these different types of stressors are processed somewhat differently in the brain and body (Alleva & Santucci, 2001; Pruessner et al., 2008), and thus could be expected to have different effects on affective and emotion-related outcomes.

Finally, we advocate for intervention research that includes not only developmental sensitivity but also sensitivity to the potential influences of life stress on emotion processing and regulation. For example, interventions targeting low-income children often consider home and neighborhood stressors as risk factors for emotional and behavioral difficulties (Dodge, Pettit, & Bates, 1994; Fantuzzo et al., 1999; Farmer, Stangl, Burns, Costello, & Angold, 1999). Because of this, emotion regulation interventions targeting stress have support in the literature. Below, we provide an overview of this emerging field.

Implications for Intervention

Emotion Regulation Interventions in Early Childhood

Early emotion regulation interventions have primarily targeted the fundamental social and emotional skills that underlie children's academic success, including competent social interactions with teachers and children and their attention to learning tasks. Some models target teacher behavioral strategies, building on the theory that teachers' behavior plays an important role in children's modulation of their attention, emotion, and behavior (Chryssanthopoulou, Turner-Cobb, Lucas, & Jessop, 2005; Hoglund & Leadbeater, 2004; Webster-Stratton, Reid, & Hammond, 2001).

In contrast, a second set of models relies on emotions-based curricula; these use organized instruction to teach specific affective and social-cognitive skills, such as emotions knowledge and social problem-solving skills (Cook, Greenberg, & Kusche, 1994; Crick & Dodge, 1994; Eisenberg, 1986; Kellam, Rebok, Ialongo, & Mayer, 1994; Spivack & Shure, 1974). Building on work that suggests that children's ability to recognize and label different emotions is critical to their development, a number of early educational programs have implemented emotions-based curricula to help children appropriately identify, choose, and enact prosocial solutions to typical social problems, such as dealing with peer conflicts. Meta-analyses of universal prevention programs during the elementary school years indicate that such programs significantly improve social-cognitive abilities and social adjustment (Beelmann, Pfingsten, & Lösel, 1994; Denham & Almeida, 1987; Durlak, 1995). The PATHS curriculum (Kusché & Greenberg, 1994) is one of the most successful of these programs, and focuses on the developmental integration of affect (and emotion language), behavior, and cognitive understanding as they relate to social and emotional competence.

Theory and empirical research would suggest that (1) social-cognitive processes are a key mediating mechanism in the link between early life experiences and aggression in later childhood and adolescence (Dodge, 2006) and (2) children's self-regulatory skills as promoted by effective classroom environments can have long-term implications for children's approach to learning (Raver, 2004). However, the work on which these theories are based is largely observational (i.e., nonexperimental) in nature. Furthermore, they neglect to consider the neurological mechanisms that undergird these processes. Emerging developmental neuroscience research has inspired a wave of interest in interventions that consider neurological systems related to cognition and emotion, but the bulk of this attention has been devoted to executive function (Diamond & Lee, 2011). Consideration of intervention-related change in the neural underpinnings of emotion regulation is a topic for further research, particularly with attention to determining the key sources of modulation within each child's environmental context and prior life experience.

An emerging line of research is investigating the role of aerobic exercise for improving executive function and emotion regulation. A supporting hypothesis for how this relationship works suggests that physiological changes induced by exercise, such as increases in capillary blood supply to the cortex and changes in neurotransmitter levels, elevate the function of emotion regulating systems in the brain (Davis et al., 2011). Indeed, animal research has shown that nonspecific neural activation associated with exercise drives durable neurogenesis in learning and memory centers in the brain (Best, 2010). To date, no intervention has addressed the relationship between exercise and emotion regulation, but a few studies have targeted the related process of executive function (Best, 2010). For instance, a randomized experiment was conducted for an exercise-based afterschool program for children between the ages of 7 and 9. Significant improvements on complex memory tasks were detected for the children who participated in 40 minutes of rigorous physical activity and then 30 minutes of an organized sport (Kamijo et al., 2011). We note the substantial overlap in the brain systems associated with executive function and those associated with emotion regulation strategies (e.g., suppression and reappraisal; Goldin, McRae, Ramel, & Gross, 2008) and suggest exercise-based interventions for emotion regulation as a topic for future research. Again, it would be of interest to determine how these effects are modulated by each child's environmental context and prior life experience.

Emotion Regulation Interventions in Adolescence and Beyond

Interventions for adolescents' emotion regulation in the context of life stress primarily concern mindfulness. This growing field of research has inspired promising interventions seeking to ameliorate the negative effects of stress and improve emotion regulation, although there has been limited attention to the neurological mechanisms of change. Mindfulness interventions targeting urban youth, coupled with basic yoga practices, have been shown to promote improved stress reactivity, depressive symptoms, and peer relations between baseline and 12 weeks later (Mendelson et al., 2010). Yoga also has an array of cognitive benefits across the lifespan into older adulthood (Hillman, Erickson & Kramer, 2008). Research is building on the underlying neurological mechanisms that drive the improvements demonstrated in mindfulness intervention, but the role of stress is not often emphasized. One study (Zylowska et al., 2008) reported lower symptoms of attention-deficit/hyperactivity disorder (ADHD), anxiety, and depression following an 8-week mindfulness meditation intervention. In another study, women diagnosed with an anxiety disorder showed increased activity in brain systems associated with attentional deployment (ventromedial and dorsomedial PFC, posterior cingulate, and amygdala), reductions in amygdala activity, and decreased negative emotion experience following a mindfulness-based intervention (Goldin & Gross, 2010). Mindfulness meditation is also associated with neuroplastic changes in the ACC, AI, and the TPJ (Hölzel et al., 2011), which are nodes in the salience network that is at the core of our triple-network model of allostasis (see the section "Stress and Salience"). Consideration of mindfulness-related change in the neural underpinnings of emotion regulation is a topic for further research, particularly with attention to isolating the ongoing effects of age, context, and prior life experience.

Eustress and Positive Core Affect

In this chapter, we have proposed relationships among the constructs of stress-related distress, salience-related aversion/avoidance, and negative core affect (Proposition 3). This, in turn, led us to propose that negative core affect is an outcome of central allostasis (Proposition 4). Is positive core affect similarly associated with the stress process?

Some researchers argue that positive core affect is at the opposite pole—but on the same axis—as negative core affect (Barrett & Bliss-Moreau, 2009; Barrett & Russell, 1999; Russell, 2003). In this case, positive core affect is entrained to negative core affect (they are inversely correlated) and changing one will change the other. Our Proposition 4 may then be expanded to say that the construct of core affect *as a whole* is linked to central allostasis.

Other researchers argue that positive core affect (manifested as positive emotionality) and negative core affect (manifested as negative emotionality) are independent from each other (Cacioppo, Berntson, Larsen, Poehlmann, & Ito, 2000; Larsen, McGraw, & Cacioppo, 2001). In this case, our new models apply to negative core affect, with few implications for positive core affect.

A third set of arguments suggests that the relationship between positive core affect and negative core affect depends on the stress level of the individual (Zautra, 2003). To understand the latter argument, it is useful to first consider the nonlinear (*U*-shaped) relationship between stressor exposure and distress (e.g., McEwen & Lasley, 2002). Both ends of the *U*-shaped curve mark progressively unhealthy levels of stressor exposure (too much stimulation or too little stimulation) that are accompanied by increased levels of distress. Healthy exercise, for example, can progress to being worked to death (Selye, 1950, 1956). At the opposite end of the spectrum, enforced immobility causes muscle wasting, dysregulated endocrine function, and sharply increased indicators of distress (e.g., Blanchard, Sakai, McEwen, Weiss, &

Blanchard, 1993; Blanchard et al., 1995; Radley et al., 2006; Vyas, Mitra, Shankaranarayana Rao, & Chattarji, 2002).[3] Closer to the bottom (middle) of the *U*-shaped curve are more normative, adaptive amounts of stimulation (e.g., healthy exercise; healthy intellectual challenge), termed "eustress" ("good stress"; Lazarus, 1966; Selye, 1974). Eustress is associated with enhanced neurogenesis (e.g., Kirby et al., 2013; McEwen & Lasley, 2002; Rhodes et al., 2003), improved brain metabolism and enhancements of neuronal architecture (e.g., Kempermann et al., 1998; Sirevaag & Greenough, 1988), improved executive and immune function (Colcombe et al., 2004; Sapolsky, Romero, & Munck, 2000), and improved psychological health (Gibbons, Dempster, & Moutray, 2008; Milsum, 1985).

Interestingly, eustress is not firmly associated with positive mental states (with positive core affect) in the same way that high levels of stressor exposure predict negative mental states (distress). In fact, at moderate levels of environmental stimulation (eustress), there is evidence that positive and negative mental states are largely independent phenomena (e.g., Cacioppo et al., 2000; Larsen et al., 2001; Reich, Zautra, & Davis, 2003; Ryff et al., 2006; Zautra & Reich, 1983). However, research suggests that positive and negative mental states become inversely coupled under stress, so that they are canalized onto a single positive/negative axis (e.g., Reich et al., 2003; Zautra, 2003; Zautra, Reich, Davis, Potter, & Nicolson, 2000). This is thought to streamline information processing (e.g., Zautra, 2003), a hypothesis that is supported by observations of enhanced negative reactivity under stress (e.g., Potter & Zautra, 1997; Zautra, Berkof, & Nicolson, 2002). Under these circumstances, central allostasis would predict overall core affect (positive *and* negative) with implications for the generation of all discrete emotions (see the section "Affect, Core Affect, and Emotion").

Stress-related canalization of positive and negative core affect may actually benefit intervention efforts. If positive core affect and negative core affect collapse onto opposite poles of the same axis, then the two states are effectively harnessed together. Under these circumstances, negative core affect (distress) can now be impacted by effecting changes in positive core affect. This hypothesis is supported by research showing that positive mental states can buffer distress in stressful situations (e.g., Keltner & Bonnano, 1997; Fredrickson & Levenson, 1998). A definitive understanding of the physiology underlying the relationships among positive core affect, negative core affect, and stress would help to optimize these interventions. It remains to future research to do this work.

New Directions in Integrative Research

We call attention here to the considerable overlap between the salience network (Plate 41.2C) and the neural locus of brain–body regulatory functions (Plate 41.2A). Brain–body medicine has taken an exciting step forward with the identification of remarkable commonalities in the brain mechanisms that regulate the human autonomic, endocrine, and immune systems (e.g., Gianaros & Sheu, 2009; Ohira et al., 2009; Urry, van Reekum, Johnstone, & Davidson, 2009; Wager et al., 2009). The neural loci of these brain–body interfaces fall along an axis that starts at the superior medial PFC and descends along the midline of the PFC and down into the brainstem. Thus, these neural brain–body regulatory mechanisms share significant common ground with the extended salience network (Plate 41.2C). Moreover, both the salience network and this brain–body "medial PFC-brainstem axis" (Lane & Wager, 2009, p. 1136) overlap with brain areas showing evidence of long- and short-term stress-related change in humans (Plate 41.2b; e.g., Ganzel et al., 2008; Gianaros, Horenstein, et al., 2007; Gianaros, Jennings, et al., 2007; Liston, McEwen, & Casey, 2009) and animals (Cerqueira et al., 2005; Vyas et al., 2002), which we have argued is indicative of central allostatic load. See Ganzel and Morris (2016) for a detailed discussion. Finally, all three of these systems share considerable overlap with the neural loci of affective processing and discrete emotion (Plate 41.2D; also called the "neural reference space for discrete emotions"; Lindquist et al., 2012, p. 126).

While this four-way overlap is highly consistent with our theoretical models, there is little research examining the linkages among life experience, emotion processing/regulation, and brain–body regulation within the context of the large-scale functional architecture of the brain. We commend this topic to future research.

Conclusion: Triple-Network Allostasis as an Organizing Concept

The goal of this chapter was to examine the relationship between stress and emotion using the newest version of our model of the stress process:

triple-network allostasis (Ganzel & Morris, 2016). To do this, we took a developmentally informed approach to bridging research on the neurobiology of the stress process (Ganzel et al., 2010; Ganzel & Morris, 2011, 2016) with research on emotion, core affect, and emotion regulation. As part of this process, we reviewed the neurobiology of the stress process and the relevant role of the salience network, as well as the neurobiology of core affect and emotion. Our analysis of these topics suggests the following propositions: (1) that stressors are intrinsically salient; (2) the neurobiology of the salience processing (for aversive stimuli) is functionally identical to that of the stress process; (3) that the construct of stress-related distress is functionally identical to salience-related aversion/avoidance and negatively valenced core affect; and, as such, (4) negative core affect is a primary outcome of allostasis. We concluded with a new triple-network model in which ongoing allostasis and accumulating allostatic load exert long-term influences on baseline core affect and/or reactivity to negative stimuli.

We offer this model as a useful tool for conceptualizing pathways to integrating research on stress, emotion, and the neurobiology of salience. In prior work, we modeled allostasis as *relational*, proposing that the stress process itself can be expected to change as a function of life experience (discussed before, see also Ganzel et al., 2010; Ganzel & Morris, 2011, 2016). In the current chapter, we have argued that if the stress process itself changes with life experience, then so will negative core affect and any discrete emotions based on negative core affect (see the section "Stress and Emotion Regulation across the Lifespan"). We have also, in prior work, modeled allostasis as *embodied*; as such, it undergoes continuous change across the lifespan as a function of systematic age-related physiological development and senescence (particularly within the brain; see Ganzel et al., 2010; Ganzel & Morris, 2016). In the current chapter, we argued that age-related change in central allostasis can also be expected to drive age-related change in baseline negative core affect, reactivity to negative stimuli, and any discrete emotions based on negative core (see the section "Implications"). This brings a developmental perspective to affective/emotion processing and emotion regulation, highlighting the sensitivity of key ages and stages, as well as the neurospecificity that a lifespan developmental view implies.

In sum, we offer triple-network allostasis as an organizing concept to aid in integrating multiple domains of academic inquiry, including biomedical and psychosocial stress research (Ganzel et al., 2010); human development and lifespan developmental neuroscience (Ganzel & Morris, 2011); developmental psychopathology and the large-scale functional architecture of the brain (Ganzel & Morris, 2016); and research on core affect, emotion, and emotion regulation (this current chapter). Given the breadth of its application, we suggest here that triple-network allostasis is most accurately characterized as a *multilevel theory of lifespan development*, rather than a model of the stress process or even a diathesis-stress model of developmental psychopathology (although we have shown that it can be informative in both of these roles; Ganzel et al., 2010; Ganzel & Morris, 2016).

Notes

1. As the brain matures, populations of neurons are increasingly able to fire rhythmically and in synchrony, creating oscillating networks that link neural activity across multiple spatial and temporal levels of analysis (Barrett et al., 2007; Dosenbach et al., 2010; Engel, 1977). In this way, the firing of a single neuron in a local network may be linked to oscillatory activity in vast neural assemblies that span the brain (Convit, Wolf, Tarshish, & De Leon, 2003; Uhlhaas & Singer, 2012).
2. Events, including social events that have value to survival and/or reproduction. Examples for humans would include social or financial threat or reward.
3. These indicators of distress vary as a function of species, sex, age, genetic characteristics (e.g., knock-out mice), physiological state, and/or environment (e.g., laboratory housing)—for example, inbred strains of laboratory mice typically differ from each other and from wild-type mice with respect to physiology, sensory, motor, and behavioral traits, and so can be expected to respond differently to stressor exposure across all of these parameters (Ward et al., 2008). In humans and other animals, distress is inferred from observable changes in behavior. In addition, many humans have the ability to report their own distress levels, but again, responses may vary as a function of age, sex, genetics, physiological state, and environment.

CHAPTER 42

Emotion-Related Symptoms of Neurodegenerative Dementias

Bradford C. Dickerson

The neurodegenerative diseases are a major medical and social burden in many societies, particularly with the growth of older population segments. Neurodegenerative diseases include dementias, movement disorders, cerebellar diseases, and motor neuron diseases. Treatments are very limited at present. In 2010, low estimates for dementia-related costs accounted for greater than 1% of the world gross domestic product. Without major "cures," projections—in the United States as well as globally—estimate potentially crippling dementia-related costs for world economies in the coming decades. But clinicians look beyond statistics; the devastation wrought by these illnesses upon each patient and family is immeasurable. Unfortunately, even today with growing public awareness, dementing illnesses often escape early diagnosis and appropriate clinical care, adversely impacting the patient, his or her family and caregivers, society, and public health in a multitude of ways.

Research investigating the neurobiology of neurodegenerative dementias and other diseases has deepened our understanding tremendously, providing insights into the pathologic accumulation of specific abnormal protein forms in these diseases. As the biology of these diseases is elucidated, hope is beginning to emerge for treatments targeted at modification of fundamental pathophysiological processes (Bertram & Tanzi, 2005; Trojanowski, 2004). However, at the same time, many clinicians points out that we desperately need new treatments targeting the symptoms of these diseases, while we continue to investigate underlying mechanisms and work toward treating them. Although cognitive symptoms are often the primary target of experimental symptomatic therapies, the field is increasingly recognizing the need to improve our understanding of and treatments for symptoms often referred to as "neuropsychiatric" or "behavioral and psychological" symptoms of dementias. At their root, many of these symptoms represent changes in normal emotional and social behavior. These symptoms can be very disruptive to relationships, often more so than cognitive or motor symptoms. A deeper understanding of changes in emotional behavior in the neurodegenerative dementias will undoubtedly help propel us toward better treatments.

Furthermore, as we develop better neuroimaging and brain mapping technologies for measuring the abnormalities of neuroanatomy, brain function, the connectivity of large-scale circuits, and molecular function and pathology in living people, we can study the neural basis of abnormal emotional behavior in patients with neurodegenerative diseases. This, along with studies of patients with other neurological and psychiatric disorders, will likely provide fundamental new insights into the brain circuitry of human emotion.

In this chapter, I review the classes of symptoms commonly used by clinicians and researchers studying abnormalities of emotional behavior in neurodegenerative dementias. I then delve into the three most common neurodegenerative dementias, describing their clinical and pathological features and probing our clinical and scientific understanding of changes in emotional behavior within each of these diseases.

Overview of Changes in Emotional Behavior in Neurodegenerative Dementias

A variety of changes in emotional behavior are well recognized as important elements of neurodegenerative dementias. These symptoms are often referred to as "neuropsychiatric" or "behavioral and psychological" symptoms. They may develop after, at the same time as, or prior to cognitive and functional impairment. Although cognitive and functional impairments in neurodegenerative dementias usually follow a more-or-less linear rate of progression, neuropsychiatric symptoms may evolve more variably, with waxing and waning characteristics. Some emotional symptoms tend to be prominent early in the disease and then remit as the disease progresses. The neuropathological correlates of neuropsychiatric symptoms are poorly understood. Generally speaking, it is thought that the reason some types of symptoms are more prominent in one of these diseases than in another is related to the localization of pathology, rather than its molecular type. Overlapping symptoms between different diseases may occur because different pathologies alter the function of one circuit. We are slowly accruing a body of neuroimaging research that is shedding light on these brain–behavior relationships.

Neuropsychiatric symptoms adversely impact not only patients but also their caregivers. Many symptoms have been shown to be associated with worse cognitive performance, reduced functional ability and quality of life, and increased caregiver and patient distress (D'Onofrio et al., 2012; Lechowski et al., 2009). They are a major reason for institutionalization and nursing home placement (Callahan et al., 2006).

Constructs of psychological and behavioral symptoms of dementias originate in long-standing concepts in psychiatry. These constructs are recently being updated to fit into new frameworks such as the Research Domain Criteria (RDoC; Insel et al., 2010), which are grounded in systems-based functional neuroanatomy. In this framework, the major domains include positive-valence systems, negative-valence systems, social function, cognitive function, and arousal/regulatory systems. In my discussion of the major types of psychological and behavioral symptoms of dementia, I attempt to refer to this new framework where possible, although research is only beginning to employ approaches such as this.

Depression

Depression is prevalent in patients with established dementia, and occurs at various stages. It occurs in 10–15% of patients with mild Alzheimer's disease (AD), but ≥ 50% of patients with moderate to severe AD. It is also very common in Lewy body dementia (LBD) and Parkinson's disease dementia (PDD), but somewhat less common in frontotemporal dementia (FTD). Depressive symptoms in AD have been shown to correlate with hypoperfusion or hypometabolism in the prefrontal cortical areas including the dorsolateral prefrontal cortex (DLPFC) and the anterior cingulate cortex (ACC), presumably as a result of the neurodegenerative process (Akiyama et al., 2008; Butters et al., 2008).

Depressive symptoms in dementia can be very similar to depressive syndromes in other contexts, such as major depressive disorder (Chemerinski, Petracca, Sabe, Kremer, & Starkstein, 2001). However, the cognitive deficits in dementia may make it difficult for the patient to realize the nature of the symptoms or describe them. The course of depression in dementia may be mild and self-remitting over time in some patients, or chronic and resistant to treatment in others (Starkstein et al., 1997). Even after remission or successful treatment, the recurrence rate of depression in dementia is high. Depression is often assessed using clinical instruments such as the Geriatric Depression Scale (Yesavage, Brink, Rose, Lum, Huang, et al., 1982), Beck Depression Inventory (Beck, Steer, & Brown, 1996), or the Hamilton Depression Scale (Hamilton, 1980).

At a high level, depression is generally considered to be related to dysfunction or imabalance of so-called positive- and negative-valence systems (Insel et al., 2010).

Apathy

The term "apathy" denotes poor motivation, goal-directed cognition or action, and/or a decrease in emotional responsiveness (Marin, 1990). Apathy is often mistaken as depression, but is thought to be a distinct syndrome with different characteristics and clinical course. Depression is neither necessary nor sufficient for apathy to be present (Levy et al., 1998). The proposed diagnostic criteria for the apathy syndrome include diminished motivation and loss of goal-directed behavior, cognitive function, or emotional expression or responsiveness (Robert et al., 2009).

Apathy is a common early feature in many neurodegenerative disorders. It is thought to result from dysfunction in the frontal-subcortical neural networks, particularly the dorso-medial prefrontal cortex and the ACC (Apostolova et al., 2007: Ott, Noto, & Fogel, 1996). The frequency of apathy in AD is unclear, from as few as 25% to as many as 75–80% (Landes, Sperry, & Strauss, 2005). It is one of the early symptoms in AD, but is also commonly seen in later disease stages. Apathy is the presenting symptom in a vast majority of patients with FTD and is nearly universal in this illness as it evolves (Mendez, Lauterbach, Sampson, & Research, 2008).

The construct of apathy is not thought to be associated with low mood, but rather with a lack of positive-valence system function that provides reward and potentially also a dysfunction of arousal and regulatory systems that drive motivated, volitional behavior.

Anxiety

Generalized anxiety is common in people with dementia, affecting as many as 40–70% of patients (Ballard, Bannister, Solis, Oyebode, & Wilcock, 1996). Anxiety often co-occurs with depression, with as many as 75% of patients with dementia and anxiety also exhibiting signs of depression. As dementia severity worsens, anxiety often becomes less prevalent, possibly in relation to loss of insight and self-awareness of impairment. Anxiety can be a feature of all major dementia syndromes, but seems to be particularly common in LBD and PDD.

Anxiety is usually thought of as originating in heightened fear circuitry, conceptualized in the framework of the RDoC as dysfunctional negative-valence systems.

Psychosis: Delusions and Hallucinations

Psychotic symptoms, including delusions and hallucinations, are less common than depression and apathy, but well recognized as part of many neurodegenerative diseases. They are traditionally classified under the rubric of psychiatric or behavioral symptoms, but rather than primarily being disorders of emotion, are usually considered to be "thought disorders." They are briefly reviewed here because they are so frequently included under the general category of psychiatric or behavioral symptoms.

Delusions are relatively common in neurodegenerative dementias, and are defined as fixed false beliefs. In patients with neurodegenerative dementias, the types of delusions often follow certain patterns, including those of theft, marital infidelity, and misidentification syndromes (Apostolova & Cummings, 2008). Misidentification syndromes include Capgras syndrome (believing that familiar individuals are replaced by an imposter), Fregoli syndrome (believing that strangers are familiar), Foley syndrome (believing that images in the mirror are of other individuals), and reduplicative paramnesia (believing that a familiar location is duplicated). Bizarre delusions, such as those commonly seen in schizophrenia are rare, but have recently been recognized as occurring in some patients with a particular genetic form of FTD due to a mutation in the chromosome 9 open-reading frame 72 gene (Boeve et al., 2012). Hallucinations are perceptual disturbances in which a patient hears or sees or otherwise perceives something that is not actually present. Visual hallucinations are more common than other perceptual disturbances in dementia, although all types of hallucinations can be seen, including olfactory and tactile hallucinations (Marin et al., 1997; Simard, van Reekum, & Cohen, 2000).

Psychotic symptoms may occur during the course of all dementias, but tend to occur early in LBD and in some cases of FTD, sometimes as the presenting symptom; they usually occur later in AD (Marin et al., 1997; Ballard et al., 1999; Simard et al., 2000). Patients with delusions or hallucinations tend to have more prominent cognitive impairment than patients without psychosis (Flynn, Cummings, & Gornbein, 1991). In many cases, psychotic symptoms improve as the disease progresses to later stages.

Psychosis is conceptualized as a thought disorder related to impairments in perceptual and cognitive systems, rather than emotional/affective systems per se.

Agitation and Irritability

"Agitation" is a term used to capture many disruptive behaviors, some of which are simply restless exploratory behaviors with no particular emotional expression, but a proportion of the behaviors described as agitated behaviors involve angry outbursts, often in relation to daily care activities. These include aggressive behaviors, angry or irritable behaviors, screaming, threatening behavior, or violent behaviors.

As many as 70% of patients with dementia exhibit agitation at some point in the illness, often in mid to later stages (Cohen-Mansfield, 1986). Agitation is common in AD and LBD, possibly less common in FTD. Agitation is associated with poorer prognosis with regard to cognitive or functional decline, and is a major reason for nursing home placement.

As is implied in the above description of a variety of behaviors, the origins of agitation vary widely. In some cases, agitation may be provoked specifically by caregiving activities, and is thought to be related to the combination of a patient's cognitive impairment and discomfort with another individual being present during an intimate activity, such as dressing or toileting. Agitation often occurs in patients with coexisting anxiety, suggesting that anxiety or fear may be a contributing factor (Twelftree & Qazi, 2006). In some cases, agitation appears to occur without an apparent environmental trigger, and may be associated with primary neurobiological changes related to the neuropathology of the disease, or active medical issues that may or may not be recognized, or may be related to medications.

Neuropsychological studies have demonstrated an association between agitation and executive dysfunction, raising the possibility that it may be another manifestation of frontal systems dysfunction (Chen, Sultzer, Hinkin, Mahler, & Cummings, 1998), possibly reflecting the loss of emotion regulation processes. Functional imaging has demonstrated frontal dysfunction in patients with agitation (Hirono, Mega, Dinov, Mishkin, & Cummings, 2000). In people with AD who have agitation, neuropathological studies have shown a greater density of neurofibrillary tangles in frontal regions compared with their age-matched peers (Tekin et al., 2001).

Agitation and irritability can be considered as disorders of the balance between negative-valence systems and regulatory or control systems.

Impulse Control and Obsessive–Compulsive Behaviors

Patients with dementia may also manifest other forms of related impulsive behaviors (such as binge eating, touching or kissing strangers, inappropriate sexual behavior, urinating in public), or of compulsive behaviors (such as collecting objects, organizing objects, walking repeated routes, rigid food preferences, or clock watching). These may be viewed as disorders of reward processing (increased positive value) or of disorders of cognitive control (reduced regulatory behavior). These changes can cause stress, frustration, and embarrassment to family and caregivers (Apostolova & Cummings, 2008).

Impulse control and compulsive behaviors are conceptualized as relating to a dysfunction of positive-valence and regulatory or control systems.

Major Neurodegenerative Dementias

Alzheimer's Disease

When first described in 1906 by Professor Alois Alzheimer (1907), the case of August Dieter, the first patient described with what was later called Alzheimer's disease (AD), this disease was believed to represent a very rare condition that caused "presenile dementia." It was not until the 1970s that experts began to realize that AD greatly contributed, if not caused, most cases of "senile dementia" in older individuals. In the past two decades, partly as a result of efforts by the Alzheimer's Association, the medical community has finally recognized that it is not normal for elderly individuals to become "senile," but rather that AD and other neurodegenerative diseases as well as cerebrovascular diseases are common pathologies that cause the loss of mental abilities with age.

AD is the most common cause of neurodegenerative dementia, affecting an estimated 5 million Americans and as many as 20–30 million people worldwide (Saxena, 2012; Wimo & Prince, 2010). With the growth of the elderly population, a worldwide pandemic of clinical AD and dementia is anticipated. And unfortunately, although great advances have been made in the past three decades in our understanding of the scope of the problem and our ability to diagnose patients, our understanding of the etiology, pathophysiology, and therapeutics of this disease remains in its infancy.

Neuropathology

In AD, like all other neurodegenerative conditions, the process that leads to symptoms is now believed to start decades prior to the onset of clinical symptoms. Jack et al. (2010) proposed a model of AD biomarker pathology that involves a progressive sequence of measurable biochemical, neurophysiological, and neuroanatomical alterations that can be potentially detected years prior to psychometrically and clinically noticeable deterioration in cognition, behavior, and function.

The neuropathology of AD usually starts and spreads in a reasonably consistent pattern. The neuropathological hallmarks of AD, visible under the microscope, include diffuse and neuritic beta-amyloid (Aß) plaques that are found outside of cells, and neurofibrillary tangles made up of tau protein that are found inside cells; in addition, there is substantial synaptic and neuronal loss (Braak, Alafuzoff, Arzberger, Kretzschmar, & Del Tredici, 2006; Hyman et al., 2012; Jellinger & Bancher, 1998; Parvizi, Van Hoesen, & Damasio, 2001). By the time of death, patients with AD have prominent loss of brain weight and atrophy (with shrinkage of gyri and widening of sulci) that is most notable in the temporal (particularly the hippocampi and medial temporal lobes), frontal, and parietal lobes. The hippocampal formation, entorhinal and perirhinal cortices, and their related memory networks show a selective vulnerability for the earliest pathology in AD. Heteromodal, paralimbic, and limbic cortices bear the brunt of the burden of AD pathology, with relative sparing of the primary motor and sensory cortices.

Though not specific to AD, the cholinergic neurons of the nucleus basalis of Meynert and substantia innominata undergo degeneration. This cholinergic deficit was the initial target for treatment, with modest success at improving symptoms. Limbic thalamic nuclei, including the anterior and dorsomedial nuclei, also appear selectively vulnerable to neurofibrillary tangles in AD and show neuronal loss. Patients with AD often also have neuropathological changes in the amygdala (Poulin et al., 2011) and in important brainstem adrenergic (locus coeruleus) and serotonergic (dorsal and median raphe) projection nuclei.

Major Clinical Features

The prototypical symptoms of AD include initial memory difficulties attributable to dysfunction of the medial temporal lobe structures, particularly the entorhinal cortex and hippocampus, and associated parietal memory processing regions (Dubois et al., 2010; McKhann et al., 2011). As the disease progresses, patients develop additional cognitive deficits especially including executive dysfunction (problems with organization, judgment, and problem solving), visuospatial impairment (including problems with navigation and complex spatial attention), and apraxia (difficulty with complex movement). Usually but not always language is disrupted later in the disease course. Most basic sensory and motor functions are preserved. Sometimes, patients will present atypically, with language or visuospatial or executive symptoms emerging before memory loss. The course of the disease is commonly 8–10 or more years from first symptoms to death, with many years of complete disability and dependence on others.

Emotion-Related Symptoms

In Professor Alzheimer's (1907) index case, he reported that the patient had significant behavioral and psychiatric symptoms in addition to memory and cognitive difficulties:

> The first noticeable symptom of illness shown by this 51-year old woman was suspiciousness of her husband. Soon, a rapidly increasing memory impairment became evident; she could no longer orient herself in her own dwelling, dragged objects here and there and hid them, and at times, believing that people were out to murder her, started to scream loudly. On observation at the institution, her entire demeanor bears the stamp of utter bewilderment. She is completely disoriented to time and place. Occasionally, she remarks that she does not understand anything and is at her wits' end. Sometimes she greets the doctor as if he were a visitor and excuses herself that she has not finished with her work; on other occasions, she screams that he wants to cut her open, and on yet others, she dismisses him, full of indignation and with expressions indicating that she fears him as a threat to her honor as a woman. At times, she is totally delirious, drags her bedding around, calls for her husband or daughter and seems to have auditory hallucinations. Often, she screams for many hours in a horrible voice.

Although AD has been viewed as predominantly a disorder of memory, executive function, and other cognitive abilities, the vast majority of patients with AD develop changes in emotional behavior, usually referred to as neuropsychiatric symptoms, during the course of the illness (Lyketsos et al., 2002). In some patients, these symptoms may emerge very early, sometimes even prior to cognitive impairment.

The neuropsychiatric profile of AD includes the breadth of neuropsychiatric symptoms described above. These symptoms may occur at any point during the course of the illness but certain features are more likely to appear at certain points along the course of the illness. A commonly used instrument to measure these symptoms is the Neuropsychiatric Inventory (NPI; Kaufer et al., 1998), a structured clinical interview (sometimes administered as a questionnaire). Research using the NPI has found that as many as 60% of patients with AD exhibit at least one neuropsychiatric symptom at the time of presentation. Two common early symptoms are depression and apathy. Apathy is present in nearly half of patients with mild AD and as many as 80–90% of patients with moderate to severe AD (Mega, Cummings, Fiorello, & Gornbein, 1996). Depressive symptoms are present in about half of patients with AD, and are associated with diminished quality of life, functional impairment, and institutionalization, as well as increased caregiver burden and depression (Chan, Kasper, Black, & Rabins, 2003). Psychotic symptoms occur in 30–40% of patients with AD, more often during the middle to late stages (Mega et al., 1996). They are a common reason for institutionalization and increased levels of caregiver burden (Steele, Rovner, Chase, & Folstein, 1990). Common delusional themes include theft, infidelity, and delusional misidentification syndromes, as described above. Hallucinations are less common, are typically visual, and tend to be relatively transient (weeks to months). Persons with AD usually have relatively intact social behavior in the early to mid stages of the disease, but a small percentage of patients who have AD pathology have a "frontal variant" clinical syndrome, in which socioaffective behavioral disturbances similar to FTD can be observed (see below; Johnson, Head, Kim, Starr, & Cotman, 1999).

LBD and PDD

LBD and PDD are neurodegenerative diseases with symptoms that include changes in movement, cognition, emotion, and autonomic function. LBD was relatively recently described, in 1961, but is thought to be the second most common cause of neurodegenerative dementia after AD, accounting for 15–30% of all dementia cases (Okazaki, Lipkin, & Aronson, 1961; Barker et al., 2002; Hulette et al., 1995; Lim et al., 1999). DLB usually appears in people 60–80 years of age (McKeith et al., 2005). The rate of decline is similar to that of AD, with average survival of 8–10 years.

LBD and PDD have overlapping clinical features with the distinction being the chronology and temporal course of symptoms. Patients who first develop a movement disorder consistent with PD and subsequently develop dementia are diagnosed as PDD, while those who develop dementia followed by parkinsonism or who develop both types of symptoms simultaneously are diagnosed as LBD. The clinical diagnostic criteria have reasonably good predictive accuracy for LBD pathology (McKeith, Perry, & Perry, 1999; McKeith et al., 2005; Emre et al., 2007).

Pathology of LBD

Both LBD and PDD are members of the class of neurodegenerative diseases collectively referred to as synucleinopathies; they are believed to represent two entities on the same disease spectrum with overlapping clinical, neurochemical, and pathological findings. The pathologic diagnosis of LBD requires the presence of Lewy bodies (LBs) within neurons. They can be seen in the brainstem nuclei (including autonomic nuclei), amygdala, basal ganglia and cerebral cortex, particularly the limbic and paralimbic cortices (Hansen et al., 1990). As with all neurodegenerative diseases, neuronal loss is also present. Alpha-synuclein is the major protein component of LBs (Spillantini, Crowther, Jakes, Hasegawa, & Goedert, 1998). In addition to LB pathology, 75–90% of patients with LBD also have amyloid plaques like AD, but in contrast to AD, neurofibrillary tangles are rare.

LBD pathology is associated with profound cholinergic and dopaminergic deficits (Perry et al., 1990). Like AD, a cholinergic deficit is present but is more prominent in LBD than in AD (Samuel, Alford, Hofstetter, & Hansen, 1997). A higher LB density in the limbic system (amygdala) is associated with visual hallucinations (Harding, Broe, & Halliday, 2002). In contrast to AD but like PD, a dopaminergic deficit is the other important neurochemical feature of LBD. Deficits may also be present in the serotoninergic and noradrenergic systems, with some evidence that this may relate to cognitive-behavioral impairment.

Major Clinical Features of LBD

Clinical features of LBD include cognitive, psychiatric, neurological, sleep, and autonomic symptoms. The cognitive profile of LBD includes major impairments in executive and visuospatial functions as well as attention (Calderon et al., 2001; Walker, Allen, Shergill, & Katona, 1997), often with minimal memory symptoms early in the disease. These symptoms typically fluctuate prominently, with pronounced variations in attention and alertness that may vary from hour to hour or day to day (Ferman et al., 2004).

Another core feature of LBD is the presence of parkinsonism, although as many as 25% of cases with LBD pathology may have had no parkinsonism. Neurologists diagnose parkinsonism when patients have a movement disorder including rigidity of the arms or legs, slowness of movement (bradykinesia), shuffling gait, stooped posture, and a "mask-like" facial expression, as well as a tremor at rest. There are many causes of parkinsonism, including so-called idiopathic PD and strokes; parkinsonism is a common side effect of many drugs used to treat psychiatric symptoms. Unlike PD, many patients with LBD do not have a resting tremor, but often have postural instability with falls.

Many patients also have prominent sleep disorders and autonomic symptoms, including blood pressure variation, impotence, urinary incontinence, or constipation.

Changes in Emotional Behavior in LBD

A core clinical feature—part of the diagnostic criteria—of LBD is persistent visual hallucinations. Hallucinations are usually present early in the course of illness; they are often recurrent, well formed, and detailed, but often do not disturb the patient (Mosimann et al., 2006). Many patients calmly describe being aware that they are seeing people or animals that are not real. Visual illusions are also common where patients perceive objects differently from their true identity. Auditory hallucinations occur in up to 25% of patients with LBD, olfactory hallucinations in 5–10%, and tactile hallucinations in up to 3%.

Delusions are less common, but may be similar to those seen in AD, such as the belief that strangers are living in the home (phantom boarder) or delusions of persecution; delusions of theft and infidelity may also occur. One neuroimaging study used single-photon emission computerized tomography (SPECT) scans in LBD patients to identify associations between visual hallucinations with reduced blood flow in the parietal and ventral occipital cortices, misidentifications with reduced blood flow in limbic–paralimbic structures, and delusions with reduced blood flow in the frontal cortices (Nagahama, Okina, Suzuki, & Matsuda, 2010).

Depression and anxiety may appear years before the onset of dementia and up to 40% of patients with LBD experience a major depressive episode in the course of their illness (Auning et al., 2011).

An important challenge in LBD is that patients tend to be very sensitive to adverse effects of antipsychotic medications, so that it can be quite difficult to treat psychosis in these patients.

Frontotemporal Dementia

In 1892, Arnold Pick described a 71-year-old patient with progressive cognitive decline, primarily manifesting as early loss of language (Pick, Girling, & Berrios, 1997), and subsequently reported three additional cases, noting the prominent frontal or anterior temporal lobe atrophy present postmortem. The associated abnormalities identified microscopically were later described by Alois Alzheimer (1907), and in the 1920s the term "Pick's disease" was coined. Subsequent investigators described the clinical course of the disease, highlighting the insidious early changes in behavior and personality and, in contrast with AD, the typical relative preservation of memory and orientation into the middle phases of the disease (Berrios & Girling, 1994). A resurgence of interest in these conditions occurred in the last two decades of the 20th century, and we now recognize patients with several major forms of the clinical entity "frontotemporal dementia" (FTD), including "behavioral variant of FTD" (bvFTD), "semantic dementia" (SD) or "semantic variant of primary progressive amnesia (PPA)," "nonfluent or agrammatic variant of PPA" (PNFA), and "logopenic variant of PPA." The neuropathological family of this complex set of conditions is termed "frontotemporal lobar degeneration" (FTLD). FTLD is a loosely knit group of neurodegenerative diseases that preferentially affect the frontal and anterior temporal lobes, with relative sparing of other cortical regions in many cases, and often affects basal ganglia and in some cases basal forebrain and brainstem nuclei.

FTLD is thought to be the third most common degenerative dementia, after AD and LBD, accounting for 5–15% of dementias. FTLD often strikes people at a younger age than AD or LBD, often in affecting patients who are 45–65 years old. It is probably the second most common cause of dementia in people younger than 65. Although detailed epidemiological studies are sparse, it is thought to be relatively rare, affecting somewhere between 50,000 and 300,000 Americans.

Neuropathology of FTLD

The hallmark of the neuropathology of FTLD is its topographic distribution—which in some cases is strikingly focal—in the frontal and anterior temporal lobes, as well as a number of subcortical structures. There are a variety of microscopic features associated with these abnormalities. In some cases, deposits of tau protein inside neurons are present; these are called "Pick bodies" (Onari & Spatz, 1926). Further investigations of this pathological form of FTLD has shown that atrophy and tau pathology occurs in the prefrontal cortex, frontoinsula, anterior cingulate, and anterior temporal cortex with relative sparing of the superior temporal gyrus, especially its posterior third, as well as the primary visual cortex (Hof, Bouras, Perl, & Morrison, 1994; Yoshimura, 1989). Prominent white matter tau pathology is commonly present (Zhukareva et al., 2002). The basal ganglia, basal forebrain, and brainstem structures are variably affected, with some patients showing minimal pathology and others exhibiting substantial pathology (Dickson, 2001). The spectrum of "pure tauopathies" (without the amyloid plaques seen in AD) also includes rare conditions called progressive supranuclear palsy and corticobasal degeneration. Other patients with FTLD have a protein called TDP-43 (transactive DNA-binding protein, molecular weight 43 kD) that is deposited in similar areas (Neumann et al., 2006; Mackenzie, Rademakers, & Neumann, 2010). Furthermore, TDP-43 has been found in most cases of amyotrophic lateral sclerosis (ALS). Thus, the FTLD spectrum is linked to multiple other neurodegenerative diseases.

It is unclear why particular brain regions are vulnerable to tau or TDP-43 pathology in FTLD. In 2006, Seeley et al. reported the selective loss of a specific cell type found in the anterior cingulate and frontoinsular cortex of great apes, whales, and humans. This spindle-shaped neuron, the von Economo cell, was reported to be reduced by more than 60% in these brain regions in FTLD but not in AD. Further research on this and potentially other selectively vulnerable cell types in FTLD may reveal new insights into the devastation of these cortical regions in FTLD syndromes.

Major Clinical Features of FTD

There are two major clinical types of FTD: the behavioral variant of FTD (bvFTD) and the language variant of FTD, also known as "primary progressive aphasia" (PPA).

Primary Progressive Aphasia. If a patient presents with an isolated, gradually progressive aphasia, he or she would be diagnosed by many specialists with PPA.

At present, such a patient would have been diagnosed as having a language-predominant form of FTD or FTLD, and further subtyped into one of three major clinical subtypes: the agrammatic variant of PPA (PPA-g, which likely captures most of the patients formerly diagnosed with PNFA), the semantic variant of PPA (PPA-s, which likely captures most of the patients formerly diagnosed with SD), and the logopenic variant of PPA (Gorno-Tempini et al., 2011). The former two subtypes are usually associated with FTLD pathology, while the logopenic variant of PPA (PPA-l) is most frequently associated with underlying AD pathology, and thus would not be considered a major clinical subtype of FTLD.

Although patients with progressive aphasias may have personality, comportmental, and social symptoms, they are by definition less prominent than the language impairment early in the course of the disorder. As PPA progresses, it evolves to affect other cognitive functions and many patients develop changes in emotional behavior (Modirrousta, Price, & Dickerson, 2013).

Changes in Emotion in PPA. Patients with the semantic variant of PPA (PPA-s) commonly exhibit neuropsychiatric symptoms, often relatively early and in a fairly stereotypical fashion. Many of these symptoms are similar to those of bvFTD, including loss of empathy, changes in eating behavior, compulsive behavior, and disinhibition (see below). In fact, in the prior diagnostic criteria for FTD, features considered supportive of a diagnosis of SD included loss of sympathy or empathy and narrowed preoccupations (mental rigidity; Neary et al., 1998). Depression is also reported as common in PPA-s in some studies; in my experience, however, at least some patients make negatively valenced statements (e.g., "I feel so stupid," "I know I'm going to die"), but express minimal affective behavior consistent with depression.

In PPA-g, neuropsychiatric symptoms are less frequent initially, but as the illness progresses it becomes increasingly common to see apathy, depression, or irritability. In some cases these symptoms are present early in the illness, which may lead to misdiagnosis as a primary psychiatric disorder (often depression).

In PPA-l, neuropsychiatric symptoms are relatively infrequent early but increase as the illness progresses and include agitation, anxiety, irritability, and apathy. In many cases we have seen, the clinical phenomenology of neuropsychiatric symptoms appears similar to that seen in AD (see above).

Behavioral Variant of FTD. Many of the core clinical features of bvFTD include disruptions of emotional behavior, described below. Cognitive symptoms are also often present, especially executive dysfunction (problems with organization, planning, sequencing, decision making, multitasking, or monitoring performance; Bozeat, Gregory, Ralph, & Hodges, 2000). Progressive loss of executive abilities may lead to job loss or mismanagement of money.

Another important clinical feature of bvFTD is lack of insight (Banks & Weintraub, 2008; Eslinger et al., 2005; Williamson et al., 2009), even when the patient is directly confronted with obvious impairments.

Compulsive, ritualistic, or repetitive behaviors are common in bvFTD, often early in the illness (Ames, Cummings, Wirshing, Quinn, & Mahler, 1994; Nyatsanza et al., 2003; Mendez, Perryman, Miller, Swartz, & Cummings, 1997), and may include repetitive "projects," chores, or playing of card or computer games or repetitive watching of a particular television show, or hoarding (Bozeat, Gregory, Ralph, & Hodges, 2000). Speech patterns may be stereotyped (e.g., catchphrases, telling of stories as if by a script). Some patients have very rigid routines that must be performed identically each day (often at a particular time, associated with "clock watching"). These symptoms may change as the disease progresses, in some cases becoming simpler.

Changes in eating behavior are common, and may include altered food preferences (such as an increased sweet tooth or a rigid stereotypy in the foods eaten from day to day) or gluttonous or binge-like eating (Bozeat et al., 2000; Miller, Darby, Swartz, Yener, & Mena, 1995).

Changes in Emotion in bvFTD. The core clinical features of bvFTD are socioaffective, and include the insidious development of changes in interpersonal and emotional behavior, commonly accompanied by executive dysfunction. Disinhibition is a common early symptom, and is often seen in social settings. For example, patients may act in an overly familiar manner with strangers, may violate social normative behavior such as public urination or changes in behavior during social meals, may make impulsive actions such as unnecessary or excessive purchasing or shoplifting (Miller et al., 1991; Miller, Darby, Benson, Cummings, & Miller, 1997; Snowden et al., 2001) or inappropriate sexual behavior. Disinhibition appears to be related particularly to orbitofrontal and cingulo-opercular abnormalities in FTD (O'Callaghan, Hodges, & Hornberger, 2013).

Another very common early symptom is apathy, including loss of interest in hobbies or social activities (Chow et al., 2009; Massimo et al., 2009; Shinagawa, Ikeda, Fukuhara, & Tanabe, 2006). In some patients with FTD, apathy is mistaken for depression, but patients with bvFTD do not usually exhibit sadness or cry and are often not particularly concerned or upset by their symptoms. Atrophy in the ACC, DLPFC (Massimo et al., 2009), and striatum (Rosen et al., 2005) has been observed in association with apathy in bvFTD.

Loss of empathy or sympathy is very common (Lough et al., 2006; Mendez & Perryman, 2003; Rankin, Kramer, & Miller, 2005). Because of the wide variability between healthy individuals in expressions of empathy, it can be difficult to be confident that some patients who may never have been particularly empathic have developed this symptom. In some cases, an abnormal response to an extreme emotional event (such as the death of a family member) may trigger a trip to the doctor. Even under these circumstances, the behavior is commonly attributed to depression or another psychiatric illness or to stress or a midlife crisis. Right anterior temporal cortex, anterior insula, and striatal abnormalities have been most consistently identified as related to loss of empathy (Perry et al., 2001; Rankin et al., 2006).

Another core feature of bvFTD is personality change. Alterations in personality can be prominent in bvFTD and also in semantic dementia (Rankin, Baldwin, Pace-Savitsky, Kramer, & Miller, 2005). Although questionnaire-based instruments to assess classical dimensional personality traits are readily available, changes in personality might be best understood by considering more specific process-oriented functions contributing to personality traits. Some symptoms may include changes in the expression or comprehension of emotion, social withdrawal or disinhibition, or loss of empathy. In some cases, a previously gruff or aggressive individual becomes docile.

Psychosis has been thought unusual in bvFTD, but the discovery of the *C9ORF72* expansion has highlighted the common presence of psychosis in patients as well as nondemented family members with this genetic mutation (Boeve et al., 2012).

Conclusions

Neurodegenerative dementias are a modern-day scourge of our society, affecting between 6 and 10 million people in the United States and an order of magnitude more around the world, and wreaking havoc not only on the patient's independent functioning but also on family life. Although cognitive and motor symptoms often receive the most attention from clinicians (particularly neurologists) providing care and conducting research in this field, emotional disorders are common problems and confer tremendous suffering. With important exceptions, neurologists are not systematically trained in the evaluation of these symptoms or their treatment, and psychiatrists who are trained in these areas are often not well versed in the neurobiology and functional neuroanatomy of neurodegenerative dementias. Contemporary behavioral neurology and neuropsychiatry training programs are beginning to provide the range of training in cognition, movement, and emotion that is required to provide comprehensive care for patients with these conditions, but in many cases, the care provided by a multidisciplinary team may be most optimal.

Constructs of psychological and behavioral symptoms of dementias are rooted in traditional psychiatry and psychology. These constructs are only recently being updated to incorporate new frameworks such as the RDoC within psychiatry (Insel et al., 2010), which are grounded in systems-based functional neuroanatomy. Insights gained from basic science studies of emotion will undoubtedly support continued progress in our understanding of the psychological processes and functional neuroanatomy of emotional disorders in neurodegenerative dementias. Hopefully, these insights will spark new ideas about treatments for these devastating symptoms.

PART VII

SPECIFIC EMOTIONS

CHAPTER 43

Fear and Anxiety

Kevin S. LaBar

What are you afraid of? What bodily symptoms accompany this sense of fear? Do specific cues or environmental contexts trigger your fear? Why are threatening experiences so memorable? These kinds of questions motivate the study of fear and its close relative, anxiety. Although scientists have yet to fully solve the mystery of fear, there has been much progress in understanding this ubiquitous emotion. Fear is an ideal emotion for scientific inquiry because it has a long evolutionary basis and thus can be studied in a variety of nonhuman animals; moreover, it is relatively straightforward to elicit and measure in a laboratory. However, ethical issues limit the kinds of threatening experiences that can be adapted to scientific investigation. Because the literature on fear and anxiety is vast, this chapter limits its scope to an affective neuroscience perspective that considers how fear signals are processed in the brain, with an emphasis on fear learning paradigms in healthy humans.

Defining Fear and Anxiety

Fear is a negatively valenced emotion elicited in response to an impending threat that motivates a defensive reaction to protect the organism. In humans, fear is accompanied by a subjective sense of apprehension or, in more intense situations, dread. Fear is typically associated with a specific elicitor. Although fear responses evolved in situations of imminent physical harm, such as predator–prey interactions, fear triggers in humans are often more psychological in nature. Regardless of the source of fear, a final common neural pathway is engaged to mobilize bodily resources in the face of threat (see the section "Defensive Motivational Systems"). Due to the high energy demands of defensive encounters, chronic fear states have profound deleterious effects on various systems of the body. Generally, fear responses subside relatively quickly upon termination of the threatening stimulus to allow the body to achieve a homeostatic state.

Anxiety is a state of unease about a distal, potentially negative outcome that is uncertain or unpredictable (Lake & LaBar, 2011). In contrast to fear, anxiety is longer lasting, is more future than present oriented, often has a less specific elicitor or terminator (Lang, Davis, & Ohman, 2000), and functionally prepares the organism to confront a threat—albeit reluctantly—rather than withdrawing from it (McNaughton & Corr, 2004). Fear can become anxiety if active coping mechanisms fail and the fear remains unresolved (e.g., when a specific source of threat in the environment is not identified). Nonetheless, fear is not a necessary antecedent to anxiety. Anxious states are maintained by a host of cognitive processes, including rumination, abstraction, risk assessment, mental time travel, and mental projection/simulation. In clinical studies, anxiety is quantified both as a dispositional trait measure and as an acute state measure.

Although fear and anxiety have different linguistic labels, the boundary between fear and anxiety is not clear-cut, as both emotions are elicited in the context of defensive motivation. Different theories abound regarding the relationship between these constructs and the varieties of their expression. Some anxiety theorists emphasize the role of appraisals (Beck, Emery, & Greenberg, 1985), whereas others emphasize information processing biases (Williams, Watts, MacLeod, & Mathews, 1997), biological factors (McNaughton & Corr, 2004), or motivational systems (Woody & Szechtman, 2011). The muddling of fear-related concepts has hampered progress in scientific understanding of the neural mechanisms of fear and anxiety and their clinical manifestation. For instance, in the development of anxiolytic drugs, divergent effects are often observed across different threat-related behavioral paradigms, complicating the interpretation of their efficacy (Blanchard, Yudko, Rodgers, & Blanchard, 1993; Panksepp, 1998). Blanchard and Blanchard (1988) have argued that rodent experimental approaches should converge with ethological approaches to more carefully delineate how emotions like fear and anxiety emerge from naturalistic situations that elicit various offensive and defensive behaviors. For the first time, the *Diagnostic and Statistical Manual of Mental Disorders* (5th ed. [DSM-5]; American Psychiatric Association, 2013) has separated obsessive–compulsive disorder and posttraumatic stress disorder from other anxiety disorders based on conceptual, neurobiological, and symptomatic differences. Yet, the remaining grouping of disorders within the anxiety disorder umbrella, such as specific phobias and generalized anxiety disorder, may further benefit from teasing apart the relative contributions of fear versus anxiety. More theoretical work is needed to clarify the distinctions among these constructs and to guide empirical and clinical investigation.

Operationalizing Fear for Scientific Investigation

From a functional perspective, the emotion fear serves to mobilize bodily resources to protect the organism from an imminent threat. Threat anticipation spurs the reorganization of metabolic priorities such that digestive, sexual, and parasympathetic autonomic functions are temporarily suppressed while sympathetic arousal, muscular blood flow, and stress hormone release (via the hypothalamic–pituitary–adrenal axis) are increased. This diversion of resources facilitates action planning, defensive response execution, and reinforcement learning in the face of threat. Researchers quantify components of these physiological changes, such as the potentiation of the startle reflex, as dependent measures of fear reactivity. An advantage to this approach is that the measurements are relatively conserved across species, facilitating the development of animal models of fear.

Physiological responses constitute only one class of dependent measures of emotion; it is important to consider these responses relative to other facets, including subjective experience (in humans) and behavioral changes. Some clinical evidence suggests that physiological responses to trauma-related cues predict symptoms of posttraumatic stress disorder better than subjective distress measures or more general emotional reactivity indices (Pineles et al., 2013). However, physiologic measures often correlate only moderately with experiential ratings of fear in humans (Busscher, van Gerwen, Spinhoven, & de Geus, 2010), and other emotions besides fear elicit changes in the same dependent measures. Thus the sensitivity and specificity of these measures has been questioned by some researchers (Quigley & Barrett, 2014). Consequently, multiple dependent measures are important to collect, and it is always important to interpret the results from a given measure with respect to the task context.

Because fear evolved to help organisms manage physical threats, there are obvious ethical limitations to studying fear in the laboratory. In nonhuman animal studies, predator exposure tasks are typically arranged to maintain a distance where direct physical confrontation is prohibitive. In humans, threat paradigms that use noxious stimuli are adjusted in intensity so as to minimize physical pain (e.g., setting electric shock delivery to the tolerance of each participant). These modifications are necessary to conduct research ethically but limit the translation of results to real-world scenarios involving high-intense fear reactions. Other innate threat paradigms that do not involve punishers can circumvent some of these ethical issues, such as predator odor exposure, but these tasks are less translatable to human investigation. Virtual reality technologies are currently being explored as a methodological advance to simulate more realistic fearful experiences. For instance, virtual reality has proven effective in simulating fear of heights for evaluating treatment outcomes in acrophobic patients (Ressler et al., 2004) and as a basic research tool to study fear and avoidance learning using dynamic virtual predators (Huff et al., 2011; Mobbs et al., 2009).

Operationalizing Anxiety for Scientific Investigation

In contrast to fear paradigms, which use phasic threats to provoke a transient fear response, anxiety paradigms manipulate the unpredictability or uncertainty of aversive events to elicit a more sustained state of apprehensive anticipation. Because anxiety is more temporally oriented to the future than the present, anticipatory anxiety paradigms typically cue the participant to the relative likelihood or certainty that a future unpleasant event will occur. For example, participants in a threat-of-shock paradigm might receive a "threat" cue that a future shock is likely to occur in the immediate future, whereas a "safe" cue indicates that shock will not occur. In other tasks, participants see a clock that counts down to the time at which an unpleasant stimulus is likely to be delivered. Across these situations, anxiety is exacerbated by providing participants with no control over the delivery of the aversive stimulus (e.g., avoidance or escape behaviors cannot be executed). Other paradigms elicit anxiety incidentally by contextual manipulations that organisms find innately anxiety provoking. For rodents and other species, placement in an open field elicits anxiety because of the potential for exposure to dangers, such as predators, without safe havens for protection. In a similar vein, humans experience more anxiety in the dark than in the light due to compromises in visual system function that hinder the identification of potential sources of threat or escape routes (the reverse is true for nocturnal organisms, which exhibit more fear in the light). Thus, experimenters can move participants from light to dark locations or from exposed to protected environments to capitalize on innate contextual triggers of anxiety.

Dependent measures of anxiety are similar to those elicited by fear but they differ in a few respects. Due to its future time orientation, anxiety engages precautionary and risk-assessment behaviors, such as repetitive visual scanning for potential threats, more so than a full-blown fight-or-flight response. In addition, dependent measures of anxiety have more protracted time courses because they are less temporally linked to the presence of a threat. For example, researchers use spontaneous fluctuations in skin conductance during threat anticipation intervals as a dependent measure of anxiety, whereas they time-lock phasic skin conductance responses to conditioned or unconditioned threat cues as a dependent measure of fear. Waiting periods during threat anticipation yield additional measures of anxiety, such as habitual or periodic motor behaviors (pacing, nail-biting, jaw clenching). Finally, anxiety is sometimes accompanied by thoughts that mull over potential sources of action to cope with or prepare for a future threat; these cognitive processes can promote defensive approach behaviors toward a future threat rather than defensive withdrawal responses away from it, as in the case of fear. These differences between fear and anxiety measures are best understood as lying along a continuum of defensive response repertoires, as described in the section "Defensive Motivational Systems."

Defensive Motivational Systems

Both fear and anxiety emerged within the evolutionary context of defensive encounters to promote survival. Thus, understanding how defensive motivation circuits are organized, even in less advanced organisms, can lead to important insights into these emotions (LeDoux, 2012). An interplay of aggression and fear manifests during defensive battles that creates opposing tendencies to fight or flee the situation. Activation of fear in these contexts confers several benefits, including (1) it promotes threat detection by motivating perceptual vigilance; (2) it promotes more flexibility in species-typical response repertoires by assessing routes for action and weighing response options given the details of the eliciting context (e.g., flight if danger is avoidable vs. freezing if unavoidable); (3) it promotes action preparation—particularly those related to withdrawal, avoidance, or escape—by redistributing metabolic resources; and (4) it promotes learning by engaging reinforcement circuits and memory consolidation for the episode. For more remote threats, anxiety serves similar functions, although anxious states prepare energy supply mechanisms but do not fully engage them as they are not immediately needed (Woody & Szechtman, 2011), and anxiety nudges the organism defensively toward approaching threats (as when test anxiety prompts studying behavior; McNaughton & Corr, 2004).

The neural organization of the defensive motivational system is organized in a hierarchical series of cortico–limbic–brainstem structures with strong connections to the autonomic nervous system (Figure 43.1). This system is organized primarily according to defensive distance (threat imminence), shifting from parasympathetic to sym-

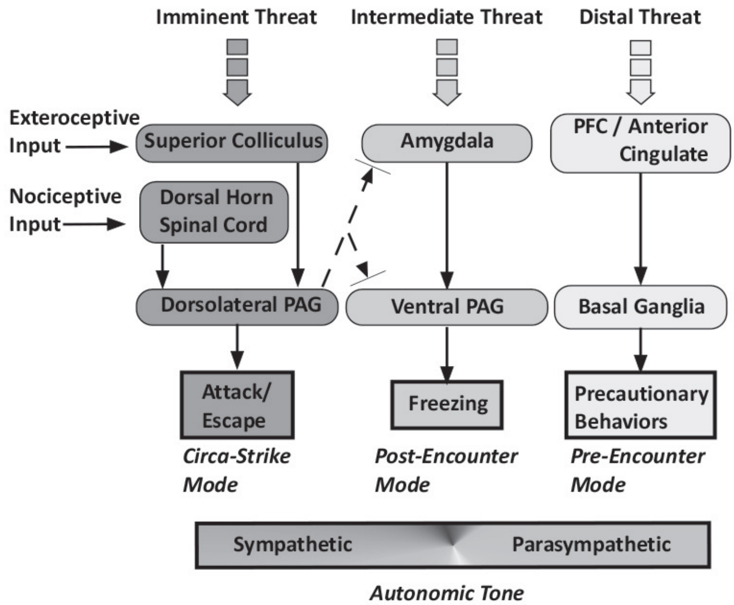

FIGURE 43.1. Motivational systems for defensive avoidance. Defensive motivation is organized according to threat imminence. For distal threats (preencounter mode), prefrontal cortex (PFC) and anterior cingulate control systems engage motor regions to execute precautionary behaviors. Once a threat is detected (postencounter mode), the amygdala evaluates sensory input and engages freezing or flight behavior according to contextual factors. For unavoidable threats (circa-strike mode), physical contact and nociceptive inputs are integrated in the dorsolateral periaqueductal gray (PAG) to coordinate behavioral attack or escape and to inhibit freezing (dashed lines). With increasing threat imminence, autonomic activity shifts from parasympathetic to sympathetic control.

pathetic autonomic tone as the threat encroaches closer in time and space. In addition, there are some specializations according to defensive direction (defensive avoidance vs. defensive approach; McNaughton & Corr, 2004) and defensive experience (for innate vs. learned threats; LeDoux, 2012). According to the tripartite model of Fanselow (1994), distal threats, such as entering an area where a potential predator lurks, prompt a *preencounter defensive mode* that reorganizes routine behaviors like meal patterns and promotes precautionary behaviors and appraisals. The neural structures enacting these effects are not well understood but likely include ventral frontal and anterior cingulate regions that monitor conflict, represent goals, and control limbic and hypothalamic-mediated autonomic functions (McNaughton & Corr, 2004).

After a predator is detected in the current environment, the organism enters a *postencounter defensive mode* that promotes freezing and potentiates startle reflexes, along with a host of autonomic changes. The amygdala coordinates these responses by targeting specific downstream structures: freezing responses in the ventral periaqueductal gray; startle reflex potentiation in the nucleus reticularis pontis caudalis; and autonomic functions in hypothalamic and dorsal medullary nuclei, such as the parabrachial nucleus for respiratory panting and the lateral hypothalamus for sympathetic activation (increased skin conductance, blood pressure, pupillary dilation, etc.). In addition, the amygdala targets basal forebrain and brainstem sites for widespread neuromodulation of arousal and vigilance (e.g., ventral tegmental area for dopamine release, locus coeruleus for norepinephrine release, and the mesopontine tegmentum and nucleus basalis of Meynert for acetylcholine release). Imminent threats, as when predator contact is inevitable, prompt a *circa-strike defensive mode* that involves threat displays, attack, and escape behaviors mediated by subcortical structures, most prominently the dorsal periaqueductal gray.

Unlike defensive avoidance, defensive approach is less well studied but is more associated with anxiety than with fear. McNaughton (Gray & McNaughton, 2000; McNaughton & Corr, 2004) hypothesizes that defensive approach involves a dorsal corticolimbic stream that links the dorsal prefrontal cortex and posterior cingulate with the septo-hippocampal system and cortico–striatal–thalamic loops for response execution. This system mediates behavioral inhibition in response to conflicting response tendencies. As with defensive avoidance, this network is organized according to defensive distance such that remote threats engage prefrontal and cingulate regions for conflict resolution mechanisms, with intermediate levels of threat engaging the septo-hippocampal system for cognitive aspects of anxiety, including negatively valenced information processing biases and exploratory risk-assessment behaviors, and the amygdala for the coordination of arousal responses. Finally, immediate threats engage circuitry in the medial hypothalamus and periaqueductal gray to generate simple behavioral reactions such as defensive quiescence. (See Davis, Walker, Miles, & Grillon, 2010, for details on neuropharmacologic research methods in fear and anxiety across humans and rodents.)

Perceptual and Attentional Processing of Threats and Fear Indicators

The failure to identify sources of threat in the environment has dire behavioral consequences. Because of the high cost of false negatives to the individual or group, brain mechanisms evolved to monitor for and react to potential threats in the environment, communicate the existence of threat to others, engage coping strategies, and learn from threatening experiences. The first step in this defensive cascade is to assess exteroceptive input for the presence of threats. Numerous behavioral studies show that threatening stimuli achieve prioritization in perception and attention. For instance, threatening stimuli exhibit faster reaction times in target detection tasks, as when a snake or spider is present among an array of fruits or plants (Flykt, 2005; Flykt & Caldara, 2006; Ohman, Flykt, & Esteves, 2001), when an angry face is present among a crowd of happy or neutral faces (Mather & Knight, 2006; Ohman, Lundqvist, & Esteves, 2001), or when a target is embedded in a fear-conditioned stimulus (Notebaert, Crombez, Van Damme, De Houwer, & Theeuwes, 2011). In some cases, these effects are stronger for threat stimuli than for those that elicit or symbolize other emotions—for example, detecting an angry face among a crowd of neutral faces has more advantages than detecting a sad or happy face (Mather & Knight, 2006). Moreover, when task-irrelevant threat stimuli are included among distractors during a neutral visual search task, reaction times are slowed, implicating a reflexive attentional effect that hinders goal-directed attentional processing (Miltner, Kriechel, Hecht, Trippe, & Weiss, 2004). Similar effects of incidental anxiety have been reported, with performance on a dual-target search task being negatively impacted by anticipatory anxiety induced by a threat-of-shock manipulation (Cain, Dunsmoor, LaBar, & Mitroff, 2011).

Both subcortical and cortical pathways contribute to threat-detection processes, with relative specializations for preattentive versus attentive modes of stimulus processing. Preattentive modes include both situations of *sensory unawareness*, when a stimulus is not consciously perceived due to its brevity or weak energy—and *attentional unawareness*, when a stimulus is readily available for conscious perception but is not selected for attentional resources (Tamietto & De Gelder, 2010). Sensory unawareness is tested using subliminal presentations of stimuli via backward masking or binocular rivalry paradigms. Backward masking involves presenting a stimulus near the threshold for perceptual awareness (for visual stimuli in humans, typically around 17 milliseconds), followed immediately by another image that masks lingering stimulus processing. Binocular rivalry achieves similar effects by presenting different stimuli to each eye simultaneously, with only one image reaching conscious perception at any point in time. Attentional unawareness is tested using various paradigms that present multiple stimuli across space or time with sufficient duration and stimulus energy to allow each one to be registered by the sensory system. In this case, attentional allocation operates to select only a subset of these stimuli to enter into conscious awareness due to attentional capacity limitations and/or task demands. Across all preattentive mode tasks, the threat potential of the stimulus is manipulated to determine whether threatening stimuli receive preferential prioritization of resources over neutral stimuli (or other kinds of emotional stimuli) in the unaware condition.

Subcortical routes of sensory input to the limbic forebrain regions, particularly the amygdala, are thought to be critical for preattentive threat detection (see Pessoa & Adolphs, 2010, for an alternative view). The lateral amygdala serves as the primary sensory gateway to the amygdala, with the exception of olfaction, which targets the cortical and medial nuclei of the amygdala via evolutionarily older pathways (Aggleton & Mishkin, 1986). Auditory input from the medial geniculate and posterior intralaminar nuclei of the thalamus projects to the lateral and central nuclei of the amygdala. Visual input from the pulvinar and lateral geniculate nuclei of the thalamus also project to the lateral nucleus of the amygdala. Interestingly, a portion of this visual input to the amygdala arises via a secondary visual pathway from the retina to the superior colliculus that does not terminate in the primary visual cortex of the occipital lobe. This magnocellular, or extrageniculate, pathway derives primarily from retinal ganglion cells that have large, nonfoveal receptive fields and high motion sensitivity but low visual acuity and color sensitivity. This pathway may have evolved principally for the detection of moving predators in peripheral vision and functioned to reflexively orient attention to the spatial location of possible threats (Tomalski, Johnson, & Csibra, 2009). Later in evolution the functional role of this circuit likely expanded to include other aspects of visual and socioemotional processing beyond threat assessment (Garrido, Barnes, Sahani, & Dolan, 2012).

Functional imaging studies in humans have provided some evidence for a role of these subcortical structures in preattentive threat detection. Subliminally presented facial expressions of fear elicit activity in the amygdala, pulvinar, and superior colliculus (Liddell et al., 2005; Morris, Ohman, & Dolan, 1999), and the functional connectivity among these structures is more positively correlated during subliminal than supraliminal presentations (Williams et al., 2006). Although functional connectivity does not necessarily imply direct anatomical connectivity, recent diffusion tensor imaging studies have validated the existence of this subcortical circuit to the amygdala in the human brain (Tamietto, Pullens, De Gelder, Weiskrantz, & Goebel, 2012). Subliminal images of the eye region of fearful faces alone are sufficient to engage amygdala responses (Whalen et al., 2004). The expression of fear widens the eye aperture, revealing a larger sclera and exposed iris. These physiognomic changes have important perceptual effects, as they increase visual acuity and make the direction of eye gaze more visible to others, thereby facilitating the social communication of threat (Lee, Susskind, & Anderson, 2013). Amygdala activation extends to unseen fearful facial expressions in binocular rivalry studies (Williams, Morris, McGlone, Abbott, & Mattingley, 2004), as well as other subliminal threat signals, including images of snakes and spiders (Carlsson et al., 2004), which also evoke autonomic responses (Ohman & Soares, 1994). Although fear is the most widely studied emotion in these tasks, there is evidence that the amygdala also responds to subliminal facial expressions of some other emotions (Killgore & Yurgelun-Todd, 2004).

Studies of patients who are cortically blind with damage to the primary visual pathways provide a unique opportunity to examine nonconscious aspects of fear perception. When faces or body gestures are presented in the blind portion of their visual field (called the "scotoma"), the patients do not consciously perceive anything but can accurately guess (better than chance) whether the stimulus expresses fear or other emotions, and these stimuli elicit rapid, appropriate changes in pupillary reflexes and facial expression (Tamietto et al., 2009). Moreover, visual stimuli presented in the scotoma elicit fear-potentiated startle responses following Pavlovian conditioning, despite not being consciously seen (Hamm et al., 2003). Such reports of *affective blindsight* are associated with activation in the subcortical circuits described above (Morris, de Gelder, Weiskrantz, & Dolan, 2001; Pegna, Khateb, Lazeyras, & Seghier, 2005).

Attentional unawareness in threat detection has been studied using numerous paradigms that present fearful stimuli as task-irrelevant distractors superimposed onto other tasks. Despite being unattended, fearful faces nonetheless enhance processing along the ventral visual pathway, including the fusiform gyrus and amygdala (Anderson, Christoff, Panitz, De Rosa, & Gabrieli, 2003; Vuilleumier, Armony, Driver, & Dolan, 2001), and these effects are stronger in trait-anxious individuals (Bishop, Duncan, & Lawrence, 2004). In an important finding, Vuilleumier and colleagues (Vuilleumier, Richardson, Armony, Driver, & Dolan, 2004) showed that the fusiform modulation of both unattended and attended fearful faces was reduced in patients with amygdala damage due to epilepsy, implicating an amygdala-dependent visual feedback pathway. This pathway, which aligns with amygdala feedback projections described in the nonhuman primate (Amaral & Price, 1984), was subsequently identified using diffusion tensor imaging in humans (Gschwind, Pourtois, Schwartz, Van de Ville, & Vuilleumier, 2012). It may function to bias processing in relevant portions of the visual cortex for extracting perceptual details of emotionally salient stimuli, including high-frequency information important for categorizing fearful facial expressions (Smith & Schyns, 2009).

Studies of patients with neglect syndrome also show some ability of threatening and other affective stimuli to reflexively grab attention in the neglected (contralateral) hemifield. These patients typically have damage to components of the attentional control system in the frontal and/or parietal cortex in the right hemisphere. Under competitive conditions in which sensory stimuli are presented to both hemispheres, the patients tend to neglect items presented to the left (contralesional) field. However, if the stimuli presented in the neglected field contain spiders, fearful body gestures, fear-conditioned stimuli, or emotional facial expressions, their detection is facilitated relative to neutral control stimuli (Dominguez-Borras, Saj, Armony, & Vuilleumier, 2012). Functional magnetic resonance imaging (fMRI) studies of these patients indicate that emotional stimuli detected in the contralesional field are processed in the superior colliculus–pulvinar–amygdala circuit described above (Morris et al., 2001; Pegna et al., 2005). A similar circuit was activated in an experimental model of blindsight in which visual cortex function was transiently disrupted using transcranial magnetic stimulation (Ro, Shelton, Lee, & Chang, 2004).

Collectively, these results implicate a dissociation between the frontoparietal attentional control system that provides a general means for selecting sensory input to guide goal-directed behavior and an amygdala-based system that prioritizes the attentional processing of emotional (Vuilleumier, 2005) and/or motivational (Lang & Bradley, 2010) stimuli. In some cases, these streams of processing act iteratively in a flexible way to shuttle processing resources between task-relevant goals and processing of irrelevant but emotionally salient stimuli (Yamasaki, LaBar, & McCarthy, 2002). At other times, the influence of these two streams is additive, and information is integrated across them (Fichtenholtz et al., 2004; Vuilleumier et al., 2001). These attentional–emotional interactions are mediated by hubs in the anterior cingulate cortex, orbitofrontal cortex, and insula that are bidirectionally connected to the two processing streams (Fichtenholtz & LaBar, 2012). The hubs are hypothesized to maintain a balance between motivational/affective processing and executive/attentional control functions to support healthy mood regulation (Mayberg, 1997). Of course, the amygdala itself can even become a target of attentional control, as demonstrated by studies of emotion regulation (Ochsner, Silvers, & Buhle, 2012), including the regulation of threat (Schiller & Delgado, 2010; see the section "Fear Regulation").

The Social Communication of Threat

Once a threat is detected in the environment, defensive vocalizations provide important signaling information regarding its presence, location, and quality. During defensive encounters, alarm cries serve dual roles: as part of a defensive display to ward off an approaching predator and to alert conspecifics to the nature or intensity of the threat (it is debated whether such cries might also signal the state of distress of the communicator). These functions can be disentangled by analyzing the spectral frequency and behavioral context of the alarm calls in ethological studies. Both wild black rats and laboratory rats emit sonic vocalizations in the presence of a predator, such as a cat, that increase with defensive proximity (Litvin, Blanchard, & Blanchard, 2007). These vocalizations do not depend on the presence of conspecifics and thus function solely as part of the circa-strike defensive display. By contrast, defensive ultrasonic cries in the 22-kHz range are emitted only in the presence of conspecifics. These cries elicit behavioral quiescence in observer rats (Brudzynski & Chiu, 1995) and they alter the frequency of response calls in rat pups (Brudzynski, Kehoe, & Callahan, 1999). Such calls serve as effective conditioned cues in fear-conditioning studies (Lindquist, Jarrard, & Brown, 2004), and central amygdala lesions block the expression of these calls during fear conditioning (Choi & Brown, 2003).

Naturalistic observations indicate that the signaling properties of defensive calls can take different forms. African elephants emit different vocal rumbles to signal the presence of local tribesmen versus a swarm of bees (Soltis, King, Douglas-Hamilton, Vollrath, & Savage, 2014). Recorder playback of these vocalizations elicit different behaviors in listener elephants, with bee rumbles selectively provoking head shaking, an adaptive deterrent to invading swarms. Across both call types, threat intensity increases the fundamental frequency of the vocalization, which results in accelerated vigilance and flight behavior in listener elephants. Thus, information about both the quality and intensity of the threat can be discerned from acoustic analysis of some (but not all) calls, and variations in the calls can yield behavioral differences in the defensive responses of the listener, implicating communicative value to the social group. Many other species exhibit similar effects. For instance, vervet monkey defensive calls indicate the presence of different predators and yield appropriate defensive behaviors in listeners: downward glances to snake calls, upward glances to eagle calls, and running to leopard calls (Seyfarth, Cheney, & Marler, 1980). In blue monkeys, not only does the defensive call discriminate the nature of the predator (eagles vs. leopards) but in some cases it also takes into consideration the level of danger to the social group; response calls to eagle shrieks grow more frequent if the social group is closer to the source of the shriek than farther away, regardless of the position of the sentinel (calling) monkey (Papworth, Bose, Barker, Schel, & Zuberbuhler, 2008).

Mammalian vocalizations are mediated by dual motor pathways (Jurgens, 2009). A limbic pathway originates from the motor sector of the anterior cingulate gyrus to the periaqueductal gray to the reticular formation in the pons and medulla, where phonatory motorneurons are targeted. The anterior cingulate cortex initiates voluntary vocalizations, and stimulation of brainstem components of this circuit is sufficient for the production of innate vocalizations. Some populations of neurons in this circuit, as well as the amygdala and auditory cortex, are tuned to the frequency of defense calls (Fanselow, 1994; Peterson & Wenstrup, 2012). A parallel, primary motor pathway produces fine, articulatory movements of the mouth and tongue, and integrates the motor cortex with feedback circuits in the basal ganglia and cerebellum for learned vocalization patterns. These pathways converge in the reticular formation. Damage to the primary motor pathway will leave affective gutteral utterances intact, a dissociation also observed for motor pathways controlling facial expression (Borod, 1993).

In humans, the social communication of threats via facial expression cues has been better studied than vocal expression cues. However, facial signals of fear and anger only operate over relatively short distances (Smith & Schyns, 2009), and thus vocal affect extends the range of defensive communication. Nonverbal defensive displays take the form of shrieks, cries, and yelps. These and other gutteral vocalizations evoke responses in the amygdala, insula, and belt regions of the auditory cortex in listeners (De Lucia, Clarke, & Murray, 2010; Fruhholz & Grandjean, 2013; Sander & Scheich, 2005). Of course, human language provides a more flexible, symbolic route for the communication of threat. These threat warnings can be quite abstract, as evidenced by the announcement of "color codes" to warn air travelers of terrorist threat levels in U.S. airports following September 11, 2001.

In order for facial or vocal expression cues to be maximally effective, they must be combined with each other, along with other forms of nonverbal communication, such as eye gaze and body gesture, to indicate the source of the threat. Vocal and facial indicators of fear are integrated in the amygdala, fusiform gyrus, and superior/middle temporal gyrus (Dolan, Morris, & de Gelder, 2001; Ethofer et al., 2006; Phillips et al., 1998). Responses in the amygdala and fusiform are stronger when fear signals are congruent between sensory channels, which enhances the overall perception of fear. Similar effects have been reported for gaze–expression combinations—when the combinations of eye-gaze direction and facial expression signal a clear threat, amygdala responses are enhanced for short stimulus durations that emphasize reflexive processing; however, with longer durations these effects reverse, which may relate to a separate role for the amygdala in resolving ambiguity (Adams et al., 2012; Graham & LaBar, 2012).

Experiential Fear and Anxiety

Whereas the neural substrates underlying perceptual and expressive components of fear are becoming better characterized, the central representation of subjective fear and anxiety states remain poorly understood. Initial insights into limbic contributions to experiential fear states come from intracranial stimulation studies of neurological patients with implanted electrodes for the surgical monitoring of epilepsy. Early studies using small numbers of patients showed that fear and anxiety were commonly felt upon initiation of amygdala stimulation (Chapman et al., 1954). Later, more controlled studies using larger numbers of patients confirmed these findings; fear was the most commonly reported emotion in response to amygdala stimulation, often accompanied by changes in autonomic function, visceral reactivity, perceptual hallucinations, memory retrieval, and/or a feeling of déjà vu (Gloor, Olivier, Quesney, Andermann,

& Horowitz, 1982; Halgren, Walter, Cherlow, & Crandall, 1978). Interpretation of these studies, however, is complicated by the anecdotal nature of the reports and the presence of epilepsy in the patients (although some results were obtained in healthy tissue that did not encompass the epileptic focus or seizure after-discharges).

Studies of emotional experience in patients with amygdala-lesions due to epilepsy or other congenital diseases have yielded mixed results. Anderson and Phelps (2002) reported intact subjective emotions, as assessed through self-report measures and a daily diary study, in postsurgical patients with medial temporal lobe epilepsy, including a patient with bilateral amygdala damage. However, Feinstein and colleagues (Feinstein, Adolphs, Damasio, & Tranel, 2011) found a selective, impoverished experience and expression of fear in a case study of a patient (S. M.) with bilateral amygdala damage. These effects were noted in S. M.'s self-report questionnaires and field sampling of life experiences, including exposure to several fear-inducing situations such as holding live snakes and spiders, viewing horror films, and going to a haunted house. By contrast, S. M. and two other patients with bilateral amygdala damage exhibited panic attacks and escape responses to carbon dioxide inhalation, which was accompanied by a subjective feeling of panic and fear (Feinstein et al., 2013). The latter finding is consistent with evolutionary models of a panic-distress system that is partially separable from fear and triggered more by interoceptive sources of sensory input (Panksepp, 1998).

Neuroimaging studies have yielded similarly mixed findings regarding central representations of fear. Several meta-analyses of emotional fMRI studies have been conducted, with the most consistent finding linking the amygdala with fear (Murphy, Nimmo-Smith, & Lawrence, 2003; Phan, Wager, Taylor, & Liberzon, 2002; but see K. A. Lindquist, Wager, Kober, Bliss-Moreau, & Barrett, 2012). However, a direct comparison of perceptual versus experiential emotion tasks showed that amygdala activity is predominantly driven by tasks emphasizing perception rather than changes in subjective experience (Wager et al., 2008). Researchers are beginning to take a new look into this question by applying multivariate statistical methods to discern how information in various brain regions and autonomic indices contributes to the classification of different emotional states (Kragel & LaBar, 2014).

Conditioning Models of Fear Learning

In order for fear to be maximally adaptive as an emotion, it must operate not only in the moment of immediate threat to prepare defensive reactions, but it must also facilitate learning from experience so that harbingers of future threats are avoided. Pavlovian fear conditioning paradigms provide an exemplary model system for characterizing how sensory cues and environmental contexts gain access to defensive networks through their association to threatening events. In a typical fear conditioning experiment, an innocuous cue, such as a tone or light (the *conditioned stimulus* [CS]), is established as a reliable predictor of a subsequent aversive event, such as a shock (the *unconditioned stimulus* [US]), that innately provokes defensive reactions. Fear learning is demonstrated by a change in the behavioral or physiological response to the CS that is indicative of fear, such as potentiated startle reflexes (see the section "Operationalizing Fear for Scientific Investigation"). This form of learning can be quite rapid, with a highly intense US yielding fear conditioning in a single training trial. A variant of cued fear conditioning called *trace conditioning* involves separating the offset of the CS and onset of the US by a brief temporal interval (a memory "trace"). Trace conditioning places additional demands on timing, attentional, and working-memory mechanisms and is mediated by partially distinct systems in the brain (Knight, Cheng, Smith, Stein, & Helmstetter, 2004). Conditioned cues, in turn, can be used to condition fear associations to other novel cues (second-order conditioning), creating a hierarchy of fear associations. These associations can even be learned vicariously, by observing others undergo fear conditioning procedures, or through social instruction, by verbally telling others about the threat value of a CS (Olsson & Phelps, 2004). Therefore, conditioned fear learning ranges from quite simple, nonconscious reflex potentiation to higher-order forms that involve complex cognitive processes or social modeling.

The spatial context in which conditioning occurs is also associated with aversive reinforcers. A return to the context, even without the CS being present, yields similar fear responses ("contextual fear"). Because phasic CSs are the most reliable predictor of the US in these studies, contextual fear is typically weaker than cued fear, and it develops later in time (LaBar & LeDoux, 1996). However, a variant of fear conditioning involves random presentation of shocks in a context with no phasic CS at all. In this case, the context is the most reliable predictor of the shock and yields robust responses (Ameli, Ip, & Grillon, 2001). This form of contextual fear is often used as a model of anxiety, as it places the organism in a state of anticipation of uncued and unpredictable aversive events (see the section "Operationalizing Anxiety for Scientific Investigation"). Because this state is driven by a specific environment in the experimental paradigms, it is most applicable to certain anxiety disorders that are exacerbated in particular situational contexts (as in some cases of social anxiety, test anxiety, or performance anxiety). Contextual fear is commonly reported in individuals who were robbed or assaulted. These aversive experiences often lead to subsequent avoidance of the location of the incident, or a return of fear and perceptual vigilance when reentering the location.

Although nearly any kind of stimulus can serve as a CS, which indicates the broad flexibility of fear learning, some stimuli and CS–US combinations are relatively more effective than others. Biological preparedness theory provides an evolutionary explanation for some of these effects (Ohman & Mineka, 2001). In particular, threat stimuli that are evolutionarily ingrained, such as snakes and spiders, may have special meaning in defensive contexts. Snakes and spiders are among the most common sources of specific phobias. Snakes and spiders can be fear conditioned subliminally, along with other biologically prepared stimuli, such as threatening or fearful faces (Ohman & Soares, 1993, 1994). These stimuli have prioritized routes of access to fear-learning systems, and the fear responses to them are harder to extinguish once they are acquired. Whether these evolutionary pressures have led to a dedicated fear module in the brain remains debated. As discussed below, cognitive processes can modulate fear learning, which invalidates the impenetrability criterion for such a module (Ohman & Mineka, 2001), at least for conscious aspects of fear processing.

Medial Temporal Lobe Contributions to Conditioned Fear Learning

Across species, the amygdala has emerged as a critical structure for both the acquisition and expression of conditioned fear learning (LaBar & LeDoux, 2002). Sensory information representing the CS and US reach the lateral amygdala through parallel afferent pathways: a subcortical route via direct thalamic connections (see the section "Perceptual and Attentional Processing of Threats and Fear Indicators") and cortical routes via each primary sensory pathway (Romanski & LeDoux, 1992; Figure 43.2). CS and US information converge onto common neurons in the lateral amygdala, providing a cellular means for integration of sensory information and synaptic plasticity underlying associative learning (Romanski, Clugnet, Bordi, & LeDoux, 1993). For simple CS–US associations, electrophysiological changes in the lateral amygdala occur quickly (within tens of milliseconds of CS onset), implicating a role for rapid processing of conditioned threats along the subcortical processing route (Quirk, Repa, & LeDoux, 1995). However, for more complex associations, the cortical pathway provides a necessary input. Conditioned-induced changes in amygdala signaling, in turn, modulate synaptic plasticity in other regions, such as the thalamus, anterior cingulate cortex, and sensory cortex (Quirk, Armony, & LeDoux, 1997; Talk, Kashef, & Gabriel, 2004). One function of these changes is to alter the profile of sensory tuning curves to favor features of the CS, such as the pitch of an auditory CS; neurons that weakly responded to the frequency of the CS respond more vigorously to it after a fear learning experience (Edeline & Weinberger, 1992). In this way, fear conditioning mechanisms retune sensory input to facilitate detection of similar threat warnings in the future.

Once processed by the lateral amygdala, information about conditioned cues feeds forward through direct and indirect projections to the central nucleus. The central nucleus also undergoes conditioning-induced plasticity and orchestrates the engagement of appropriate defensive responses (Wilensky, Schafe, Kristensen, & LeDoux, 2006). Disconnection of a specific central nucleus efferent target yields selective deficits in the expression of fear conditioning while leaving other dependent measures intact. For instance, disrupting the connections to the ventral periaqueductal gray area eliminate freezing (conditioned immobility) but do not impact changes in fear-induced autonomic outflow or startle reflex potentiation. Because lateral or central nucleus lesions yield global deficits, these regions are thought to provide the minimum core circuitry necessary for fear conditioning to occur (Nader, Majidishad, Amorapanth, & LeDoux, 2001).

Information about environmental contexts associated with fear conditioning experiences enters the basal and accessory basal amygdala from the

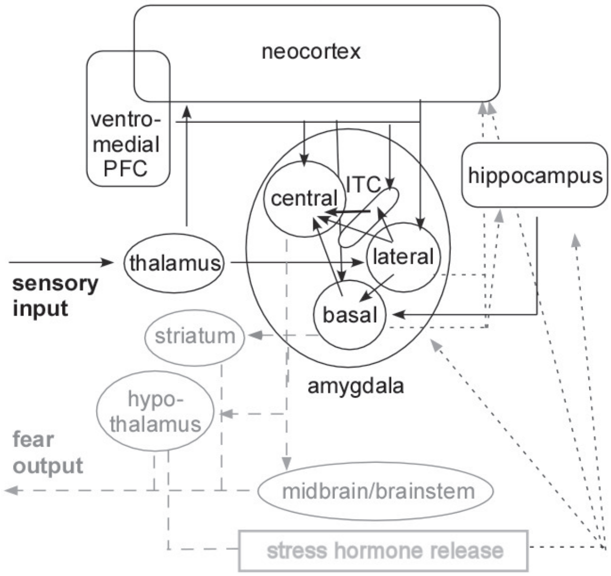

FIGURE 43.2. Processing pathways for fear conditioning. Sensory information arising from subcortical and cortical inputs into the amygdala (solid black lines) are integrated for conditioned fear learning. Within the amygdala, threat cues are processed from the lateral nucleus to the central nucleus directly and indirectly via the basal and intercalated nuclear cells (ITC). Contextual cue information arising from hippocampal input enters the circuit primarily via the basal nucleus. The central nucleus coordinates defensive reactions (light gray dashed lines) by targeting various brainstem structures responsible for engaging specific somatomotor and autonomic functions, such as reflex startle potentiation, breathing and heart rate changes, and sweat gland activity. Central nucleus outputs also activate the hypothalamic–pituitary–adrenal stress axis, and basal nucleus outputs to the striatum initiate coping strategies. Feedback pathways (dark gray dotted lines) from the basolateral nuclei to the hippocampus and neocortex, as well as more diffuse stress hormone release, serve to consolidate the fear memory and tune sensory representations to features of the threatening cues. Consolidation and recall of fear extinction involves regulatory input from the ventromedial prefrontal cortex (PFC).

hippocampus and is projected forward to the central nucleus. The hippocampal–amygdala pathway is another site of synaptic plasticity that is important for contextual, but not cued, fear conditioning (Maren & Fanselow, 1995). Therefore, parallel pathways to the amygdala are involved in different aspects of fear learning, and these routes merge in the central nucleus as a final common pathway for coordinating defensive reactions. In contrast to the central nucleus efferent projections, the basolateral nuclear complex sends widespread projections to the neocortex and basal ganglia, which are thought to be important for initiating coping strategies, for balancing threat processing with other behavioral priorities, and for consolidating the memory for the fear learning episode.

The role of the amygdala in fear conditioning has been validated and extended in human fear conditioning investigations. Neurological patients with amygdala lesions are consistently impaired in acquiring conditioned fear (Bechara et al., 1995; Glascher & Adolphs, 2003; LaBar, LeDoux, Spencer, & Phelps, 1995; Phelps et al., 1998; Weike et al., 2005). These deficits occur despite intact awareness of the CS–US contingency (but see Coppens, Spruyt, Vandenbulcke, Van Paesschen, & Vansteenwegen, 2009) and intact defensive reactions to innate, unconditioned threats. The impairments in these patients span from simple subliminal and supraliminal forms of fear conditioning to more complex paradigms involving discrimination among multiple cues.

The lesions in these patients often encompass surrounding tissue in the medial temporal lobe, which can complicate interpretation of results (Ahs, Frans, Tibblin, Kumlien, & Fredrikson, 2010). Therefore, it is important that neuroimaging studies with finer anatomic resolution have corroborated a link between amygdala activation and conditioned fear learning in healthy subjects (reviewed in Sehlmeyer et al., 2009). Amygdala activation tends to be stronger at the beginning of acquisition training when the emotional contingencies are initially being learned (Buchel, Morris, Dolan, & Friston, 1998; LaBar, Gatenby, Gore, LeDoux, & Phelps, 1998), although pattern classification of high-resolution fMRI reveals conditioning effects in the basolateral and centromedial amygdala that are maintained or even increased over training trials (Bach, Weiskopf, & Dolan, 2011). Amygdala activation is tightly coupled with the expression of conditioned fear, as measured either as an individual difference variable or as within-subjects correlations with concurrent startle (van Well, Visser, Scholte, & Kindt, 2012) or skin conductance responses (SCRs; Buchel et al., 1998; Cheng, Knight, Smith, Stein, & Helmstetter, 2003; Furmark, Fischer, Wik, Larsson, & Fredrikson, 1997; LaBar et al., 1998). Compared with supraliminal forms of conditioning, subliminal fear conditioning evokes tighter functional coupling between the amygdala and subcortical processing circuits (Morris et al., 1999) and may rely on interoceptive information processing to a greater extent (Katkin, Wiens, & Ohman, 2001). As with the patient studies, neuroimaging results have extended the amygdala's role to more complex forms of fear conditioning, including trace fear conditioning (Knight et al., 2004), contextual fear conditioning (Alvarez, Biggs, Chen, Pine, & Grillon, 2008), and socially instructed fear learning (Phelps et al., 2001).

The hippocampus, by contrast, contributes selectively to human fear conditioning tasks that place demands on spatial and temporal processing, such as trace conditioning (Knight et al., 2004) and contextual conditioning (Alvarez et al., 2008) paradigms. As with the amygdala findings, these results are consistent with the nonhuman animal literature, implicating a conservation of function across species. Interestingly, patients with selective hippocampal lesions show the opposite pattern to patients with amygdala lesions with regard to implicit and explicit measures of fear learning. Whereas bilateral amygdala damage manifests as impaired fear conditioning (measured physiologically) but intact explicit knowledge of the stimulus contingencies, bilateral hippocampal damage manifests as intact fear conditioning but poor explicit memory for the conditioning episode (Bechara et al., 1995; LaBar & Phelps, 2005). In a famous early anecdote, the Swiss neurologist Claperède (1911/1995) noted that a patient with Korsakoff's amnesia, whom he had previously pricked with a pin hidden in his hand, subsequently avoided shaking hands with him, despite having no recollection of the prior threatening episode. These kinds of dissociations have provided further support for the idea of multiple memory systems in the brain. However, in healthy subjects explicit knowledge and conditioning processes likely interact, given the extensive connectivity between the amygdala and adjacent sectors of the medial temporal lobe, and thus the two kinds of learning mechanisms may normally operate iteratively or interactively (LaBar & Disterhoft, 1998; Lovibond & Shanks, 2002).

Fear Generalization

In his seminal discoveries, Pavlov (1927) originally noticed that the conditioned value of a stimulus can transfer to other stimuli that resemble the CS but have never been paired with a reinforcer. The most famous historic example of fear generalization in humans is the study of Little Albert. John Watson and Rosalie Rayner (1920) conditioned an 11-month-old infant to the sight of a white rat by pairing it with the delivery of a loud-noise US. After a few training trials, Little Albert displayed distress and avoidance responses to the rat, which generalized to include other furry objects, including other animals, fur coats, and a Santa Claus beard. The generalized responses lasted up until the last time Little Albert was tested 30 days later. Although this study was fraught with ethical and scientific integrity issues, it ignited an interest in fear generalization and conditioning-based accounts of affective disorders.

Fear generalization can occur across perceptual and conceptual attributes of cues, as well as across environmental contexts. Perceptual forms of cue generalization include mechanisms based on feature similarity, physical intensity, and emotional intensity. These different forms of perceptual generalization can be distinguished by the shape of the generalization gradient when a perceptual attribute of the CS is varied along a continuum, such as brightness or hue. Whereas feature-based generalization exhibits symmetric generalization functions, with fear indices peaking near the CS value and decreasing on opposite sides of the continuum, physical and emotional intensity gradients exhibit asymmetric generalization functions, with fear indices selectively increasing toward the end of the continuum with the most intense values (Dunsmoor & LaBar, 2013; Dunsmoor, Mitroff, & LaBar, 2009; Vervliet, Baeyens, Van den Bergh, & Hermans, 2013). For example, when a 1,000 Hz tone is used as a CS, conditioned fear responses generalize in a symmetric gradient to tones that are both higher and lower in frequency than 1,000 Hz (e.g., moderate fear to 800 and 1,200 Hz tones and low fear to 400 and 1,600 Hz tones). By contrast, fear selectively generalizes to tones that are louder but not softer than the CS (an asymmetric physical intensity gradient). Fear generalization may also be guided by conceptual knowledge, even when the generalized stimuli bear little physical resemblance to the CS. For instance, conditioned fear transfers more readily to items that are semantically related to a CS than those that are not (Dunsmoor, White, & LaBar, 2011), or to other exemplars from the same superordinate category as the CS, as in natural object categories (Dunsmoor, Martin, & LaBar, 2012). These generalization mechanisms extend beyond classical fear conditioning to include operant forms of conditioning and reward learning.

Despite the long history of generalization in behaviorist traditions, only recently have researchers begun to unravel the brain mechanisms mediating fear generalization. Initial neuroimaging results indicate that brain regions that contribute to the acquisition of conditioned fear also mediate the generalization of conditioned fear responses. Generalization to faces that vary along a continuum of fearful expression intensity engages the amygdala and insula, whose hemodynamic response amplitude correlates with physiological indices of fear to the generalized face stimuli, as well as the thalamus and brainstem (Dunsmoor, Prince, Murty, Kragel, & LaBar, 2011). Generalization to these fearful expressions also induces enhanced functional coupling between the amygdala and face-processing regions of the fusiform gyrus. The dorsal frontoparietal and cingulate regions are activated to the offset of the generalized faces at the point where the US appeared during the initial learning. This pattern is suggestive of an omission response due to the violation of a cognitive expectancy that an aversive event should occur following the presentation of the generalized fear stimuli (Dunsmoor & LaBar, 2012). Finally, generalization to safety cues presented during conditioned learning (e.g., to a cue that is never paired with a US) involves the subgenual anterior cingulate and ventromedial prefrontal cortex, which counteract the spread of fear and limit the breadth of the generalization gradients.

Fear generalization on the basis of shared conceptual features among object category exemplars elicits activity in the amygdala, dorsal anterior cingulate gyrus, insula, thalamus, and occipitotemporal cortical regions that process the conditioned object category (Dunsmoor, Kragel, Martin, & LaBar, 2014). In this case, the amygdala becomes more functionally coupled to the cortical representations of the aversively reinforced object category; but, as predicted by biological preparedness theory, this effect has only been observed thus far with animate object categories whose cortical representations are anatomically connected with the amygdala. Multivariate pattern analysis shows that fear conditioning experiences alter the representation of the CS object category in the amygdala and occipitotemporal cortex, such that exemplars of the category are signaled more similarly when the category is reinforced with an aversive US than when it is not. This shared signal may contribute to the generalized fear responses to the items across the category.

The extent of fear generalization to cues that resemble a CS is often predicted by individual differences in anxiety, with the strongest generalization occurring in individuals high in anxious or obsessive–compulsive traits (Dunsmoor, Prince, et al., 2011; Dunsmoor, White, et al., 2011; Kaczkurkin & Lissek, 2013). These effects are even more pronounced in anxiety disorders, for which fear responses can broadly overgeneralize (Lissek et al., 2009, 2014). In generalized anxiety disorder, fear generalization on the basis of perceptual information is associated with alterations in the integrity of the ventromedial prefrontal cortex and its functional and structural connections with corticolimbic structures, including the amygdala (Cha et al., 2014). An important question for future research is how the forces of generalization can be thwarted or reversed to improve functioning in these disorders.

Consolidation and Reconsolidation of Fear Memories

Once a learning episode takes place, numerous processes contribute to consolidating the learning into a long-term memory trace. Over a period of several hours, local synaptic processes, including long-term potentiation, strengthen the connections that represent the constituent parts of the learning experience. Further replay and consolidation of the memory trace occurs during sleep the night after the event occurred. Finally, over an extended period of weeks to years, the storage of memories can shift across different systems in the brain. At each of these stages of memory consolidation, neuromodulatory influences alter the nature of the representations to either strengthen or weaken the integrity of the memory trace. For instance, engagement of the hypothalamic–pituitary–adrenal stress axis around the time of a fear conditioning episode enhances long-term retention of fear memories across species (Rodrigues, LeDoux, & Sapolsky, 2009; Zorawski, Blanding, Kuhn, & LaBar, 2006).

In recent years, it has come to be appreciated that memories undergo a period of reconsolidation upon their retrieval, which provides an opportunity for further modification of the memory trace. For cued fear conditioning, this period of postretrieval memory lability lasts up to a few hours of the reactivation of the fear memory (usually triggered by presenting the CS alone) and requires protein synthesis and engagement of calcium-dependent second messenger systems in the amygdala (Finnie & Nader, 2012). If these molecular cascades are blocked or down-regulated pharmacologically, the fear memory becomes unstable, perhaps even "erased." For instance, administering the protein synthesis inhibitor anisomycin into the basolateral amygdala within 6 hours of presenting a CS that had already undergone fear conditioning blocks the retention of fear to the CS (Nader, Schafe, & LeDoux, 2000). However, older memories are more resistant to reconsolidation effects (Suzuki et al., 2004), perhaps because they are already stored across multiple memory systems.

While these animal investigations have raised considerable clinical interest for remediation of anxiety disorders, the translation of these paradigms into human investigations are complicated by ethical and methodological challenges. Drugs that block protein synthesis are toxic to humans, and other drugs that have modulatory influences on emotional memory processes, such as propranolol—a beta-adrenergic blocker—have yielded mixed results in the human reconsolidation studies conducted to date (reviewed in Schiller & Phelps, 2011). These initial findings have led researchers to consider using behavioral manipulations that may update the value of fear memory representations during the reconsolidation window as a novel intervention. In particular, presenting the fear-conditioned CS without reinforcement within 6 hours of reactivating the conditioned fear memory (through a CS-reminder trial) attenuates conditioned fear responses up to a year later (Schiller et al., 2010). Presentations of the CS that had undergone reconsolidation of this sort reduce conditioned fear responses and concomitant amygdala activity (Agren et al., 2012). While this translational work remains in its infancy, it is opening up avenues for novel intervention strategies by capitalizing on the temporary lability of fear memories. Yet, it is not clear whether a permanent reduction of fear to a potentially threatening stimulus is adaptive, and ethical dilemmas surround the "erasing" of unwanted fear memories in the context of clinical treatment.

Fear Regulation

As a form of protection from threats, learned fear behaviors are enduring. However, given its high metabolic cost, fear is important to relinquish as warranted by situational indicators of relative safety. Voluntary and involuntary forms of emotion regulation are recruited to inhibit fear when and where it is no longer appropriate to express. These regulatory controls establish new memories of safety value for the formerly fearful cues or contexts that compete with the original fear memory for behavioral expression. To decide how to respond to recurrent themes of threat, an organism must balance the expression of these opposing memory traces to guide defensive behaviors. Because the latent fear memory is almost always available for later retrieval, the return of fear plagues long-term treatment outcomes in anxiety disorders.

Involuntary aspects of fear regulation include brain mechanisms sensitive to temporal cues and spatial contexts that indicate that the threat is no longer present. These mechanisms have been detailed in animal models of extinction learning and the contextual control of conditioned fear. *Extinction learning* occurs when the contingency between the CS and US is removed by repeatedly presenting the CS without reinforcement. Over time, the organism learns that the CS no longer predicts an aversive event, following which conditioned fear responses subside. Repeating extinction training over intervals of days is beneficial, as a period of memory consolidation solidifies the extinction memory trace. A recent study even showed that presenting olfactory reminders of extinction training during slow-wave sleep facilitates the extinction process in humans (Hauner, Howard, Zelano, & Gottfried, 2013). The long-term consolidation and recall of extinction learning is mediated by the infralimbic cortex (ventromedial prefrontal cortex in primates), which inhibits fear processing in the amygdala, most prominently by engaging the intercalated nuclei of the amygdala to block central nucleus signaling (reviewed in Milad & Quirk, 2012). In humans, the ventromedial prefrontal cortex, including the subgenual portion of the anterior cingulate gyrus, plays a similar role in extinction recall, as revealed by both functional and structural imaging studies (Milad et al., 2005, 2007; Phelps, Delgado, Nearing, & LeDoux, 2004). Engaging this inhibitory neural circuitry is thought to be critical for successful exposure therapy treatment in anxiety disorders, as these therapies are based on extinction learning principles. Initial clinical studies indicate that in posttraumatic stress disorder, there is an imbalance in prefrontal–amygdala signaling of extinction, as the amygdala exhibits a prolonged response during initial extinction learning and the ventromedial prefrontal cortex is less activated during extinction recall. Consequently, physiological indices of fear conditioning persist into the extinction training period for these patients, along with activation of the dorsal anterior cingulate gyrus, which enhances fear expression (Milad et al., 2009). Current efforts are under way to identify how to augment extinction learning pharmacologically or behaviorally in order to restore the integrity of these regulatory pathways.

In addition to learning that conditioned fear cues no longer portend danger, it is also important to learn where learned threats are more or less likely to be encountered according to contextual cues of danger and safety. Understanding the contextual regulation of conditioned fear is also relevant to improve treatment outcomes in anxiety disorders (Vervliet, Craske, & Hermans, 2013). When patients leave the safe confines of the therapeutic setting and enter other environments, fear responses tend to recover (*fear renewal*), especially for novel contexts with unknown threat value or those that are associated with prior threat experiences. Fear responses also recover in contexts where patients experience stressors after extinction-based training regimens (*fear reinstatement*). Both of these context-dependent fear recovery phenomena rely on the hippocampus, consistent with its role in acquiring fear to environmental contexts (Corcoran & Maren, 2001; Holland & Bouton, 1999). For the contextual recovery of fear, the hippocampus modifies fear expression in the amygdala through both direct neural interactions with the basal nuclei and indirect effects through the ventromedial and dorsomedial prefrontal cortical interfaces to the amygdala (Orsini, Kim, Knapska, & Maren, 2011; Sotres-Bayon, Bush, & LeDoux, 2004). In humans, hippocampal lesions impair fear reinstatement (LaBar & Phelps, 2005), and hippocampal–ventromedial prefrontal activity that signals extinction retention is attenuated in a stressful context following fear reinstatement (Kalisch et al., 2006). Researchers are currently exploring ways to combat the return of fear by making extinction training less context specific. For instance, by conducting extinction in multiple contexts, it is possible to mitigate the context-dependent return of fear in some circumstances across both rats and humans (Dunsmoor, Ahs, Zielinski, & LaBar, 2014; Laborda & Miller, 2013).

Voluntary forms of fear regulation have rarely been studied in conjunction with conditioned learning, but the mechanisms are likely similar to those involved in effortfully regulating other aspects of emotional processing. For instance, when individuals cognitively reappraise the meaning of aversive stimuli to lessen their emotional impact, negative affect reduction is accompanied by activity increases in the lateral prefrontal, cingulate, and parietal regions, and activity decreases in the limbic areas, such as the amygdala (Ochsner et al., 2012). One study showed similar mechanisms at play in the cognitive reappraisal of conditioned fear stimuli (Delgado, Nearing, LeDoux, & Phelps, 2008). When participants used visual imagery to decrease the aversiveness of the CS, physiological indices of conditioned learning were attenuated, CS-evoked activity in the amygdala was reduced, and CS-evoked activity was enhanced in the prefrontal cortical regions. An additional study indicated that this form of active coping is successful in attenuating conditioned fear responses and subjective fear reports up to 24 hours later (Shurick et al., 2012). More work is clearly needed to evaluate the relative effectiveness of different emotion regulation strategies on reducing negative affect associated with conditioned fear memories.

Role of the Bed Nucleus of the Stria Terminalis in Anxiety

Most of the research discussed in this chapter focuses on phasic aspects of fear processing, such as responses to facial expressions of fear or conditioned fear cues. However, research over the past decade has begun to dissociate the brain regions mediating fear processing from more sustained forms of anxiety. Several paradigms have been developed to model state anxiety, including presentation of long-duration or unpredictable threats, or manipulation of environmental factors that enhance a sense of apprehension, such as open/elevated field exploration tests or presenting startle probes in dark environments for humans (or light environments for rodents). Rodent studies using these kinds of paradigms have shown that fear and anxiety can be partially dissociated with respect to their neurobiological substrates. Whereas fear-potentiated startle relies on the central nucleus of the amygdala, light-enhanced startle relies on the bed nucleus of the stria terminalis (BNST), a region of the "extended amygdala" that protrudes anteriorly into the basal ganglia (reviewed in Davis et al., 2010; Figure 43.3). Rats with lesions of the BNST exhibit nonanxious phenotypes when confronted by an elevated maze and show low contextual fear, but they exhibit normal conditioned fear to a CS (Duvarci, Bauer, & Pare, 2009). In humans, individual differences in anxiety predict BNST activation in response to contextual threat indicators in a threat-of-shock paradigm, with enhanced tracking of anticipated proximal threats as a sign of hypervigilance (Somerville, Whalen, & Kelley, 2010). Pharmacological dissociations also distinguish fear from anxiety in some of these paradigms. Whereas blockade of corticotropin-releasing factor (CRF) receptors, which are especially high in the BNST, attenuate light-enhanced startle and long-duration threats, they have little effect on fear-potentiated startle or short-duration threats (Lee & Davis, 1997; Walker, Miles, & Davis, 2009). Similarly, CRF1 and CRF2 genetic knockout mice exhibit selective impairments on context-potentiated startle but not fear-potentiated startle (Risbrough et al., 2009). These initial findings suggest avenues for disentangling the neuropharmacological mediation of fear and anxiety, and can lead to more refined clinical treatments.

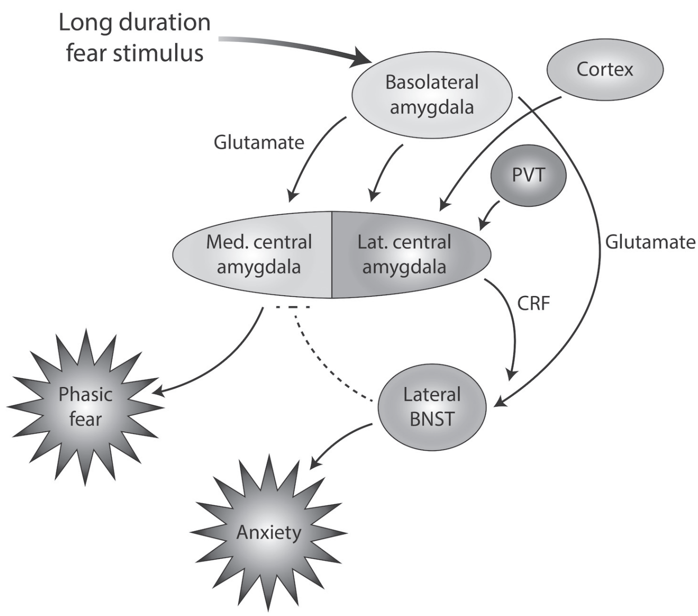

FIGURE 43.3. A proposed neural model for the partial separation of phasic fear and prolonged anxiety. Information about threats is evaluated by the basolateral amygdala. Projections to the medial division of the central nucleus of the amygdala promote phasic fear responses, whereas prolonged anxiety is mediated by projections to the lateral division of the bed nucleus of the stria terminalis (BNST). BNST projections include both direct and indirect pathways via the lateral division of the central nucleus of the amygdala. The BNST is further modulated by stress through release of corticotropin-releasing factor (CRF) and paraventricular thalamic (PVT) inputs via the lateral division of the central nucleus of the amygdala. Dashed lines indicate putative inhibitory projections that help transfer phasic responses to sustained ones. Adapted from Davis, Walker, Miles, and Grillon (2010). Conclusions

Defensive motivation systems evolved to optimize the management of physical threats to survival and are organized according to threat imminence. The emotions fear and anxiety serve adaptive functions in defensive encounters by facilitating the detection of threats, reorganizing metabolic processes and behavioral priorities to prepare appropriate defensive action repertoires, and enhancing memory for these experiences. Threatening stimuli gain preferential access to perceptual and attentional systems through both reflexive and endogenous means across subcortical and cortical processing pathways. Clinical disorders such as hemispatial neglect and cortical blindness provide unique opportunities to investigate the preattentive detection of threat. Limbic regions, especially the amygdala, integrate sensorimotor aspects of fear processing and initiate coping strategies. Whether these regions are also central to the experience of fearful and anxious states remains debated. For organisms that live in social groups, defense calls promote the safety of the group through modulations of vocal acoustics that often indicate contextual details of predatory threats and elicit specific behavioral patterns in listeners.

Mechanisms of fear learning allow a broad range of stimuli to gain access to defensive motivation systems, yet these mechanisms exhibit some biases for evolutionarily engrained threats. Because of the high cost of "false positives" in threat analysis, fear learning systems exhibit rapid learning, a resistance to extinction, retuning of sensory experience toward signaling features of prior threats, and stress-enhanced memory consolidation. Corticolimbic structures exhibit a degree of specialization across fear and anxiety paradigms, including the amygdala for the acquisition, expression, and generalization of fear conditioning; the hippocampus for contextual fear acquisition, context-dependent fear recovery, and explicit memory for conditioning experiences; the ventromedial prefrontal cortex for the recall of extinction and the generalization of safety cues; and the BNST for some aspects of anxiety.

In anxiety disorders, fear processing pathways become maladaptive as revealed by greater attentional biases, stronger resistance to extinction, and overgeneralization of fear learning. Treatment efforts for anxiety disorders are focusing on ways to pharmacologically or behaviorally enhance extinction learning, to use voluntary emotion regulation strategies to dampen the experience of fear and anxiety, and to take advantage of memory reconsolidation mechanisms to update stored representations of threatening experiences. Better theoretical delineation of fear and anxiety constructs and their neural substrates will permit more precise targeting of such therapeutic interventions.

CHAPTER 44

Anger

Eddie Harmon-Jones and Cindy Harmon-Jones

Anger likely serves a variety of adaptive functions. It organizes and regulates psychological processes, such as self-defense and mastery. It regulates social and interpersonal processes, and it organizes processes to assist with goal-directed action. However, anger may also be associated with negative intra- and interpersonal consequences, including child maltreatment and violence (Holtzworth-Munroe & Clements, 2007) and coronary heart disease (Niaura et al., 2002). For these reasons, individuals and societies often try to down-regulate anger to attempt to reduce these negative consequences.

Emotions are processes that involve involuntary action readiness (Frijda, 1986; Lewis & Michalson, 1983). Emotions provide organisms with complex and biologically prepared behavioral potentials that assist in coping with challenges to their welfare (Panksepp, 1998). However, these inherited behavioral potentials only imply ways of behaving as organisms evolved to have larger, more complex brains. While we as humans may possess the same emotional instincts as lower animals, we are not as constrained by their dictates and we have more choices (Panksepp, 1998). Consequently, our emotions can be controlled and may not directly influence behavior.

An emotion is a multicomponent process made up of basic processes such as feelings of pleasure or displeasure; facial/bodily expression components; particular appraisals; and motivational components such as particular action plans and activation states (Frijda, 1993; Lewis, 2014). Moreover, these components are not perfectly correlated with one another (Lang, 1995). For example, anger is an unpleasant feeling, described using words like "annoyed," "angry," and "enraged," which, in our view, express differences in intensity of experience (Berkowitz & Harmon-Jones, 2004a, 2004b; cf. Lewis, 1993, who suggested that rage and anger are qualitatively different). Anger is associated with appraisals of other blame, and it often motivates approach and attack behaviors.

When left uncontrolled or uninhibited, the facial expression of anger involves the muscles of the brow moving inward and downward, "creating a frown and a foreboding appearance around the eyes, which seem to be fixed in a hard stare toward the object of anger. The nostrils dilate and the wings of the nose flare out. The lips are opened and drawn back in a rectangle-like shape, revealing clinched teeth. Often the face flushes red" (Izard, 1977, p. 330). However, because most humans are taught to control anger and its expression, the facial expressions of anger vary considerably among people. However, "on the face of an angry person there is almost always one or more of the innate components of the natural expression which signals his or her internal state" (Izard, 1977, p. 330).

In this chapter, we review research and theoretical advances in the study of basic processes involved in (primarily human) anger. We focus our review on the causes of anger, and its subjective feeling and motivational components. We do not review the vast literature on angry facial expressions, as it is beyond the scope of this chapter (see Russell & Fernández-Dols,1997, for a review).

Causes of Anger

Several theorists have proposed that anger results from physical or psychological restraint or from interference with goal-directed activity (Darwin, 1872/1965; Izard, 1977; Lewis, 1993). This perspective on understanding the causes of anger is consistent with proposals made by other major theoretical perspectives on the causes of various emotions.

Reinforcement Approaches

Neo-behaviorists proposed that the actual or signaled arrival or termination of pleasant or unpleasant events, referred to as positive or negative reinforcers, respectively, is the primary cause of emotions (Mowrer, 1960). Gray (1987) extended these early ideas by including stimulus omissions and interactions with individuals' resources, such as ability to cope with events (see also Rolls, 1999). According to these theories, angry emotions—like frustration, anger, and rage—are caused by the omission of positive reinforcers or the termination of positive reinforcers.

Similarly, Lewis (1993) posited that the thwarting of goal-directed action is an unlearned cause of anger. In one experiment testing this idea, 2- to 8-month-old infants were first conditioned to move one of their arms in order to see a picture of another baby's smiling face as well as hear happy music. Then after they had learned this association, they were exposed to an extinction phase in which their arm movement did not result in the happy events. This termination of the positive reinforcer ("frustrating" event) caused the majority of the infants to have anger-like facial expressions (Lewis, Alessandri, & Sullivan, 1990; Lewis, Sullivan, Ramsay, & Alessandri, 1992).

In another model based on neo-behavioristic ideas, Berkowitz (1989) extended the original frustration–aggression model (Dollard, Doob, Miller, Mowrer, & Sears, 1939) in his cognitive neo-associative model of anger and aggression. Berkowitz proposed that any unpleasant event, such as frustration, pain, discomfort, or social stress, causes negative affect. According to Berkowitz (1989), this negative affect is associated with motivations to fight as well as flee; he has referred to this as a *fight-and-flight* motivation. His model goes further to propose that an individual's prior experiences have created associations that provide cues that will influence what happens in any given situation. If these cues are associated primarily with a desire to escape, then the flight system will be activated and the person will experience mostly fear. If, however, these cues are associated primarily with a desire to attack, then the fight system will be activated and the person will experience mostly anger.

Cognitive Appraisal Approach

Another prominent theoretical approach to understanding the causes of anger is the cognitive appraisal approach. Broadly speaking, these theorists posit that emotions are caused by an individual's appraisal or interpretation of a situation. Thus, it is not the situation itself that causes the emotion, but the way in which the person interprets the situation (e.g., Roseman, Spindel, & Jose, 1990). According to these theories, individuals constantly appraise situations in which they find themselves, and these appraisals, which can be conscious or nonconscious, always precede emotions.

According to appraisal theorists, anger is an unpleasant emotion that often occurs in response to an appraisal of a blocked goal. An appraisal of a blocked goal may consist of perception of the absence of a reward or presence of a punishment (Roseman, 1991), or of an obstruction to obtaining a goal (Lazarus, 1991; Scherer, 2001). To define the term "goal," some theorists refer to an outcome that is personally significant (Lazarus, 1991; Scherer, 2001). Other researchers define goals very broadly, such that every desired outcome would qualify, from the fulfillment of basic needs to achieving long-term, self-relevant plans. According to these broad definitions, pain may produce anger because the individual experiences it as blocking his or her goal of being physically comfortable.

Appraisal theories hypothesize that appraising situations as negative produces negative emotions, including, among others, anger, fear, sadness, and disgust. Thus, other appraisals, besides general negativity, are necessary to produce the discrete emotion of anger. The specific appraisal that is proposed to evoke anger, rather than one of the other negative emotions, is "other-blame," that is, a belief that the unpleasant situation was wrongly caused by someone or something (Lazarus, 1991; Ortony, Clore, & Collins, 1988). An appraisal of other-blame suggests a belief that the person who caused the event acted in a manner that was improper or unfair (Shaver, Schwartz, Kirson, & O'Connor, 1987; Frijda, Kuipers, & ter Schure, 1989; Roseman, 1991). Lazarus (1991) additionally proposed that anger only occurs when individuals perceive a threat to their self-esteem.

The appraisal of "high coping potential" has been proposed as another evaluation necessary for anger to occur. High coping potential refers to the individual's perceived likelihood of being able to resolve the negative situation (Lazarus, 1991; Scherer, 2001; Stein & Levine, 1989). In contrast, if an individual believes he or she is unlikely to be able to resolve the negative situation satisfactorily (i.e., low coping potential), sadness, fear, or anxiety will be experienced rather than anger.

Problems with the Appraisal Accounts

Appraisal theories have generated much interest concerning the causes of emotions, and they are intuitively appealing. For instance, the idea that anger results from negative self-esteem threatening situations that are perceived to be caused by others and that one expects to be able to resolve favorably seems to explain many instances of anger. However, these intuitions may be incorrect. Several theorists have criticized the appraisal theories for not providing empirical evidence demonstrating that appraisals cause emotion. These theorists have suggested that the available evidence could be interpreted to indicate that emotions are the cause of appraisals rather than the converse. For instance, Frijda (1993; Frijda & Zeelenberg, 2001) and Parkinson and Manstead (1992) argued that because of the self-report methods used in tests of appraisal theories, it is difficult to determine whether the identified appraisal patterns preceded or followed the emotional experience. Parkinson and Manstead (1992) wrote, "Nothing in the data resists the interpretation that the relevant appraisals were consequences rather than precedents of the emotional reactions" (p. 129).

Are the appraisals mentioned above necessary for anger, specifically? Appraisals may be involved in the experience of anger, but occur later in the emotion process—that is, they may occur simultaneously with anger or may result from anger, rather than being the cause of anger (Berkowitz & Harmon-Jones, 2004a, 2004b). Berkowitz (1989) proposed a model in which anger is triggered through the fight-or-flight system when an aversive event, such as pain, occurs. His model proposes that once the fight system and anger are activated, the individual then makes appraisals and engages in other cognitive processing to determine whether to attack, who or what to attack, and exactly how to attack. In this model, emotions are a more basic response to an unpleasant event, and cognitive processes, such as appraisals, serve to organize actions in service of emotions and their associated motivations. Berkowitz and Harmon-Jones (2004b) also noted that appraisal theorists' definitions of "goals," "cognitions," and "appraisals" are sometimes so broad that they are untestable (e.g., the "goal" of not experiencing discomfort is not normally active prior to the experience of discomfort).

The appraisal commonly proposed to cause anger, other-blame, also may not be necessary to cause anger. Instead, anger may motivate individuals to seek someone or something to blame for the negative situation. Frijda (1993) reviewed a number of cases where angry persons blamed, and aggressed against, inanimate objects. These cases support the idea that appraisals of other-blame may result from, rather than cause, anger.

The idea that self-esteem threats are necessary to evoke anger has also been questioned. Of course, self-esteem threats may evoke anger, but experiments have found that individuals report feeling anger in response to situations that would not threaten self-esteem (e.g., Berkowitz, 1989; Harmon-Jones, Lueck, Fearn, & Harmon-Jones, 2006). For example, simple physical pain increases anger and aggression, even though it is not associated with a failure or other threat to the self (e.g., Berkowitz, 1999, 2000; Berkowitz, Cochran, & Embree, 1981).

Last, the idea that high coping potential is necessary to create anger has been challenged by research that manipulated coping potential and found the manipulated coping potential influenced brain activations related to approach motivation (see below) but not self-reported anger (Harmon-Jones, Sigelman, Bohlig, & Harmon-Jones, 2003).

Subjective Feelings and Anger

We conceive of anger in a relatively broad way, proposing a commonality of anger rather than there being different kinds of anger (cf. Ellsworth & Scherer, 2003, p. 575). Spielberger and colleagues (Spielberger, Jacobs, Russell, & Crane, 1983; Spielberger, Reheiser, & Sydeman, 1995) also posited this view when they proposed that anger encompassed low-intensity feelings such as irritation or annoyance as well as high-intensity feelings such as fury and rage. Their factor analysis of the items in their State Anger Scale (containing items such as "I am furious" and "I feel irritated") produced only a single factor, suggesting that the angry experiences measured by these items were a unitary affective state varying in intensity. Spielberger et al.'s (1983, 1995) distinction between "anger in" and "anger out" refers to differences in the trait of openly expressing the behavioral concomitants of anger rather than qualitative differences in the nature of the angry feelings (Spielberger et al., 1995). Our conception of anger experience is in agreement with the prototype view of emotion concepts of Shaver and colleagues (1987). Shaver et al. (1987) found that the anger prototype includes a variety of feelings such as *irritation, annoyance, exasperation, disgust*, and *hate*. Thus, various "nuances" of anger experience may not be distinctly different affective states.

Compared with moods, emotions are generally held to have a more specific, consciously recognized cause, a shorter duration, and a definite target. Although some emotion theorists consider moods and emotions to be unique entities, others consider the distinction to be "unsharp" (Frijda, 1986, pp. 59–60), a factor of the degree of clarity individuals believe they possess regarding their affective experience. Regarding varieties of anger, the terms "irritation" and "hostility" tend to be used for mood-like states, whereas "anger" and "rage" refer to more emotion-like states. However, these are merely attempts to capture the variety in the specificity, duration, and intensity of angry affects, as it is difficult to draw a firm dividing line in the continuum between mood and emotion.

The Valence of Anger

Although the valence (positivity vs. negativity) of emotion is considered by many theorists to be one of the most important dimensions of affect, theorists do not always clearly define what is meant by valence. When they do, various emotion researchers have defined this concept in three different ways (Lazarus, 1991): (1) according to whether the conditions that brought about the emotion were pleasant or unpleasant, (2) according to whether the consequences of the emotion were adaptive or maladaptive, or (3) according to whether the emotion feels subjectively pleasant or unpleasant.

Anger can be viewed as a negative affect using the first definition of valence. That is, anger is evoked by negative events, as described in the section "Causes of Anger." The second definition of valence is unwieldy, because it is difficult to definitively state whether the consequences of anger are good or bad. For example, a particular incidence of anger may be adaptive in the short run (a person gets his or her way following an angry outburst) but maladaptive in the long run (the target of the angry outburst avoids him or her in the future and he or she loses a friend), or may be beneficial to the individual, but harmful to others. Using the third definition of valence, anger would be categorized as a negative emotion if individuals dislike the experience of anger, and as a positive emotion if individuals enjoy the experience of anger.

Most appraisal theorists focus on the way the stimulus is evaluated in determining the valence of emotion, and thus, they subscribe to the first definition of valence. From this viewpoint, anger is a negative emotion because it occurs when a person appraises a situation as unpleasant. However, other emotion theorists focus on the responses evoked during the emotion, including physiological changes, facial expressions, subjective experiences, and molar behavior. These response-based theories of emotion tend to use the third definition of valence—that is, whether the individual's experience of the subjective feeling is pleasant or unpleasant.

Most individuals evaluate the subjective experience of anger negatively. However, research has found variance among individuals in the degree of negativity with which anger is experienced (Harmon-Jones, 2004; Harmon-Jones, Harmon-Jones, Amodio, & Gable, 2011). Greater trait anger, measured by the Aggression Questionnaire (Buss & Perry, 1992) or by the hostility subscale of the Positive and Negative Affect Schedule—Expanded form (PANAS-X; Watson & Clark, 1994), is correlated with a more positive attitude toward anger (Harmon-Jones, 2004). Attitude toward anger does not relate to affect intensity or social desirability (Harmon-Jones, 2004). Furthermore, liking for anger relates negatively to trait fear (Harmon-Jones, 2004), and positively to interest in viewing anger-evoking stimuli (E. Harmon-Jones et al., 2011). Thus, when evaluated according to the pleasantness to unpleasantness of the subjective state, anger is a negatively valenced emotion. However, individuals vary in the degree to which they evaluate anger negatively.

Blends of Anger and Positive Affects

Anger may be the primary emotion evoked in a given situation, but it also commonly occurs in combination with other negative emotions (Berkowitz, 1989). Less intuitively, anger may also be positively related to the experience of certain positive emotions. Interpersonal insult, a manipulation often used to evoke anger experimentally, produces greater self-reported anger compared with a no-insult condition, but also produces higher ratings of PANAS positive activation (PA; Harmon-Jones, Vaughn-Scott, Mohr, Sigelman, & Harmon-Jones, 2004). The increase in both anger and PANAS PA was replicated following different anger manipulations (Harmon-Jones, Harmon-Jones, Abramson, & Peterson, 2009). In these studies, anger and positive affect were correlated, and both state anger and state positive affect were also related to trait behavioral activation sensitivity (BAS; Carver & White, 1994), a measure of approach motivation.

One possible explanation for these surprising results is that the PANAS items intended to measure positive affect may not actually reflect pleasantness. These items that comprise the PA subscale are "active," "alert," "attentive," "determined," "enthusiastic," "excited," "inspired," "interested," "proud," and "strong." Notably, "happy" is not included, nor are its common synonyms such as "joyful," "cheerful," or "delighted." The perplexing absence of these terms for positive affect from the PA subscale may be due to the methods used to develop the PANAS. The PANAS items were selected from a large set of emotion words using factor analysis. Items on the PA subscale were chosen because they had a large loading on the first factor and a near-zero loading on the second factor, whereas items chosen for the negative affect subscale had the converse loading (Watson, Clark, & Tellegen, 1988). This technique may have led to elimination of items that measure positivity per se (e.g., happy) and retention of items that measure something besides pure positivity. We suspect that that "something" is approach motivation, and the relationship between PANAS PA and anger supports this idea.

A study examined the hypothesis that the relationship of PANAS PA and anger is due to their common relationship with approach motivation (Harmon-Jones, Harmon-Jones, et al., 2009). Participants listened to either an insulting or a neutral radio broadcast, and then reported their anger, sadness, happiness, and PANAS PA. A factor analysis conducted within the insult condition revealed three factors, with PANAS PA and happiness loading on the first factor, all of the sadness-related items loading on the second factor, and all of the anger-related items loading on a third factor. In the neutral condition, only two factors, positive and negative, emerged. Participants in the insult condition reported greater anger, sadness, and greater endorsement of five PA items (active, alert, determined, interested, and strong), compared with the neutral condition. Participants in the insult condition also reported less happiness and less endorsement of one PA item (enthusiastic). Anger was positively correlated with PA, but negatively correlated with happiness. Furthermore, when happiness was controlled for using regression, the strength of the relationship between anger and PA increased. Similar results were found when anger was induced via autobiographical recall (Harmon-Jones, Harmon-Jones, et al., 2009).

Anger has also been found to relate positively to PANAS PA at the trait level (Harmon-Jones & Harmon-Jones, 2010). Participants completed the PANAS, several measures of trait anger, and a measure of trait happiness. At the zero-order level, PA was positively related to happiness, but not consistently correlated with the anger measures. However, when happiness and anger were used to predict PA in a simultaneous regression, PA was positively correlated with anger. These results, like experimental results assessing state emotions, suggest that happiness acts as a suppressor in the relationship of PA and anger.

Pettersson and Turkheimer (2013) have found conceptually similar results. They created a "balanced PANAS" by adding an antonym with the same valence as each of the original words on the PANAS. For example, the balanced PANAS added the similarly valenced antonym "meek" to account for the PANAS word "hostile," and the similarly valenced antonym "laid-back" to account for the PANAS word "excited." Results revealed that participants' endorsements of these items clustered around valence, and not content. In other words, meek and hostile were positively correlated. However, when variance associated with valence was statistically controlled, words assessing anger "(hostile," "irritable") clustered close to words assessing approach-related positive affect ("proud," "excited," "strong"). Moreover, these approach-related words were not clustered near positive and negative words suggesting vigilance, such as "guilty," "ashamed," "alert," and "attentive." These results support the idea that anger is related to approach, but more importantly, suggest that the relationship between anger and some other measures of approach may be obscured because valence is represented more strongly than content in self-report measures.

Although anger was correlated with PA in these studies, the results do not suggest that anger is experienced as pleasant, because self-reported happiness was less in the anger conditions and anger negatively correlated with happiness. Rather, the results suggest that, in the context of an anger-evoking stimulus, certain items on the PA subscale may measure approach motivation rather than, or in addition to, pleasantness. With this in mind, PA more accurately refers to *pounce affect*, as pouncing can reflect anger or desire.

Motivational Components of Anger

The evidence that anger is an approach-motivated emotion comes from diverse fields within psychology, including social, clinical, behavioral, and developmental (Carver & Harmon-Jones, 2009; Lewis, 2010). Although negative emotions are often presumed to be related to withdrawal motivation (e.g., Norris, Gollan, Berntson, & Cacioppo, 2010; Watson, 2000), many sources of evidence suggest that anger violates this expected relationship. Anger is negative, both in terms of the evoking stimulus and the subjective experience, but as hinted by its relationship with the PANAS PA, it is most often associated with the urge to approach rather than to withdraw. In humans, anger is associated with attack and aggression (Berkowitz, 1993). In animals, an analogous behavior is irritable aggression, which arises from the behavioral facilitation system (Depue & Iacono, 1989).

Developmental researchers have found a relationship between anger and approach motivation even in young infants. Infants were taught to pull a string in order to see a rewarding photograph and hear rewarding music. Their emotional expressions were recorded when the reward was withdrawn and when the contingency was subsequently reinstated. The infants who displayed the greatest anger when the reward was withheld demonstrated the strongest arm pull, and greatest interest and joy, when the reward was reinstated (Lewis et al., 1990, 1992). These results suggested that anger increased task engagement and persistence in response to goal blocking.

Psychological reactance, like anger, is a response to blocked goals, suggesting a link between reactance theory (Wortman & Brehm, 1975) and anger. According to the model that integrated reactance theory and learned helplessness theory, how individuals respond to an undesired outcome depends on both the importance of the outcome and the degree to which they expect control. When expectations for control are high and a desired outcome fails to occur, psychological reactance is aroused, producing increased effort to achieve the desired outcome. However, after repeated, uncontrollable undesired outcomes, individuals show decreased motivation (learned helplessness). In support of the idea that psychological reactance is equivalent to anger, research has found that individuals who reported anger in response to an unsolvable puzzle performed better on a subsequent cognitive task compared with participants who exhibited less anger, presumably because the angry participants were more approach motivated (Mikulincer, 1988).

Other research in adult humans suggests that anger is related to approach motivation, at both the state and trait levels. For example, whereas fear is associated with pessimism, state and trait anger are associated with optimism (Lerner & Keltner, 2001). Similarly, traits reflecting approach motivation—including self-assurance, physical strength, and bravery—relate positively to state anger (Izard, 1991).

Research using facial expressions of emotion also suggests similarities between anger and high-approach positive emotions (Harmon-Jones, Schmeichel, Mennitt, & Harmon-Jones, 2011). To select a high-approach positive emotion to compare with anger, approach motivation was evoked by asking participants to write about an important, personal goal and how they intended to achieve it. This "implemental mind-set" has been shown to produce approach motivation in past studies (Harmon-Jones, Harmon-Jones, Fearn, Sigelman, & Johnson, 2008; Taylor & Gollwitzer, 1995). In a low-approach positive comparison condition, participants wrote about a very pleasant event that had happened to them because of someone else's actions. Participants were then asked to name the emotion they experienced most strongly while engaging in this task. In the implemental mind-set condition, the most commonly freely generated word was "determined," whereas in the low-approach positive condition the most common word was "happy" (or a synonym). These results suggested that determination may be the most prototypical high-approach emotion (C. Harmon-Jones et al., 2011).

In subsequent studies within this same article, participants then made voluntary emotional expressions intended to express determination, anger, joy, and other basic emotions (sadness, fear, disgust, and neutral)—that is, the participants were simply instructed to make the facial expression so that anyone would know what they were feeling (i.e., the participants were not given muscle-by-muscle instructions on making facial expressions). Naïve judges then attempted to identify the emotions in the photographs. The photographs of intended determination expressions that were most often correctly identified were more likely to be misidentified as anger, but not more likely to be misidentified as any other emotion, including joy. These results suggest that determination, a high-approach positive emotion, is perceived as similar to anger (C. Harmon-Jones et al., 2011).

In another follow-up study, naïve judges rated the intensity of joy, anger, and determination expressed in photographs (C. Harmon-Jones et al., 2011). For the determination expressions, the intensity of perceived determination was positively correlated with the intensity of perceived anger and was negatively correlated with the intensity of perceived joy. For the anger expressions, the intensity of perceived anger was positively correlated with the intensity of perceived determination and negatively correlated with the intensity of perceived joy. These results support the idea that anger is approach related, by showing the perceptual similarity between anger and determination, a positive, high-approach emotion.

Anger and Individual Differences in Approach Motivation

Research on bipolar disorder suggests that a hyperactive approach system may underlie mania (Depue & Iacono, 1989; Fowles, 1993; Urošević, Abramson, Harmon-Jones, & Alloy, 2008), and interestingly, the emotions anger and euphoria often co-occur during manic episodes (Cassidy, Forest, Murry, & Carroll, 1998; Depue & Iacono, 1989; Tyrer & Shopsin, 1982). Lithium carbonate, used to treat bipolar disorder, reduces aggression, also suggesting that anger and aggression are part of the syndrome of bipolar disorder (Malone, Delaney, Luebbert, Cater, & Campbell, 2000). In addition, approach motivation is associated with activity in the left frontal cortical region of the brain, as research on individuals who have suffered lesions has shown that damage to the right frontal cortex commonly produces mania (see Robinson & Downhill, 1995, for a review), suggesting that mania and hypomania involve increased left frontal brain activity.

Research on BAS suggests that anger is also related to trait approach motivation within the nonclinical population. In two studies, BAS, measured with Carver and White's (1994) scale, correlated positively with trait anger, measured by the Buss and Perry (1992) aggression questionnaire. In one of the studies, anger also related positively to behavioral inhibition sensitivity (BIS), but when general negative affect was controlled statistically, the association between anger and BIS was eliminated, while the association between anger and BAS remained (Harmon-Jones, 2003). Trait BAS has also been found to predict anger in response to experimental provocations (Carver, 2004). In concert with the clinical studies on mania, the relationship between BAS and anger supports the idea that anger is approach motivated.

Anger has also been found to be associated with selective attention toward rewards but not threats. In one experiment, participants were induced to experience an angry, fearful, excited, or neutral state (Ford et al., 2010). Then, their selective attention toward images depicting threats, rewards, or high arousal controls was measured using eye tracking. Results revealed that participants induced to feel angry showed selective attention toward rewarding images when they were paired with threatening or control images. A follow-up study revealed a conceptually similar pattern of results: Trait anger (and aggression) correlated with more selective attention toward rewarding images (Ford, Tamir, Gagnon, Taylor, & Brunyé, 2012).

Animal behavior research also suggests that anger is associated with approach motivation. In one study, mice, which were selected according to being high or low in exploratory temperament, were tested in several behavioral tasks. Compared with mice that were low in exploratory temperament, mice high in exploratory temperament displayed less-anxious behavior in anxiety-evoking situations. Most important, they demonstrated more aggressive behavior in the intruder test (Kazlauckas et al., 2005).

Similarly, research has revealed that in children (4–9 years old) approach/positive anticipation is positively correlated with frustration/anger, and both of these variables are positively correlated with overt aggression (assessed using mothers' reports; Deater-Deckard et al., 2012).

Other evidence suggestive of anger being associated with approach motivation comes from research examining the startle eye-blink reflex. A reduction in the magnitude of the startle eye-blink reflex during the viewing of arousing/pleasant stimuli has been suggested to be due to the increased approach motivation evoked by the arousing/pleasant stimuli. The researchers who discovered this phenomenon, Lang, Bradley, and Cuthbert (1990), wrote, “when a foreground stimulus engages an appetitive response, a negative probe of that foreground should prompt a reflex of lower amplitude” (p. 381). In a study examining the relationship between individual differences in self-reported trait emotions and the emotion-modulated startle-eye-blink reflex (Amodio & Harmon-Jones, 2011), it was found that trait anger, enjoyment, and surprise were each correlated with reduced startle eye-blink reflexes during the viewing of arousing/pleasant pictures but not aversive pictures.

Asymmetrical Frontal Cortical Activity

Much research has focused on examining the relationship of anger with asymmetrical frontal cortical activity. The interest in examining the relationship between these two variables emerged from research that had suggested that relative left frontal cortical activity was associated with positive affect and approach motivation, whereas relative right frontal cortical activity was associated with negative affect and withdrawal motivation (Davidson, 1998; Harmon-Jones & Allen, 1997). For most emotions, the valence of the emotion (positivity/negativity) is related to its motivational direction (approach–withdrawal). Joy is often associated with approach motivation, and fear and disgust are often associated with withdrawal motivation. Thus, interpreting the research on asymmetrical frontal cortical activity and emotion/motivation in the above manner seemed valid. However, valence and motivational direction are not perfectly related as is illustrated with the emotion of anger—that is, anger is a negative emotion but it is often associated with approach motivation. Consequently, research on anger was conducted in part to test whether asymmetrical frontal cortical activity was associated with affective valence, motivational direction, or both.

In this research literature, the difference between activity in the left and right frontal cortical regions has been considered the variable of interest. In the electroencephalographic (EEG) research, the choice to use this difference score as the variable of interest was originally determined by methodological reasons, such as the need to control for individual differences in skull thickness and volume conduction, which could influence the measured EEG signals recorded from the scalp’s surface. However, subsequent research using a variety of methods has suggested that the difference between activity in the left and right frontal cortical regions may in fact be the variable of interest at a psychological/conceptual level of analysis (Schutter & Harmon-Jones, 2013)—that is, it may be the dynamic relationship between the left and right frontal regions that is responsible (in part) for greater approach versus withdrawal motivation. Consequently, when referring to this difference score, we often use terms like “relative left frontal cortical activity” to indicate greater left than right frontal activity.

Trait Anger

The first studies followed the lead of many past frontal asymmetry studies by simply examining the correlation of the affective/motivational trait with resting, baseline EEG activity measured over 4–8 minutes. The first study found that individual differences in anger, as measured by the anger subscale of the Buss and Perry (1992) Aggression Questionnaire, correlated with greater left frontal activity and lesser right frontal activity (Harmon-Jones & Allen, 1998). A follow-up study addressed an alternative explanation for the results of this study (Harmon-Jones, 2004). According to this alternative explanation, individuals who score high in trait anger may experience anger positively, and this positive feeling or attitude toward anger could explain why anger was correlated with greater relative left frontal activity. This study first developed a valid and reliable assessment of attitude toward anger, and then measured resting baseline EEG activity. Results revealed that trait anger correlated positively with attitude toward anger; individuals who scored as more chronically angry also evaluated their anger more positively. More important, however, greater relative left frontal activity correlated with trait anger but not with attitude toward anger. In addition, the relationship between trait anger and relative left frontal activity remained significant even when attitude toward anger was statistically controlled in regression analyses. Subsequent studies have revealed that trait aggression is also associated with greater relative left frontal activity (Rybak, Crayton, Young, Herba, & Konopka, 2006) even among imprisoned violent offenders (Keune et al., 2012).

State Anger

Given these findings, experiments were conducted to address the limitations inherent in correlational studies. In these experiments, anger was manipulated to test the effects of state anger on asymmetrical frontal brain activity. In the first experiment, participants wrote an essay about an issue they regarded as important and then they received (via random assignment) feedback from another person that was insulting or neutral (Harmon-Jones & Sigelman, 2001). Immediately following the participants' reading of the feedback, EEG was collected. As expected, participants who received the insulting feedback had greater relative left frontal activity than individuals who received neutral feedback. Moreover, within the insult condition, self-reported anger and behavioral aggression were positively correlated with relative left frontal cortical activity. Within the neutral condition, neither of these correlations was significant. Thus, left frontal activation was correlated with more subjective anger and behavioral aggression in the insult condition. This experiment provided the first evidence supporting the hypothesis that anger caused greater relative left frontal cortical activation.

Several experiments have directly and conceptually replicated these results (e.g., Jensen-Campbell, Knack, Waldrip, & Campbell, 2007). For example, in one experiment (Harmon-Jones et al., 2004) participants were insulted (or not) in the same manner as used by Harmon-Jones and Sigelman (2001). They were also induced to sympathize (or not) with the person who would insult them prior to receiving the insult. Results revealed that the manipulated increase in sympathy caused a reduction in the effects of insult on relative left frontal activity. These results suggest that experiencing sympathy for another person may reduce aggressive behaviors (e.g., see Miller & Eisenberg, 1988, for a review) by decreasing the relative left frontal activity associated with anger.

Ostracism from others has been found to evoke anger in a number of experiments (Williams, 2007). EEG experiments have replicated these results and also found that the degree of relative left frontal cortical activity that occurs in response to ostracism correlates with self-reported anger in a standard ostracism paradigm (Cyberball; Peterson, Gravens, & Harmon-Jones, 2011). Moreover, the degree of relative left frontal cortical activity that occurs in response to ostracism correlates with self-reported jealousy in a "romantic/sexual partner" ostracism paradigm (Harmon-Jones, Peterson, & Harris, 2009). In another experiment, Verona, Sadeh, and Curtin (2009) found that an impersonal stressor (high-pressure air blasts assigned by a computer) also evokes greater relative left frontal activity, and this increased left frontal activity correlated with more aggression in an "employee–supervisor" lab task.

Independent Manipulation of Approach Motivation within Anger

The experiments presented so far were designed so that the anger evoked was approach oriented. Although most experiences of anger involve approach motivation, not every experience of anger involves approach motivation. For example, situational variables such as threats of punishment and personality variables such as punishment sensitivity may reduce the approach motivation that occurs with anger (and cause anger to be mixed with anxiety and fear). Variables that cause a lower approach motivational response may also cause sadness to be mixed with anger. However, if anger is associated with greater left frontal cortical activity because of anger's association with approach motivation, then variables that influence the level of approach motivation of anger should influence relative left frontal activity. Several experiments have tested this idea by manipulating approach motivation independently of anger.

Past research and theory has suggested that coping potential influences motivational intensity (Brehm & Self, 1989; Wright, Tunstall, Williams, Goodwin, & Harmon-Jones, 1995). In other words, when individuals expect to be able to act to resolve a particular problem, they should experience more motivation, particularly if it is moderately difficult to act. Consequently, we predicted that expecting to be able to act to resolve an anger-producing situation will increase approach motivational intensity as compared with expecting to be unable to take action. Thus, because relative left frontal activity is associated with approach motivational intensity, the expectation of high coping potential within an anger-inducing situation should cause greater relative left frontal activity. Three experiments have found evidence consistent with this prediction (Harmon-Jones et al., 2003, 2006).

In the Harmon-Jones et al. (2003) experiment, participants were led to believe that they could or could not act to attempt to change an upcoming event that angered them (i.e., a tuition increase at their university). Participants in both conditions reported significant increases in anger over baseline, and the two conditions did not significantly differ from each other. More importantly, participants who believed they could engage in approach-related action to resolve the anger-producing event had greater left frontal activity than participants who expected to be unable to engage in such action. In addition, within this action-possible condition, participants who had greater left frontal activity to the angering situation also reported more anger; this correlational result suggests that their angry experience was approach motivated. In the condition where action was impossible, relative left frontal activity was not correlated with self-reported anger. Taken together with the high level of anger reported in this condition, this correlational result suggests that even though anger is usually associated with approach motivation, when approach-related action is not possible, approach motivation is low, even though angry feelings can be high. Last, within the action-possible condition, participants who had greater left frontal activity to the angering event were more likely to act in ways that would decrease the possibility of the angering event from occurring (i.e., they were more likely to sign a petition and take petitions with them for others to sign to try to eliminate a possible tuition increase at their university). This latter correlational result implies that greater approach motivation, as suggested by greater relative left frontal cortical activity, was associated with more overt behaviors aimed at resolving the angering negative situation.

This finding of greater left frontal cortical activation occurring when individuals are angered and expect to engage in approach-related action has been replicated (Harmon-Jones et al., 2006). In these two experiments, participants who scored low in racial prejudice were presented photographs depicting racist events as well as standard positive, negative (fear/disgust), and neutral photographs from the International Affective Picture System (Lang, Bradley, & Cuthbert, 1997). As expected, these racist photographs evoked self-reported anger. Prior to viewing all of the photographs, participants were assigned (or not) to expect an opportunity to act on their anger immediately after the viewing—that is, they were told that they would write essays discussing how racism was unjust, unfair, and immoral, and these essays would be used in prejudice-reduction studies in the future. In addition to that manipulation, the personal relevance of the photographs was manipulated by having participants either complete a self-report measure of racial prejudice or a comparable questionnaire about a neutral topic. As predicted, the greatest left frontal cortical activity occurred in response to the anger-inducing photographs when the photographs were made more personally relevant and when participants expected to act on their anger. These results conceptually replicate the results of the previous experiment and suggest that increasing the approach motivational character of anger increases relative left frontal cortical activity. The second experiment revealed that this effect was indeed strongest among those participants who scored lowest in racial prejudice.

We believe that these results do not indicate that heavy-handed, explicit manipulations of action possibility are necessary to cause greater relative left frontal activity. These manipulations of action possibility probably only increase the effects of the emotion manipulations on relative left frontal cortical activity. In line with this interpretation, a follow-up study revealed that the anger-inducing pictures evoked a nonsignificant effect on relative left frontal activity when participants were given no manipulations to influence action expectations or personal relevance. However, individuals who scored high on trait anger did show greater relative left frontal activity to the anger-inducing pictures—that is, individual differences in trait anger correlated with greater left frontal activity to anger-producing pictures (controlling for activity to neutral pictures; Harmon-Jones, 2007).

Further support for the importance of approach motivational intensity in determining the relationship of anger and asymmetrical frontal cortical activity comes from an experiment in which whole body posture was manipulated (Harmon-Jones & Peterson, 2009). This experiment tested the hypothesis that a supine body posture or lying flat on one's back would reduce approach motivation and correspondingly the increase in relative left frontal activity that occurs in response to angering events. The idea that a supine posture would reduce approach motivation was based on the observation that individuals often recline backward after acquiring goals and that the posture itself may prevent one from easily moving toward goals (see Price, Peterson, & Harmon-Jones, 2012, for a review). In the experiment, participants were randomly assigned to sit in an upright or reclined position. Then, they received neutral or insulting interpersonal feedback, as described above (Harmon-Jones & Sigelman, 2001). For participants assigned to the upright body posture, results replicated past research: Those who received insulting feedback had greater relative left frontal activation than those who received neutral feedback. More important, participants assigned to the supine body posture had a level of relative left frontal activation that was similar to those in the upright/neutral feedback condition and significantly less than those in the upright/insulting feedback condition. This whole body posture research illustrates the importance of approach motivation in the anger–relative left frontal activity relationship.

Manipulation of Asymmetrical Frontal Cortical Activity and Anger Processing

In the above research, anger was manipulated and regional brain activation was measured, as is commonly done in affective neuroscience research. Another less commonly used method involves the manipulation of regional brain activity and the measurement of a psychological variable. This method permits stronger causal inferences about the role of a particular brain region in a psychological process than the method of measuring regional brain activity to a psychological manipulation, because with the latter method, the measured variable may only be a correlate of the psychological process and not critically involved in the process.

One of the first experiments to manipulate brain activity and measure anger-related processes was conducted by d'Alfonso, van Honk, Hermans, Postma, and de Haan (2000). They used slow repetitive transcranial magnetic stimulation (rTMS) to inhibit activity in the left or right prefrontal cortex. Slow rTMS has been found to cause inhibition of cortical excitability. When slow rTMS is applied to the right prefrontal cortex, the right prefrontal cortex becomes less active and the left prefrontal cortex becomes more active. When slow rTMS is applied to the left prefrontal cortex, the left prefrontal cortex becomes less active and the right prefrontal cortex becomes more active. d'Alfonso et al. found that rTMS to the right prefrontal cortex caused more attention toward angry faces, whereas rTMS to the left prefrontal cortex caused more attention away from angry faces. These researchers interpreted these results to indicate that the increase in left prefrontal activity caused participants to attentionally engage with angry faces, as in an aggressive or dominance confrontation. On the other hand, the increase in right prefrontal activity caused participants to attentionally avoid angry faces, as in a fearful avoidance or submissiveness. These results are conceptually similar to other research that has found that attention toward angry faces is associated with high levels of self-reported anger and that attention away from angry faces is associated with high levels of fear responses (van Honk, Tuiten, de Haan, van den Hout, & Stam, 2001; van Honk et al., 1998, 1999). These results with rTMS have been replicated using other tasks (Donhauser, Belin, & Grosbras, 2014; van Honk & Schutter, 2006).

This research using rTMS has been extended using a different manipulation of asymmetrical frontal cortical activity and a different outcome variable related to anger. Past research has found that contraction of the left hand increases right frontal cortical activity and contraction of the right hand increases left frontal cortical activity (Harmon-Jones, 2006). These unilateral hand contractions also influence emotive responses (Harmon-Jones, 2006; Schiff & Lamon, 1989, 1994).

To test whether the unilateral contraction of hands would influence asymmetrical frontal cortical activity and angry aggression, participants were randomly assigned to contract their right or left hand. Then, they received insulting feedback from another participant, as in previous research (Harmon-Jones & Sigelman, 2001). Afterward, they performed a reaction time game against this other (ostensible) participant. The reaction time game was based on Buss's (1961) aggression paradigm and it was used so that behavioral aggression could be measured. In the game, participants could deliver blasts of white noise, ranging from 60 to 100 decibels and for any period of time up to 10 seconds if they won the reaction time trial (i.e., fastest to press the shift key when an image appeared). As predicted, participants who contracted their right hands gave louder and longer noise blasts to the other participant than those who contracted their left hands (Peterson, Shackman, & Harmon-Jones, 2008). Moreover, within the right-hand contraction condition, greater relative left frontal activation correlated with more behavioral aggression.

Another brain stimulation technique that has been used in the study of anger and asymmetrical frontal cortical activity is transcranial direct current stimulation (tDCS). This methodology uses two electrodes, an anode and a cathode, to simultaneously modulate activity in opposite directions in the left and right frontal cortices. Anodal tDCS increases excitability, whereas cathodal tDCS decreases cortical excitability in the targeted brain region (Ardolino, Bossi, Barbieri, & Priori, 2005; Nitsche & Paulus, 2000). Thus, this method is perfect for studies of asymmetrical frontal activity and emotive states where the psychophysiological variable of interest—the asymmetry—shows greater activity in one hemisphere and lesser activity in the contralateral hemisphere.

So far, two tDCS experiments on anger have been conducted. In both, participants were randomly assigned to one of three tDCS conditions: anodal to right frontal cortex and cathodal to left frontal cortex; cathodal to right frontal cortex and anodal to left frontal cortex; or sham, which is a condition that gives stimulation for a few seconds at the beginning of the 15-minute stimulation period. In both experiments, participants were unable to correctly guess which condition they had experienced, thus suggesting that the sham stimulation was successful. After 10 minutes of stimulation, participants in both experiments received insulting interpersonal feedback similar to that used in past experiments such as Harmon-Jones and Sigelman (2001). In the first experiment (Hortensius, Schutter, & Harmon-Jones, 2012), at the beginning of the session, participants were led to believe that they might interact with the other person participating in the session (which was ultimately the person who insulted them). After the 15 minutes ended, participants played a competitive reaction time game against the other person, so that behavioral aggression could be measured. Finally, self-reported emotions about the feedback were measured. Results revealed that only within the condition in which left frontal cortical activity was increased did self-reported anger relate to aggression. In other words, when individuals were angry and their left frontal cortex was made more active, they behaved more aggressively. In the other two conditions, this effect did not emerge.

In the second experiment (Kelley, Hortensius, & Harmon-Jones, 2013), at the beginning of the session, participants were *not* led to believe that they might interact with the other person participating in the session. After the 15 minutes ended, participants completed two self-report measures of rumination. Based on past work that had linked rumination with more depression (Nolen-Hoeksema, 2000) and depression with greater relative right frontal activity (Thibodeau, Jorgensen, & Kim, 2006), it was expected that the manipulated increase in right frontal activity might cause more rumination about the angering feedback as compared with the other two tDCS conditions. Indeed, it did. These results are conceptually consistent with earlier results obtained from a study examining how individual differences in depression versus mania relate to asymmetrical frontal cortical activity to angering events (Harmon-Jones et al., 2002). In this study, greater mania related to greater relative left frontal cortical activity and greater depression related to greater relative right frontal cortical activity to the anger-evoking event.

Conceptual Interpretation of the Anger–Approach Relationship

One issue that has arisen in the consideration of anger being an approach-oriented emotion is exactly how it is approach oriented. On one hand, anger is associated with approach motivation because anger occurs when approach-oriented goals are blocked—that is, when an individual is motivated to gain a desired reward and is blocked from progress toward the reward, then anger occurs (Carver & Harmon-Jones, 2009). This interpretation of the anger–approach relationship employs the stimulus (i.e., blocked approach motivation) as the determinant of the relationship.

Because anger occurs when desires are blocked, anger itself may orient individuals toward positive outcomes. Indeed, the reviewed research suggests this to be the case (e.g., Ford et al., 2010). However, does anger always orient individuals toward positive outcomes? We suspect that anger will not always do so, because one of anger's main motivational imperatives is to attack the source of anger (Berkowitz, 2012). In these cases, anger may cause individuals to temporarily abandon the original blocked goal so that the angering stimulus or person can be attacked. This latter case may illustrate the difference between anger and rage (Lewis, 1993).

Another, parallel interpretation, however, employs the response as the determinant of the anger–approach relationship—that is, anger is linked to approach motivation, because anger is tightly linked to approach-related responses. Moreover, anger appears to occur in a wide array of situations that do not appear to result from goal blocking (e.g., Berkowitz & Harmon-Jones, 2004a, 2004b). For example, simply adopting physical expressions of anger, even when individuals are not aware that they are creating angry expressions, causes physiological and cognitive responses that are approach oriented (Coan, Allen, & Harmon-Jones, 2001; Keltner, Ellsworth, & Edwards, 1993). Also, angry moods and trait anger appear to be linked to approach motivation, and it seems that these characteristics are at least occasionally linked with approach motivation that did not result from blocked goals. Thus, we suggest that anger may evoke approach motivation even in situations that do not contain an obstacle to a desired outcome.

Anger and Withdrawal Motivation

The research reviewed so far suggests that anger is associated with greater relative left frontal activation because anger is often associated with approach motivation. This conclusion is supported by the experiments that manipulated approach motivation independently of anger and found that it was the approach motivational intensity of anger that determined relative left frontal activation.

Could anger ever be associated with withdrawal motivation and increased relative right frontal activation? Based on past research, we suspect that anger may be evolutionarily prepared to be associated with approach motivation. In support, research with infants (Lewis et al., 1992) and nonhuman animals (Blanchard & Blanchard, 1984) suggests that anger is predominantly associated with approach motivational tendencies.

However, anger may become associated with other response tendencies in addition to approach ones over the lifetime. Moreover, although the blocking of approach motivation may be the primary elicitor of anger, the situations that block approach may also contain threats of punishment that elicit other emotional states. Thus, some situations may cause and/or persons may experience some withdrawal tendencies and increased relative right frontal cortical activity during the experience of anger. As we review below, a few studies have tested these ideas.

One of the first experiments designed to test this idea had soccer players *imagine* that their coach unfairly prevented them from playing a soccer game (Wacker, Heldmann, & Stemmler, 2003). In the anger–approach condition, the players imagined approaching the coach and protesting, whereas in the anger–withdrawal condition, they imagined backing out of the locker room and silently swearing at the coach. In both conditions, the players reported feeling angry; however, the two conditions did not differ from each other in relative left frontal activation, even though both anger conditions evoked greater relative left frontal activation than the neutral comparison condition.

Another study (Hewig, Hagemann, Seifert, Naumann, & Bartussek, 2004) examined the relationship between resting baseline frontal asymmetry and trait anger out, trait anger in, and trait anger control, measured with the State–Trait Anger Expression Questionnaire (Spielberger, 1988). These three measures of anger traits are designed to measure how individuals express anger. Anger out is defined as "expressing angry feelings in aggressive verbal or motor behavior directed toward other people or objects in the environment" (e.g., "When angry or furious, I lose my temper"; Spielberger et al., 1995, p. 57). Therefore, anger out appears to be assessing an approach-related response of anger. Anger in is defined as the degree to which individuals suppress anger and/or direct it at themselves (e.g., "When angry or furious, I keep things in"). Anger control is defined as the degree to which individuals monitor and prevent the expression of anger (e.g., "When angry or furious, I control my angry feelings"). Hewig and colleagues (2004) found that trait anger out correlated with greater relative left frontal activity at resting baseline, but that trait anger control correlated with greater relative right frontal activity. Trait anger in was not correlated with resting frontal asymmetry. Hewig and colleagues (2004) interpreted the results with anger control as suggesting that individuals who score high in anger control may be particularly high in withdrawal motivation. This latter correlation may be due to individuals who score higher in anger control being higher in anxiety or sadness, as these emotions may reduce approach motivation (Lewis & Ramsay, 2005).

As revealed above, the evidence in support of the idea that anger can be associated with withdrawal motivational tendencies is mixed. Anger may be associated with withdrawal motivation but this may occur only when the angering situation also arouses punishment concerns. Thus, these types of situations may evoke feelings of anger as well as anxiety.

A study designed to test these ideas created a situation in which anger was considered particularly socially inappropriate (Zinner, Brodish, Devine, & Harmon-Jones, 2008). This study built on past research suggesting that norms exist that encourage political correctness and discourage expressions of racial prejudice, but that some individuals are angered by the pressures to behave in accord with these norms (Plant & Devine, 1998). These individuals, rather than outwardly expressing their anger, may withdraw when they experience anger in response to situations that emphasize these norms. Indeed, other research has found that some individuals reporting being angry when socially pressured to respond without racial prejudice (Plant & Devine, 2001). In the EEG study, white participants (university students in the United States) were led to believe they were about to interact with a black person. To increase the possibility of anger among some participants, the experimenter mentioned that the study concerned the importance of harmonious interracial interactions. The participants were then instructed to "mentally prepare" for the interaction, and EEG was recorded. Then, prior to the (ostensible) interaction, participants completed a self-report affect measure that asked them to indicate how they felt about the upcoming interaction. In this particular situation, self-reported anger correlated with greater relative right frontal cortical activity as well as increased skin conductance levels and more spontaneous eye blinking. Taken together, these results suggest that the individuals who felt the most anger may have been motivated to withdraw (as suggested by relative right frontal activity), were aroused (skin conductance), and were attempting to suppress their anger (eye blinking; Gross & Levenson, 1993). These individuals may have been motivated to withdraw and suppress their anger because they did not want to appear socially inappropriate. Importantly, the self-reported anger was correlated with anxiety; these results suggest that this social context may have evoked punishment concerns among those who were angry.

Much evidence supports the idea that anger is associated with approach motivational tendencies. Less evidence supports the idea that anger is associated with withdrawal motivational tendencies. In the studies that have examined this latter idea, the results have revealed that state anger may be associated with relative right frontal cortical activity (and possibly withdrawal motivation) when individuals also experience anxiety and are perhaps concerned about punishment (Zinner et al., 2008). In addition, individuals who score high in the trait of anger control tend to have greater relative right frontal activity at rest, suggesting that they may be motivated to withdraw when angry (Hewig et al., 2004).

Conclusion

In this chapter, we have reviewed theories and research related to understanding the causes of anger, the subjective feeling of anger, and the motivational components of anger. In doing so, we also reviewed research relating anger to asymmetrical frontal cortical activity, which led to a better understanding of the role of asymmetrical frontal cortical activity in emotive processes but also suggested new insights into understanding anger.

In addition to increasing our understanding of anger, the reviewed research has pointed to the importance of delineating emotional experience from emotional expression and emotional valence from motivational direction. The reviewed research contributes to a better understanding of the conceptualization of emotional space. Previously, much research and theory emphasized emotional valence and arousal as primary dimensions underlying emotions (Lang, 1995; Watson, 2000). These perspectives have also suggested that valence relates directly to motivational direction, such that positivity is approach oriented and negativity is withdrawal oriented (e.g., Norris et al., 2010). However, research on anger suggests that the valence of an emotion is independent of the motivational direction of an emotion. Negative emotions such as anger may be associated with approach motivation.

CHAPTER 45

Self-Conscious Emotions

Embarrassment, Pride, Shame, Guilt, and Hubris

Michael Lewis

Elsewhere (Chapter 15, this volume) I have tried to show that the first major event in emotional development in the human child occurs with the rise of consciousness.[1] The rise of consciousness alters the nature of the early emotional action patterns, present as part of the evolved biological features of the infant. The advent of consciousness also gives rise to a new set of action patterns that serve as the stimulus for the cognitive-attributional system. These new emotions have been called the self-conscious emotions. They are captured by our language as such statements as "I am so proud of winning first prize in the spelling bee."

This sentence captures my view of the self-conscious emotions, and in particular, pride. There are two references to myself, the reference to an experience, "I am so. . . . " and the cause of that state, "my winning." The emergence of consciousness is defined by this self-reflection. It is important to note that the cause of the pride is the success of some behavior. The sentence itself specifies the cause for the pride, which implies that what was done succeeded in meeting some standard, rule, or goal that the speakers had in regard to their behavior.

With the emergence of consciousness, a person's emotional life is transformed. In addition to the early action patterns, elicited by physical properties of the literal world, the child has now acquired added ideas as elicitors of an emotion, in particular, ideas about the self. It is these ideas that now become the elicitors of new emotional action patterns. Make no mistake, these new action patterns are as biologically derived as the original ones; neither the experience of it nor the action patterns associated with it are taught. It should be pointed out that once ideas emerge, these ideas can also be the elicitors of the early emotional action patterns. Sadness at loss of the mother in the literal world now can be sadness caused by the idea of her loss. Because these self-conscious emotions require the emergence of self-reflection, they appear in the middle of the second year of life. And because some of these self-conscious emotions require the development of other ideas, such as ideas about the standards, rules, and goals (SRGs) of the family and culture, as well as ideas about personal responsibility, their development spans the period from the emergence of consciousness, around 15–24 months, to the end of the child's third year, around 30–36 months. We therefore can think of the child's emotional life as consisting of three periods: the period of the early emotions or at least of their action patterns, the period of the emergence of consciousness, and the period of the development of the self-conscious emotions. However, the set of self-conscious emotions itself needs to be divided between the early ones, what I call the "self-conscious exposed emotions," and the later ones, what I call the "self-conscious evaluative emotions." The major difference between these two sets of emotions centers on the development of knowledge about the SRGs of the family and the greater culture, and the incorporation of this knowledge into the child's mental life. The exposed self-conscious emotions appear to be tied directly to the emergence of a mental representation of self and include at least embarrassment, jealousy, and empathy. The evaluative self-conscious emotions also require the mental representation of the self, but in addition to the knowledge of some of the SRGs the child has acquired, there is a need to develop some ideas about responsibility for the child's actions and thoughts. These evaluative emotions include shame, guilt, pride, embarrassment, and hubris. Hubris is used to denote pride that is not focused on actions but on the global self. Because the overall model, the earlier action patterns, and the emergence of consciousness have already been discussed, this chapter focuses on the self-conscious emotions.

The Self-Conscious Emotions

The self-conscious emotions—in particular, shame—can help us distinguish between those who would attribute mental representation involving the self at an early age and those who see it emerge in the middle of the second year of life. While it is the case that shame can be elicited by many causes, the claim that it exists early within the first year is similar to the claim that all emotions exist in the first months of life, for example, jealousy (Masciuch & Kienapple, 1993). Historically, it has been thought that the self-conscious emotions such as shame took time to develop. Freud (1936/1963), for one, believed that the child needed to have developed an ego and a superego in order to experience guilt and shame. Tomkins's (1963) view had as its central theme how children think of others' thoughts about them as the elicitor of shame. Children's thinking about others thinking about them needs time to develop. Darwin (1872/1965) thought that the self-conscious emotions required a developed cognitive system in which a mental representation of "me" is needed. Darwin related the self-conscious emotions to the process of thinking about what others are thinking about oneself. He wrote about the nature of the mental states that induce blushing. For example, he noted that the self-conscious emotions "consist of shyness, shame and modesty; the essential element in all being self-attention." Notice that Darwin's term, "self-attention," is what we have called "consciousness," or the ability to reflect on oneself. Darwin believed that

> many reasons can be assigned for thinking that originally self-attention directed to personal appearance, in relation to the opinion of others, was the exciting cause; the same effect being subsequently produced, through the force of association, by self-attention in relation to moral conduct. It is not the simple act of reflecting on our own appearance, but the thinking what others think of us, which excites a blush. (1965, pp. 326–327)

While various theories have argued for some universal elicitor of self-conscious emotions, such as failure at toilet training, exposure of the backside, or the interruption of an ongoing action, the idea of an automatic noncognitive elicitor of these emotions does not make much sense. Cognitive processes have to be the elicitors of these complex emotions. It is the way we think about ourselves that becomes the elicitor. There may be a one-to-one correspondence between thinking certain thoughts and the occurrence of a particular emotion; however, for these emotions, the elicitor is still a cognitive event. This does not mean that the earlier emotions, those called primary or basic, are elicited by noncognitive events. Cognitive factors play a role in the elicitation of any action pattern; however, the nature of the cognitive events is much less complex in the earlier emotions (Plutchik, 1980).

While the emotions that appear early—such as joy, sadness, fear, and anger—have received considerable attention, the set of emotions that appear later, which are considered here, has received relatively little attention. There are likely to be many reasons for this lack of interest. One reason is that these self-conscious emotions cannot be described solely in terms of a particular set of facial movements; identification of the self-conscious emotions requires the observation of bodily actions as well as facial cues. A second reason for the neglect of the study of these later emotions is the realization that there are no clear specific elicitors of these particular emotions. While happiness can be elicited by seeing a significant other, and fear can be elicited by the approach of a stranger, there are few specific situations that will always elicit shame, pride, guilt, or embarrassment. These self-conscious emotions are likely to require classes of events that can only be identified by the individuals themselves. For these reasons, little research has been conducted on their development.

Darwin (1872/1965) saw these later emotions as involving the self, and emerging around age 3 years, but he was not able to distinguish among the various types. His observation and concern in regard to blushing reveals his interest in appearance and consciousness. Darwin's use of blushing as an example raises particular difficulties in large part because blushing (1) usually occurs around embarrassment rather than shame or guilt; (2) not all children or adults blush; and (3) blushing usually takes place in the presence of others, while shame can be experienced alone.

The Self-Conscious Exposed Emotions

The emergence of consciousness is seen in some children as early as age 15 months, but all normally developing children show self-referential behavior by age 24 months. Whatever the age when self-referential behavior can be observed is the age when the exposed self-conscious emotions appear. If self-recognition is shown by children at age 18 months, they will start to show these self-conscious emotions at age 18 months, and if it is shown at age 21 months by another child, then for those children they will start to be seen at that age. They are temporally tied to the emergence of self-reflection. This association between them has been studied in terms of exposure embarrassment, discussed next. In our studies, we have found that while fearfulness is unrelated to self-recognition, embarrassment is such that children who do not show self-recognition do not show embarrassment (Lewis, Sullivan, Stanger, & Weiss, 1989).

The work on these exposed self-conscious emotions has centered on three emotions: exposure embarrassment, jealousy/envy, and empathy. Let us start with embarrassment because it is one of the early self-conscious exposed emotions for which there is some information.

Embarrassment

Almost all theories speak of embarrassment as an unpleasant feeling having to do with some form of the discrediting of one's own image, either through the loss of self-esteem, the loss of the esteem of others, or both. However, one of the critical issues in the study of embarrassment has to do with terminology usage. The problem concerns the difference between embarrassment and shame, on the one hand, and between embarrassment and shyness, on the other. Historically, the psychoanalytic approach made little distinction between embarrassment and shame; most of the confusion in this approach has been between guilt and shame (see Broucek, 1991; Lewis, 1971; Morrison, 1989, for exceptions). Freud writes mostly of shame and does not employ another word that might be translated as "embarrassment" (Goffman, 1959). If shame is discussed, it is usually discussed in terms of nakedness or in terms of impulses, either sexual or exhibitional, that need to be held in check. Of more interest is the existential approach. In this approach, embarrassment is seen as an alienation of one's own body. Goffman, for example, discusses the act of blushing as occurring when individuals become aware of their own bodies, which is similar to Darwin's (1872/1965) idea about embarrassment. Unfortunately, the term "alienation" suggests some negative attribution as in being separate from one's own body; however, I think that alienation should be viewed as self-awareness or self-reflection.

The interpersonal approach to embarrassment suggests that individuals feel embarrassed when they project an image of themselves incompatible with their own view *in the presence of others*. "Embarrassment . . . reflects a failure to present oneself in the way one would have wished" (Edelmann, 1987, p. 14). Such theories assume the need for three features: the presence of another person, people becoming aware that they are the center of attention, and the people feeling that they are being judged. As we shall see, this last feature is questionable, since the distinction between embarrassment and shame is not well articulated in this approach. One could argue that the same three conditions are necessary for the production of shame, although this view of embarrassment is quite common (see Lewis, 1971; Semin & Manstead, 1981; and earlier, Izard, 1977; Tomkins, 1963).

Embarrassment is often considered to be similar to shyness, especially to the extent to which embarrassment can be viewed as having a fear component. When we think of a shy child, we tend to think of a child who is reluctant to engage in interpersonal interactions. But this factor of sociability may have less to do with evaluation and more to do with dispositional factors (Eysenck, 1956). Kagan argues for what he calls "inhibition," which bears a striking similarity to shyness (Kagan, Snidman, Arcus, & Reznick, 1994). Even when embarrassment is viewed as a form of shyness, it has a negative evaluation component. For example, Zimbardo (1977) argues that people feel most shy at being the center of attention of a large group of people (see also Jones, Cheek, & Briggs, 1986). For him, a person being watched implies being seen in the best light. Being seen as such, in turn, implies an evaluation of the self against some kind of ideal self. Shyness also has been related to aspects of social anxiety, which also implies an evaluative component (Buss, 1980; Cheek & Buss, 1981; Fenigstein, Scheier, & Buss, 1975).

Since Darwin (1872/1965) described all self-conscious emotions as including the phenomenon of blushing, the use of blushing to indicate shame, embarrassment, and guilt means that blushing as a measure of any one emotion is ineffective. By utilizing a combination of the criteria suggested by others, we have come up with an overall measure of embarrassment that is useful in studying young children. This scoring system for embarrassment agrees with those of others who have attempted to find behavioral manifestation of this emotion (Buss, 1980; Geppert, 1986). In general, the behaviors believed to reflect embarrassment are (1) a smiling facial expression; (2) gaze aversion; and (3) movement of the hands to the body such as touching hair, clothing, face, or other body parts. These hand gestures appear to capture the category of nervous movements that previous investigators believed were characteristic of the emotion. Such body touching can accompany smiling/gaze aversion or immediately follow it. All three classes of behavior appear to be associated with embarrassment.

Embarrassment differs from shame or anxiety/fear in a number of critical ways. First, embarrassment seems to be marked by a "sheepish" grin or a "silly" smile as described by others. In both shame and fear, smiling behavior is usually absent. Moreover, the smiling in embarrassment does not appear to be a frozen type of smile; rather, it is an active engagement with the other people present. Perhaps most important in differentiating embarrassment from other emotions is the gaze behavior and bodily action. In embarrassment, people are more apt to tilt their heads and to engage in gaze-avert/look-at behavior. It is not gaze aversion with the head bowed as in an avoidance response and it is not the immobility of action as in removing one's self from the situation. Instead it is a gaze-avert, gaze-return motion toward the other person present. This on/off sequence is typical of embarrassment, whereas in shame it is more a turning away and remaining away. Finally, nervous touching of the body, including hair, clothing, and face, seems to reflect the subject's engagement in self-directive behavior, reflecting an active focus on the self. In shame or shyness, the person is likely to be immobile, and not inclined toward self-directive behavior. The use of such behavioral criteria is in keeping with the idea that embarrassment appears to be related to the self and requires another social object. The active nature of bodily action in embarrassment, unlike that seen in shame, suggests that embarrassment and shame are readily distinguishable. Blushing, which received so much attention in Darwin's (1872/1965) analysis, would be a likely candidate for indexing embarrassment. However, blushing does not always occur; there being large individual differences in the likelihood of this response. Differences may be due, in part, to different physiology; it is certainly related to skin coloration with light-skinned people blushing more visibly than dark-skinned people. In our research on self-conscious emotions, blushing in children is a relatively infrequent event. Even when children above the age of 3 years show embarrassment in terms of other behaviors, it is rare to observe blushing in those children. This should not be surprising since it is relatively unusual to see blushing in adults. Given the self-reports indicating the high incidence of embarrassment, it is interesting to note that the occasions of blushing seem to be disproportionately low (see Leary & Meadows, 1991).

Since embarrassment has been related to shyness, we need a working definition for this term. Shyness for some researchers is itself not an emotion. For example, Izard and Tyson (1986) describe shyness in terms of sheepishness, bashfulness, and the feeling of uneasiness or psychological discomfort in social situations. They suggest that shyness results from a vacillation between fear and interest or between avoidance and approach. They related shyness to fear, not to self-evaluation. Individuals who are considered shy are not too much concerned with the evaluation of their performance vis-à-vis their standards, as they are with being observed. Thus, our own observations, as well as those of others, indicate that shyness is related to a constellation of factors not related to self-evaluation. Moreover, there is some reason to believe that these individual differences have a dispositional or constitutional basis (Eysenck, 1956; Kagan, Reznick, & Snidman, 1988).

For some researchers, embarrassment is closely linked to shame (Izard, 1979; Tomkins, 1963). While shame appears to be an intense and destructive emotion, embarrassment is less intense and not does involve the same degree of disruption of thought and action as in shame. In terms of body posture, people who are embarrassed do not assume the shame posture of body collapse. Their bodies reflect an ambivalent approach–avoidance posture. In shame situations one rarely sees gaze aversion accompanied by smiling behavior. Thus, from a behavioral point of view these two action patterns appear to be different. Phenomenologically, embarrassment is less differentiated from shame, as people often report that "embarrassment" is less intense than "shame." Situations similar to those that invoke shame are found to invoke embarrassment. Even so, the intensity and duration of the disruptive quality of shame is reduced in embarrassment. These different descriptions of behavior appear to be indicating two different types of embarrassment, because, as our studies of toddlers suggest, one type occurs earlier than the other, and different elicitors are involved.

Embarrassment as Exposure, Not as Evaluation

Embarrassment as exposure appears to be more similar to shyness than to shame, and it is the first type of embarrassment to appear. In certain situations in which children are observed, they become embarrassed. This type of embarrassment is not related to negative evaluation. One of the best examples of this kind of exposure embarrassment is being complimented. The phenomenological experience of embarrassment when complimented is well known. The adult public speaker, when introduced with praise, is often embarrassed. While complimenting may elicit the social rule of modesty in adults or older children, it is not typical for infants as young as 15–18 months of age who are unlikely to have learned the rule of modesty, yet show embarrassment when complimented. Another example of this type of exposure embarrassment can be seen in children's reaction to their public display. When young children observe someone looking at them, they are apt to become embarrassed, look away, and touch or adjust their bodies. When the observed person is an adult woman, she will often adjust or touch her hair. An observed man is less likely to touch his hair, but may adjust his clothes or change his body posture. Observed people look pleased or concerned, rarely sad.

To examine the development of embarrassment my colleagues and I conducted a study with 15- to 18-month-olds, about half of whom showed self-recognition. To induce exposure embarrassment during a free-play situation both the experimenter and the mother pointed to the toddler and repeated her name while pointing. Many of the toddlers who showed self-recognition showed clear examples of embarrassment to this event, suggesting that being the object of another's attention can produce a kind of embarrassment that appears to be unrelated to any evaluation of behaviors. Interestingly, in an earlier study (Lewis, Stanger, Sullivan, & Barone, 1991), children 12–33 months old were asked to dance to music, first by their mothers in the presence of a stranger, and then by the experimenter. In another situation they were also overly praised. Those who showed embarrassment also showed self-recognition, although not all children who showed self-reflection showed embarrassment when made the object of another's attention.

In order to explore this individual difference in the display of embarrassment, in another study, measures of temperament as well as measures of reaction to pain caused by inoculation were obtained for infants along with measures of embarrassment to being the object of others' attention (DiBiase, & Lewis, 1997; Lewis & Ramsay, 2002). The results strongly suggest that individual ease of embarrassment once consciousness emerges is a function of temperament, with young children with difficult temperaments as measured by a variety of indexes more likely to show this type of exposure embarrassment. These findings support the idea that exposure embarrassment is not evaluatively related. The elicitor was simply being the object of another's attention. To support this idea we found that several children with a particularly difficult temperament, when pointed to by their mothers and the experimenter, not only showed embarrassment but they became upset and cried. They were reported by their mothers to be very shy.

Further support for exposure embarrassment can be seen in an experiment I often perform in front of large groups of people. In lecturing to audiences, I demonstrate that embarrassment can be elicited just by exposure. To demonstrate this point, I inform the audience that "I am going to *randomly* point to someone." I further inform the audience that "my pointing has no evaluative component and is not related to anything about the person since I will close my eyes before pointing." Following these words, I turn around several times and I point to someone in the room, who, of course, immediately acts embarrassed. Everyone agrees that the person chosen will be embarrassed if pointed at, yet, since it is random, it cannot reflect anything personal.

There are other examples of embarrassment in which an evaluation is evoked, yet it may be that simply being the object of others' attention can be the real elicitor. Take the simple act of walking into a crowded room and having people stare at your entrance. On such an occasion, one is likely to experience embarrassment and this embarrassment turns into a negative self-evaluation, such as "I hope I have worn the correct dress." I believe, however, that the experience of embarrassment may not be caused by the negative self-evaluation, but by simple public exposure. However, rather than believe that it is the exposure that produces the embarrassment, people often look for a negative evaluation. In other words, the negative evaluation follows embarrassment due to exposure as people attempt to explain why they are embarrassed. The reason is that as adults we also possess a second type of embarrassment that occurs around a standard failure.

Embarrassment as a Function of Evaluation

This type of embarrassment is related to negative self-evaluation and to shame, topics that are covered in more detail later when the self-conscious evaluative emotions are discussed. It emerges later in development than the exposure embarrassment. This second type of embarrassment emerges after the incorporation of the SRGs of the family, which does not occur until the end of the third year**.** Although both types are measured in the same way, the elicitors of this type of embarrassment are quite different from those for exposure embarrassment.

Functional Significance of Early Embarrassment

To ask about the functional significance of a certain behavior runs the risk of storytelling since it is always difficult to test such ideas. Nevertheless, I believe that embarrassment emerges at the same time that children obtain consciousness. Why, then, should self-reflection have a negative component? The emergence of consciousness carries both advantages and disadvantages. This emerging capacity allows children to reflect on themselves; to use the self to make comparisons to others; and ultimately to develop evaluative behaviors, desires, and goals that will guide their actions. At the same time, this capacity to reflect on the self can be dangerous. The dangers reside in the child being entrapped in a circular-like reaction: it is possible to think about the self thinking about the self thinking about the self. Such circularity would lead children into a hopeless cycle of thought, preventing them from acting. To prevent such circular reactions, it would seem reasonable to imagine that self-reflection should be accompanied by arousal containing a slight negative tone. If self-reflection is a little uncomfortable, engaging in it becomes costly.

Thus, it is possible to be too self-reflective. Under such conditions people also have difficulty focusing on action. From a clinical perspective, we have reason to believe that much self-consciousness is related to a variety of problems. On this issue, Csikszentmihalyi and Csikszentmihalyi's (1988) analyses of flow may be relevant. For them, flow is a state of mind that is achieved when the adult's capacity matches some environmental challenge. Under such conditions, adults stop making reference to themselves—that is, self-reflection stops. For example, when one is deeply engaged in work, one often "loses track of the time." This phenomenological experience indicates that it is possible to lose self-reflection, at least some of the time (Csikszentmihalyi & Csikszentmihalyi, 1988). The dangers of self-reflection, as well as its advantages, suggest that embarrassment, as related to exposure to others, reflects an emotion likely to occur some of the time to inhibit self-referential behavior when it develops.

This present model proposes a sequence that starts with embarrassment related to exposure and then is captured, in yet unexplained ways, and utilized in the evaluative processes centering on SRGs. Rozin suggests that disgust also has this developmental pattern (Rozin, Haidt, & McCauley, 1993). By the second half of the second year of life, children show embarrassment to exposure; by the age of 3, children show embarrassment both to exposure and to violating a standard. Both types of embarrassment are available as a consequence of the developmental process.

The other two exposed types of self-conscious emotions that have been studied are jealousy and empathy, although empathy is considered by some as both an emotion such as sympathy and as social cognitive action.

Jealousy

Jealousy usually arises from the loss of something valuable to another, and is most often used when talking about children as being jealous about the attention or time their mothers spend with another, not with them. To be sure, jealousy and envy are often confused and used interchangeably; however, envy refers more to wanting something another possesses. In the case of children and their mothers, the child could be both jealous of the time the mother spends with a sibling and envious of the sibling for being the focus of their mother's attention. As can be seen from this example, these two ideas are not at all clear or distinct, which accounts for their mixed usage. Whether we use the term "jealousy" or "envy," implied in these emotions is a self-referent, the I of consciousness that wants something it does not have. Thus, for these emotions to emerge, consciousness is required. Other cognitive capacities may also be needed; however, jealousy over a mother's attention turned elsewhere, say to a sibling, does not require elaborate cognitions since the direction of another's attention is readily discriminable. A recently published handbook on jealousy contains several essays suggesting the existence of jealousy in the very young child, so that a careful analysis is necessary to determine if such a view is reasonable (Hart & Legerstee, 2010).

Hart's work is a good example of the studies exploring this emotion. In one of her studies, infants and their mothers play together and then on signal the mother turns away from her infant and for a few minutes, while ignoring her, attends to and talks to a doll. The 4-month-old infants show such behavior as interest, joy, anger, and sadness, as well as intense negative emotionality to their mother's attention to the doll. Infants showed increases in their emotionality and did so more when their mothers expressed more positive than neutral vocal behaviors toward the doll. Such findings were taken to indicate that infants this young show jealousy. However, whether these behaviors reflect jealousy or protest around the loss of the mother's attention is not clear, although I would think protest the more likely.

In studying infants, a child's protest over loss of the attention of others generally has been considered in two ways, either as the departure of the mother, as in the attachment paradigm in which the mother leaves the child alone in a strange room, or when the mother is present but is separated from her child either by a physical barrier or by her not directly attending toward the child as in the still-face paradigm (Ainsworth & Bell, 1970; Lewis & Ramsay, 2005; Weinberg & Tronick, 1996).

In the attachment paradigm, the loss of the mother most often results in protests of sadness and crying, as well as anger, as actions designed to get the mother back (Weinraub & Lewis, 1977). The same behaviors can be seen in situations where the mother is separated from the infant by a see-through barrier. While the 1- and 2-year-olds in the experiments can see their mothers, they cannot get close to them. The behaviors of crying, looking at the mother, and trying to get over the barrier are exhibited (Feiring & Lewis, 1979; Goldberg & Lewis, 1969; Wasserman & Lewis, 1985). The same can be said for the infant's behavior when the mother turns away from her interaction with the child (Lewis & Ramsay, 2004b Tronick, Als, Adamson, Wise, & Brazelton, 1978). Also, looking at the very young infant's response to the frustration of a blocked goal in its object world also shows these same behaviors. Thus, in situations involving the loss of the mother's attention, measured by her nonavailability as when behind a barrier, or by her complete disappearance as in the attachment paradigm, or by her lack of interaction as in the still-face procedure, there are similar infant responses, namely, protest. To call these behaviors "jealousy" seems premature, unless one wishes to attribute mental status to the infant's behavior. Although many would, there is no reason to do so unless one is caught in anthropomorphizing about how the adult would feel in the context of one's loss of one's mother (Bradley, 2010; Hobson, 2010; Keller & Lamm, 2010; Trevarthen & Aitken, 2001).

As suggested in Chapter 15, this volume, early action patterns, in this case the blockage of a valued object or person, can become the material for a self-conscious emotion once the emergence of the capacity for self-reference appears. Recent work indicating that young children tend to share their toys with others because of a biological disposition and do not show jealousy and possessiveness until the emergence of consciousness around age 2, lends some support for these ideas. It is also at this time that the idea of ownership emerges (Braten, 2009; Friedman, 2011).

Empathy

Whether empathy is considered an emotion like sympathy or a cognitive act, it seems to involve the ability to place oneself in the role of another. What is important about this ability is the idea that empathy allows for knowing about you, your feelings, what you may be thinking, and what the meaning of your behavior has to you. While we discussed this topic earlier, it is necessary now to think about its development since there is the strong belief that children show empathy long before the emergence of consciousness. Consider, for example, Hoffman's demonstration that in the newborn nursery the crying of one infant elicits the crying of others, or Zahn-Waxler's demonstration that toddlers react by comforting their mothers if they show distress (Roth-Hanania, Davidov, & Zahn-Waxler, 2011; Sagi & Hoffman, 1976).

Clearly, if empathy requires taking the perspective of the other, it is difficult to reconcile an infant crying to another infant's cry with this idea. For many of these early matching behaviors the idea of contagion should be considered. It would seem reasonable that all social creatures are by definition affected by the actions of conspecifics and maybe even by the actions of others who resemble them. Contagious behavior is most apparent in the emotional realm, although it can also be seen in other behavior. As we all have experienced, we are likely to feel sad if others around us are crying and to feel happy when others are laughing. The same is true for the emotions of fear, disgust, and anger. The contagious effects of the emotional behavior of others are well known; witness the contagion of yawning or even of the coordination of menstruation of women living together.

Although some claim a form of mentalism for these coordinated emotional action patterns between the baby and the adult, it seems more likely that this coordination reflects contagion as a basic biological necessity of all animals that live with conspecifics. It may even involve the use of motor neurons. It does not involve mentalism, although, as for other action patterns, it may become the material from which mentalism is formed. The simultaneity of action between two people through contagion may be the material out of which adult empathy grows. However, in the mature form of empathy one does not have to be in the presence of the other's distress to feel upset since it is a mental act that does not need the presence of the other's emotional action pattern to produce one's own action pattern.

This, of course, is the problem with much of the research on early empathy. For example, in many studies, the mother pretends that she has pricked her finger on a pin and makes a hurt, sad face and groans in front of the toddler. It is difficult to know whether the toddler's response is caused by contagion or is caused by modeling and learning to comfort another who is showing pain. Indeed, infants often try to comfort their mothers by patting them or hugging them, but at the same time they do not look distressed and may even show a happy-like face. It is necessary to separate out contagion or imitation from empathy around distress in order to see its relation to the emergence of consciousness. Bischof-Kohler (1991) demonstrated that empathy around the distress of another represents neither imitation nor contagion *if* the child's behavior is well organized so that both facial expression and behavior are in accord. She was able to show that this occurs only once the child showed self-recognition behaviors (Bischof-Kohler, 1991). In other words, mentalism is associated with true empathy, whereas its earlier forms are likely to be contagious action patterns. As de Waal has pointed out, elaborate, empathy-like responses certainly can be seen early in the child's life, but the adult human form of the behavior is unlikely to emerge until the development of consciousness (Preston & de Waal, 2002).

From a developmental point of view, we are confronted with the conundrum of the same behavior being supported by very different processes, and need to be careful to make sure that we do not commit the error of assuming that just because behaviors appear similar on the surface, they are supported by the same underlying process. Indeed, one of the difficulties in the study of development is that, on the one hand, the same process may result in very different behaviors during the developmental sequence, while, on the other hand, the same behavior at different points in time may be supported by very different processes. I think it is safe to conclude that any theory of the development of empathy needs to incorporate the emergence of a self-representation. The distress of the newborn to the cries of other newborns, and the generous charitable donations given by people to the victims of the 2012 Japanese earthquake and tsunami disaster or Hurricane Sandy, should not be considered as having similar underlying processes as the yawning of one person producing yawning in another.

Although other early self-conscious emotions need consideration, what appears to be the case is that all of them are dependent at a minimum on the emergence of consciousness. Few other cognitive capacities besides perception and memory are needed for their emergence, unlike the next set of self-conscious emotions, which rest on the development of complex self-attributions, including self-responsibility, which allows for evaluation of the self in regard to the socialization SRGs of family and culture.

The Self-Conscious Evaluative Emotions

Returning to the sentence "I am so proud of winning first prize in the spelling bee," anchors the discussion of the evaluative self-conscious emotions, since this statement requires consideration of the idea of self-evaluation. When the speaker says that she is proud of what she did, it is because some action on her part has met some standard that she holds. It also implies that she accepts responsibility for her actions. Finally, the experience is her own and while the sentence focuses on her verbal behavior, it is she, her whole self, that is at fault. These aspects of her evaluation lead her to feel proud.

Here, now perhaps for the first time in the child's development, the emotional action pattern called pride is elicited by a set of ideas about herself. The behaviors and feeling of pride that make up this action pattern are for the most part not learned, but are part of the biological capacity of our species. However, it is the kind of ideas about the self and how the action pattern is expressed that is acquired as part of the child's learning engagement with the social world. Children learn about the SRGs of their culture in both direct and indirect ways according to the social nexus in which they are raised. This nexus includes parents, grandparents, siblings, and peers, as well as teachers and others.

These self-conscious evaluative emotions are the basis of our moral behavior, and therefore have been called by some the "moral emotions." The eliciting events of these evaluative self-conscious emotions are ideas about self. While there are theories, such as those of psychoanalysis, that have argued for some universal elicitors of these self-conscious emotions, such as failure at toilet training or exposure of the backside, the idea of an automatic noncognitive elicitor of these evaluative emotions does not seem to make much sense. This does not imply that there are no specific elicitors, rather that the elicitors are the ways we think or what we think about, and there is likely some correspondence between thinking certain thoughts and the occurrence of a particular emotion; however, in the case of this class of emotions, the elicitor is always a way of thinking. This does not mean that the earlier emotions, those called primary or basic, are elicited by noncognitive events. Cognitive factors may play a role in the elicitation of any emotion; however, the nature of cognitive events are much less articulated and differentiated in the earlier ones (see Plutchik, 1980).

The idea that these emotions are elicited by ways of thinking was recognized by Darwin (1872/1965). However, because he focused on blushing and did not pursue the implications of his idea about thoughts of others and the sensitivity to the opinion of others, whether good or bad, he was not able to differentiate among the various kinds of evaluative self-conscious emotions. This failure restricted his analysis. An additional reason may be that because Darwin was arguing for a connection between the emotions of animals and humans, he might not have wanted to consider the leap that might exist between what animals and humans think. Therefore, he did not pursue the idea that humans have the capacity, which animals are unlikely to have, to think about themselves and to think about themselves in ways quite different from how the great apes think about themselves. In part, this might explain Darwin's focus on the issue of physical appearance without giving much thought to ideas about standard, rules, and goals (Herrmann, Hernandez-Lloreda, Call, Hare, & Tomasello, 2010; Premack, 2010).

Let us begin our discussion of the self-conscious evaluative emotions by showing the central role of consciousness in the evaluation process. To summarize what is to follow, let us look at the evaluation of the self, which requires consciousness of ourselves. The self-conscious evaluative emotions involve a set of SRGs. These SRGs are inventions of the culture that are transmitted to children and involve their learning of, and willingness to consider, these SRGs as their own. This process of incorporating SRGs appears to take place by age 3 years, at least in part, since SRGs are constantly being learned throughout life (Stipek, Recchia, & McClintic, 1992). Moreover, SRGs imply self-evaluation because children need the capacity to evaluate their actions with respect to them. Having self-evaluative capacity allows for two distinct outcomes: children can evaluate their behavior and hold themselves responsible for the action being evaluated or children can hold themselves not responsible. In attribution theory, these outcomes have been called an "internal" versus an "external" attribution. If children can conclude that they are not responsible, then evaluation of their behavior ceases. However, if children evaluate themselves as responsible, then children can evaluate their behavior as successful or not vis-à-vis their particular SRGs. The determination of success or failure resides within the individual and is based on the nature of the SRGs. For example, if a student believes that receiving only an A on an exam constitutes success, then receiving a B represents a failure for that student; on the other hand, another student may consider a B a great success. Still another type of cognition related to the self has to do with the evaluation of oneself in terms of specific or global attributions. "Global self-attributions" refer to the whole self, whereas "specific self-attributions" refer to specific features or actions of the self (Dweck & Leggett, 1988; Weiner, 1986). It is these types of self-attributions or ideas about the self that give rise to these self-conscious evaluative emotions. Success or failure vis-à-vis SRGs is likely to produce a self-reflection.

The importance of such a view suggests three factors. First, the model does not attempt to specify what constitutes a success or failure, or how the person goes about evaluating success or failure. Second, the model does not specify any particular SRG. In other words, it is not clear whether there are any specific stimuli that uniquely contribute to any of the self-conscious emotions. Third, the model assumes that self-attributions leading to specific emotions are internal events that reside in people themselves, although the SRGs are taught by others. Although this model is based on a phenomenonological and cognitive-attributional model, it does not mean that the self-conscious emotions are epiphenomenological or deserve a different status than the cognitive-attributional processes themselves. These self-conscious emotions are action patterns that are innate and are bodily in nature. They are not action patterns that existed earlier, since it is ideas that serve as elicitors of these specific action patterns in the same way as do other stimuli. The important point here is that specific action patterns and therefore emotions can be elicited through a variety of self-attributions. The idea that cognitions can lead to emotions has been poorly received by some, who believe that this idea implies that cognitions have real status, whereas emotions are epiphenomenological (Schachter & Singer, 1962). I mean to give emotions that same status as cognitions. Just as cognitions can lead to emotions, emotions can lead to cognitions. The theory implies no status difference.

There is very little agreement as to the specific elicitors of shame, guilt, or embarrassment. Many events are capable of eliciting any one of them. No particular stimulus event has been identified as the trigger for shame and guilt. It would be easier to understand these self-conscious emotions if we could specify the class of external events likely to elicit them. If it were true that shame and guilt are similar to anxiety and that they reflect the subject's fear of uncontrollable impulses, then we could consider the causes of shame to be sexual or aggressive impulses (Freud, 1905/1953, 1936/1963). Alternatively, if we could prove that situations having to do with toilet or genital functions are likely to elicit shame, or if we could prove that the way we appear physically, or how we behave in front of others may automatically elicit shame, we could then specify situations that would help us to define these self-conscious emotions and increase our understanding of what causes them. While there are no known literal events that are likely to cause these self-conscious evaluative emotions, certain ideas may have a more universal-like quality of eliciting certain emotions. So, for example, if an attachment figure says to a child, "I do not love you," this statement may well lead to certain negative ideas about the global self, and thus to the emotion of shame, since a global, stable, and negative self-attribution is likely to occur as a consequence of the statement. However, this example has strong cognitive features and is likely therefore to take place after the first year or two of life.

Before we go into the details about the development of these evaluative self-conscious emotions, the formal qualities of the ideas about the self are presented below. This structural model identifies the ideas about the self that serve as the elicitors of each of four self-conscious evaluative emotions. This model is symmetrical with regard to positive and negative self-evaluative emotions in that it accounts not only for shame and guilt in response to failure but also for pride and hubris, sometimes called "alpha" and "beta" pride, in response to success (Heckhausen, 1984; Stipek, 1983; Tangney, 1995; Tracy & Prehn, 2012). The model also proposes that the immediate elicitors of specific self-evaluative emotions are the qualities of self-related attributions. Given the three sets of judgments shown in Figure 45.1, the model accounts for and distinguishes among four self-conscious evaluative emotions. The immediate elicitors of these are the cognitive self-evaluative processes as described.

Cognitive Self-Evaluative Processes

Standards, Rules, and Goals

The first feature of the model has to do with the SRGs that govern our behavior. All of us have beliefs about what is acceptable for others and for ourselves in regard to SRGs having to do with actions, thoughts, and emotions. This set of beliefs,

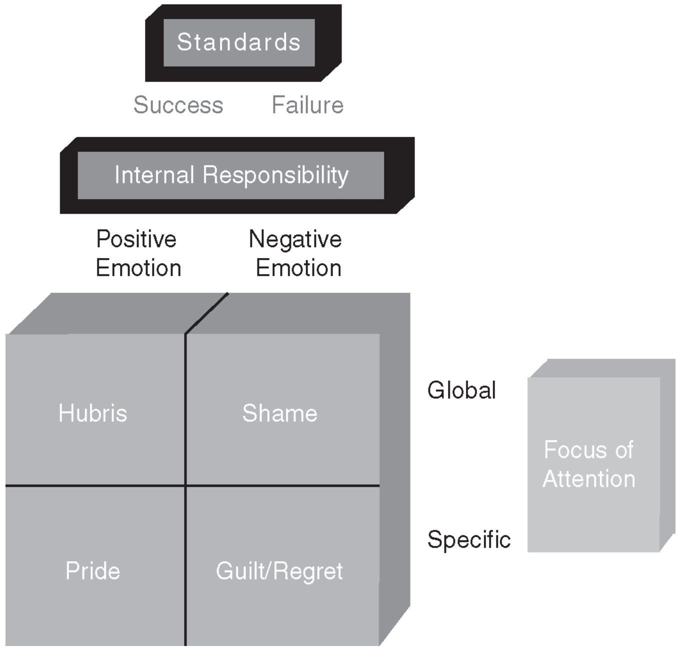

FIGURE 45.1. A model of self-evaluative processes and their relation to four self-evaluative emotions: hubris, shame, pride, and guilt/regret. From Lewis and Sullivan (2005, p. 189). Copyright 2005 by The Guilford Press. Reprinted by permission.

or SRGs, constitutes the information the person acquires through culturalization. SRGs differ across different societies, across groups within societies, across different time epochs, and among individuals of different ages. The standards of our culture are varied and complex, yet each of us knows at least some of them. Moreover, each of us has a unique set. To become a member of any group requires that one must learn that group's SRGs. SRGs are acquired through a variety of processes. They are always associated with human behavior. They are prescribed by the culture, including the culture at large, as well as by the influences of specific groups, such as clan, peers, and family.

While 1-year-olds are learning about some do's and don'ts, their behavior is controlled by the presence of the adult; the specific do's and don'ts are not incorporated into the child's mental life. Instead, they are likely controlled by direct rewards and punishments. By the second year of life, children show some understanding about appropriate and inappropriate behavior, but these nascent SRGs are not yet incorporated and so still require the presence of an adult. Research indicates that by the end of the second and the beginning of the third year of life children have already incorporated some SRGs and seem to show distress when they violate them (Stipek et al., 1992). Another source of support comes from the work on children's understanding of ownership. Kagan (1981) has shown that 2-year-olds can already identify their drawings from others, and Lewis and Ramsay (2004a) have found an association between personal pronouns such as "mine" and the movement of an object toward their own bodies. More recently, Nancekivell, Van de Vondervoort, and Friedman (2013) have reviewed the work on children's understanding of ownership and have also found evidence that it emerges early (see also Noles, Keil, Bloom, & Gelman, 2012). Such findings suggest that 3-year-olds have already begun to incorporate some SRGs, thus do not require the presence of others to make the judgment of success and failure. The acquisition of these SRGs continues across the lifespan.

Evaluation

The evaluation of one's actions, thoughts, and feelings in terms of SRGs is the second cognitive-evaluative process that serves as a stimulus. Two major aspects of this process are considered here; the first has to do with responsibility. For the model to work in describing the process of eliciting emotions, responsibility for the success or failure of an SRG is necessary. Individuals differ in their characteristic evaluative responses. Moreover, situations differ in the likelihood that they will cause a particular evaluative response. The second consideration has to do with how individuals make a determination about success or failure in regard to any specific standard.

Responsibility

Within the study of self-attribution, the problem of internal versus external responsibility has received considerable attention. People violate SRGs but often do not attribute the failure to themselves. They may explain their failure in terms of chance or the actions of others. Responsibility evaluations are functions both of situational factors and individual characteristics. There are people who are likely to blame themselves no matter what happens. Dweck, in studying causes of success and failure, found that many children blamed their success or failure on external forces, not themselves, although there were just as many who were likely to evaluate success and failure in terms of their own actions (see Dweck, 1991; Dweck & Leggett, 1988; Seligman et al., 1984; Weiner, 1986).

Success or Failure

Another feature of the self-evaluation process has to do with the socialization of what constitutes success or failure. Once one has assumed responsibility, exactly how one comes to evaluate an action, thought, or feeling as a success or a failure is not well understood. This aspect of self-evaluation is particularly important because the same SRGs can result in radically different feelings, depending upon whether success or failure is attributed. Many factors are involved in producing inaccurate or unique evaluations of success or failure. These include early failures in the self-system leading to narcissistic disorders, harsh socialization experiences, and high levels of reward for success or punishment for failure (see Alessandri & Lewis, 1996; Morrison, 1989). The evaluation of one's behavior in terms of success and failure is a very important aspect of the emotional response to SRGs, and consequently of the organization of plans and the determination of new goals and plans.

Specific and Global Attributes about the Self

Another attribution in regard to the self has to do with *global* or *specific* self-attribution. "Global" attribution refers to an individual's propensity to focus on the total self. Thus, for any particular behavior violation, some individuals, some of the time, are likely to focus on the totality of the self; they use such self-evaluative phrases as "Because I did this, I am bad or good." Janoff-Bulman's (1979) distinction between "characterological" and "behavioral" self-blame is particularly relevant here (see also Beck, 1979; Dweck, 1991; Lewis, 1971; Weiner, 1986). When a global evaluation is made, the focus is on the self both as an object and as a subject. The self becomes embroiled in the self. It becomes embroiled because the evaluation of the self by the self is total. There is no way out. The focus is not on the individual's behavior, but on the total self. There is little wonder that in using such global attribution one can think of nothing else except the self, and one becomes confused and speechless. Because of this focus on the total self, one is unable to act and is driven from the field of action into hiding or disappearing, or wanting to die.

"Specific" attribution refers to individuals' propensity in some situations, some of the time, to focus on specific actions of the self—that is, their self-evaluation is not global but specific. It is not the total self that has done something good or bad, or right or wrong, but instead some particular specific behavior. Notice that for such occurrences, an individual's focus is not on the totality of the self, but on the specific behavior of the self in a specific situation. The focus here is on the behavior of the self in interaction with objects or persons. Here attention is on the actions of the self or the effect on other selves and on reparation.

Global versus specific self-focus may be a personality style. Global attributions for negative events are generally uncorrelated with global attributions for positive events. It is only when positive or negative events are taken into account that relatively stable and consistent attributional patterns are observed. Some individuals are likely to be stable in their global and specific evaluations; under most conditions of success or failure, these subjects are likely to maintain a global or specific posture with respect to self-attribution. In the attribution literature, such dispositional factors have important consequences upon a variety of fixed personality patterns. So, for example, depressed individuals are likely to make stable global attributions, whereas nondepressed individuals are less likely to be stable in their global attributions. These dispositional factors are likely to arise through both temperament and as socialization factors.

The idea that beliefs and attributions about the self are related to emotions has been proposed by others, although in the past models have been developed primarily for adults and older children, typically with regard to achievement behavior and emotion (see Beck, 1979; Lewis, 1987; Nolen-Hoeksema, Girgus, & Seligman, 1992; Nolen-Hoeksema, Wolfson, Mumme, & Guskin, 1995; Seligman, 1975; Weiner & Graham, 1989). However, Dweck (2006), who worked with school-age children, has offered a similar model. She calls global and specific attributions "orientation toward performance" (global) or "orientation toward the task" (specific). Children who are performance oriented view failure as the result of an incompetent, stable self, while children with a task-orientation focus on "what I did" and tend not to experience their failures as negative, do not blame themselves, and are more confident that they can succeed in similar tasks in the future. They are more likely to believe that ability is "what you learn" with time and experience. Thus, these motivational dispositions appear to capture the responsibility dimension as well as the focus of attention described in my model (Dweck, 1991; Dweck, Chiu, & Hong, 1995; Smiley & Dweck, 1995). In my view, a performance orientation is consistent with, and perhaps an early form of, a stable and global attribution and can lead to shame and thus avoidance. Dweck's (2006) motivational constructs may measure one or more aspects of emerging attribution processes important to the expression of shame, guilt, pride, and hubris. These constructs are particularly relevant since young children who are performance oriented when they fail a task are likely not to want to try again, which would appear to be related to shame.

In addition to the dispositional factors relating to specific or global attributions, there are likely to be situational constraints as well. Some have called these "prototypical situations." That is, although there are dispositional factors, not all people all the time are involved in either global or specific attributions. Unfortunately, these situational factors have not been well studied. It seems reasonable to believe that certain classes of situations should be more likely than others to elicit a particular focus, but exactly what classes of stimuli are likely to elicit global or specific attributions remain unknown.

These attributions—(1) the establishment of one's SRGs; (2) the evaluation of success or failure of one's actions in regard to these SRGs; and (3) the attributions of the self, with responsibility as either internal or external, as well as either global or specific—give rise to the four evaluative self-conscious emotions presented in the model. It is the cognitive evaluative processes of children themselves that elicit these action patterns. Now let us turn to these four self-conscious emotions presented in Figure 45.1.

Shame

Shame is the consequence of a set of complex ideas about the self. First, it is accepting responsibility for a failure in terms of fulfilling SRGs, the consequence of the evaluation of one's actions, thoughts, or feelings. Second, the self-evaluation is global. The phenomenological experience of the person having shame is that of a wish to hide, disappear, or die. It is a highly negative and painful experience and is accompanied by a large increase in the stress hormone cortisol (Gruenewald, Kemeny, Aziz, & Fahey, 2004; Lewis & Ramsay, 2002). This painful experience also results in the disruption of ongoing behavior, confusion in thought, and an inability to speak. The other feature of the action pattern accompanying shame includes a shrinking of the body, as in a collapse of shoulders and head, which is a physical manifestation of the desire to disappear from the eye of the self or the other. Because of the intensity of the action pattern of shame on the whole self, this resulting state is difficult to dissipate. A variety of cognitive strategies—including reinterpretation, forgetting, and conversion—are used to cope with the feeling (H. B. Lewis, 1971; M. Lewis, 1992). Shame is often public, but it is just as likely to be private, unlike embarrassment.

In discussing the early form of embarrassment, the claim was made that two forms of embarrassment are possible: the first having to do with being the object of another's attention, and the second having to do with self-evaluation. Evaluative embarrassment is often classified as shame (Izard, 1979; Tomkins, 1963). The most notable difference between shame and embarrassment is the intensity level. While shame appears to be associated with an intense and disruptive action pattern, embarrassment is less intense and does not appear to invoke disruption of thought and speech as shame does. Moreover, the bodily action does not show a desire to hide, disappear, or die. Phenomenologically, embarrassment is less differentiated from shame than from guilt. The difference of intensity between shame and embarrassment may be due to the nature of the failed SRG. Some SRGs are closely associated with the core of the self, others less so. Failures associated with core self-evaluations are likely to be more intense than those associated with lesser core values. Moreover, while shame can be experienced in private as well as in public, embarrassment is strictly associated with public events.

Guilt

Guilt also occurs in response to accepting responsibility for a failure of an SRG. It is not as intense a negative emotion as shame, since guilt is the consequence of focus on the person's specific actions that result in the failure rather than on the totality of the self. The action pattern of guilt is directed outward toward reparation rather than inward toward withdrawal as seen in shame's collapse of the body and disruption of thought. In fact, the emotion of guilt always seems to have an associated corrective action, something the individual can do to repair the failure (Cole, Barrett, & Zahn-Waxler, 1992).

Guilt can be experienced with different degrees of severity, which are tied to the ease and availability of a corrective action. Should a corrective action not be possible, either in thought, words, or deeds, it is possible that a guilt experience can become one of shame. Here, then, appears another difference between shame and guilt. While it is possible to be ashamed of a guilty action, it is not readily possible to be guilty about being ashamed (Freud's [1936/1963] two types of guilt appear to conform to the differences between shame and guilt).

Pride

Pride is the consequence of a successful evaluation of a specific action. The phenomenological experience is joy over an action, thought, or feeling well done. The focus of pleasure is specific and related to a particular behavior. In pride, the self and the object are separated, as in guilt, and the person focuses attention on the behavior leading to success. Some investigators have likened this state to achievement motivation, an association that seems particularly apt (Heckhausen, 1984; Stipek et al., 1992). This form of pride should be related to achievement constructs, such as "efficacy" or "mastery" feelings and "personal satisfaction." Because positive self-evaluative emotion is associated with a particular action, individuals can identify the means by which they can re-create this rewarding state at a future date.

More recently, Tracy, Robins, and colleagues have studied the emotion pride, and have added to our understanding of the difference between what they call authentic pride and hubris, making the distinction between them (Tracy, Cheng, Robins, & Trzesniewski, 2009; Tracy & Robins, 2014). Tracy and colleagues have found that pride is easily identified within the U.S. culture, as well as cross-culturally, and that there are nonverbal as well as verbal cues (Tracy & Robins, 2008). We have found that pride and/or hubris can be measured by a facial expression of joy and with bodily movements of chest expansion, often with arms raised or out (Lewis, Alessandri, & Sullivan, 1992), a finding more recently found by Tracy and Matsumoto (2008).

Pride can easily be distinguished from joy, as the following example makes clear. When adolescents are asked if they would feel proud if they won a large amount of money from a lottery, their reply is no, since responsibility for winning was chance and not their action. While this distinction is valuable, there have, however, been a few cases where the answer was yes, and upon questioning, they made statements such as "If I used my birthdate (or driver's license number) I might be proud." In other words, it is possible for some to find a way in which their responsibility for the win can be made. It would be of interest to determine whether such responses reflect the other type of pride, which we call hubris.

Hubris

Since the English language does not have two different words for pride (i.e., pride that is associated with a task well done, or pride that is arrogant), the term "hubris" is used for the latter, as it represents the pride "that goeth before the fall." Tracy and Robins (2007) have also described these two types of pride and shown that children can discriminate between them.

When people perceive success and assume responsibility for it, a global or performance focus on the self leads to hubris, or arrogant pridefulness. Hubris is a highly positive and self-rewarding state—that is, people feel extremely good about themselves. When displaying this emotion, children and adults are often described as "puffed up," "full of themselves," or even conceited, insolent, or contemptuous. In extreme cases, hubris is associated with grandiosity or with narcissism (Morrison, 1989). Perhaps the most complete work is that of Tracy and colleagues. In one study, Tracy and Prehn (2012) found that contextual information rather than facial or bodily behavior was utilized to differentiate hubris from pride. In this case, the contextual cues included that the target person was arrogant, and in the other case, there was no evidence that the target worked hard for success. Although hubris is felt as a high reward for the person experiencing it, this emotion is unpleasant for others and therefore socially undesirable. People who are hubristic have difficulty in their interpersonal relations since their hubris is likely to interfere with the wishes, needs, and desires of others, leading to interpersonal conflict and possibly performance deficits. For example, Mueller and Dweck (1998) state that too much praise of children and their resulting overly high self-esteem can lead to their negative performance (see also Baumeister, Campbell, Kreuger, & Vohs, 2003; Kamins & Dweck, 1999). The presumed mechanism in this case might be that excessive pride leads to less effort. Three problems associated with hubris are that (1) it is a transient but addictive emotion; (2) it is unrelated to any specific action, and thus requires continually altering goals or reinterpreting what constitutes success; and (3) it interferes with interpersonal relationships because of its insolent and contemptuous nature (Ashton-James & Tracy, 2012).

Studying Differences in Shame, Embarrassment, and Pride

Individual differences in the self-conscious emotions appear by age 3 years. There seems to be at least two major sources of individual differences: the first is constitutional and has to do with temperament, while the second is in the socialization process.

There is evidence that differences in temperament are related to various self-conscious emotions in children. Recent analyses suggest that temperament involves individual differences in the tendency to express positive as well as negative emotion, as well as differences in reactivity level. These aspects of temperament are likely to be related to the self-conscious evaluative emotions. For example, higher anger and fearfulness are associated with later guilt (Kochanska, 1995; Kochanska, Coy, & Murray, 2001; Kochanska, DeVet, Goldman, Murray, & Putnam, 1994; Ramsay & Lewis, 2001; Rothbart, Ahadi, & Hershey, 1994). Reactivity to stress is an important aspect of temperament that is related to negative self-evaluation, such that higher cortisol responses to stress are associated with greater expression of evaluative embarrassment and shame. Collectively, these findings suggest that greater levels of evaluative embarrassment, and shame in particular, are related to temperament through individual differences in self-focus that may arise, in part, because of a lower threshold for pain and an inability to gate or block internal physiological signals. This results in more attention directed toward the self and thus more self-reference. I have proposed that greater stress reactivity leads to greater attention to the self. Following failure, greater self-attention increases the likelihood that children will attribute negative outcomes globally, rather than specifically, thereby increasing the tendency toward shame and/or evaluative embarrassment. Thus, aspects of temperament influence the tendency toward self-attention, which in turn is likely to promote self-conscious evaluative emotions (Csikszentmihalyi, 1991; Lewis & Ramsay, 1997, 2002).

Socialization can influence individual differences in the self-conscious emotions in many different ways, including influences in the acquisition of the SRGs, an internal focus of responsibility, and global versus specific focus of attention. The methods used to teach SRGs—that is, how children are rewarded and punished—influence children's style of self-evaluation, and therefore their self-conscious evaluative emotions.

As indicated earlier, the self-conscious emotions have been little studied and their development studied even less. Dweck (2006) has studied attributional style, mostly around achievement motivation. Nevertheless, her studies of attribution are one of the essential pieces of data we have. My colleague Sullivan and I have been studying the development of these emotions by using success and failure on tasks we have given toddlers and young children. While we also have been studying achievement, our focus has not been on achievement per se since we construct our own paradigm for studying these emotions by manipulating whether a child fails or passes some task. The child's response to succeeding or failing gives us the opportunity to study our model of the causes of shame, guilt, pride, and embarrassment (Lewis et al., 1992).

Given our work on the self-conscious emotions, the nature of the paradigm for studying them may be of some interest. Children 30 months and older are given at least four tasks, one at a time, to complete. These tasks are either matching colors with animals or solving puzzles and are easy, having few items, or more difficult, having many items. We tell the children that the task they are working on is either easy or difficult. In front of the children is a large clock and children are told that they have to finish each task before the time is up and a loud bell sounds. They are told that if they finish before the bell, they have succeeded, but if they have not finished, they have failed. They are given at least two easy tasks and two difficult tasks.

Because we can manipulate the clock, making it go slower or faster, we can arrange for each child to succeed or fail on each task we give them. By having them fail or succeed by manipulating the clock, we can control their achievement—so their task behavior has nothing to do with their real ability. On half the tasks they succeed and on half they fail. Half of the successes are on easy tasks and half are on difficult ones, while half of the failed tasks are easy and half difficult. We measure their action patterns, which include facial expressions and bodily actions. We also ask them a series of questions about their self-attributions after each task. In our studies, children from 30–72 months have been seen in this experimental situation. Children do not seem to notice the slowing down or speeding up of the clock, especially given that their attention is directed toward solving the tasks (Bennett, Sullivan, & Lewis, 2010; Lewis et al., 1992; Lewis & Sullivan, 2005).

It needs to be kept in mind that this manipulation does not always cause shame, embarrassment, or pride. We would estimate that about 55% of the children show these action patterns to our manipulation. Other methods have been tried: for example, giving the children a doll to play with and after a moment or two of play the arms, legs, and head of the doll fell off. While we could produce failure with this task, we needed another type of task to evaluate the emotional behavior of children when they succeeded. Given that no more children showed shame, guilt, or embarrassment when playing with the dolls than when using our tasks, and since we could produce both success and failure, we have stuck with these tasks.

That not all children show the self-conscious emotions on all the trials again points to the difficulties in studying these emotions. The children's self-conscious emotional responses may or may not be elicited by what we do. For example, if the children did not feel responsible for their success or failure, we do not see these emotions. While there are a few other studies on these emotions in children, my discussion is for the most part organized around our work. Because of the ages of the children studied, we are able to examine such issues as the elicitation of these self-conscious emotions, the attributions children give them, and the differences among children both as a function of their attributions as well as their histories of socialization.

We observe pride as well as happiness when children of any age succeed. The facial and bodily action patterns are quite clear, with some children jumping up and throwing their hands in the air. They are puffed up with their chests extended. They also show some embarrassment, but we are not sure as to why. When we observe Japanese children in the success task situations, we also see embarrassment, which is more than what we see for the American children. This behavior may be related to being the object of the attention of the experimenter. Thus, the best guess is that embarrassment during success means that even in situations of success, being the object of attention is likely to produce exposure embarrassment for some children. A good example is that of school-age children who do well in class, and when the teacher points this out to the other students they become embarrassed. Being the object of attention causes embarrassment, especially for some children (Lewis, Takai-Kawakami, Kawakami, & Sullivan, 2010).

In situations involving failure we see sadness but also shame and embarrassment, and very rarely guilty behavior. We only see guilt when children, on hearing the bell ring in the task described earlier, keep on working even though they know the time is up. Such children seem to show by their body actions that they need just a little more time to finish their task. This appears to be a form of reparation in response to the fact that they did not finish and therefore had failed the task (Alessandri & Lewis, 1993). Shame is indexed by the dropping of the head, hunched-up shoulders, and a sad or blank facial expression. These physical signs occur very quickly and then readily disappear. We also see embarrassment during failure, which is similar in behavior to the embarrassment we see during success. It differs from shame in the way described earlier: there is no bodily collapse but there is a grin.

While in these studies we cannot see the children's physiological behavior, when we do measure their stress hormones, we find differences between shame and some forms of embarrassment. There are significant increases in cortisol stress response when children fail and show shame and evaluative embarrassment. However, when they show embarrassment at being the object of another's attention they usually do not show cortisol increases. Certainly, they do not show stress hormone increases when they succeed. Such findings should alert us to the powerful effects that shame and evaluative embarrassment can produce (Lewis & Ramsay, 2002).

Individual Differences

We find little change when we observe children's behaviors in these situations over the course of their development from age 3 to 6 years—that is, shame and pride are already present by age 3 years and can be elicited by success and failure. However, we do find sex differences, with girls showing more shame and embarrassment across age when they fail than do boys, although there are no sex differences for pride. When we examine these sex differences in shame, we find that girls and boys do not differ in the amount of shame they show when they fail an easy task, but girls show more shame than boys when they fail a difficult task (Lewis et al., 1992). This result may be due to attribution differences, with girls accounting themselves more responsible for the failure, while boys attribute the failure to the difficulty of the task, a similar finding reported for adult women and men.

Sex differences have been widely reported in internal global attribution styles for negative events. In a study of parental response to children's performance on academic tasks, we found that both mothers and fathers make significantly more specific positive attributions to boys than to girls. Specific positive feedback such as "That's a good way of getting the piece of the puzzle into the box" was higher for 3-year-old boys than for 3-year-old girls. Conversely, specific negative feedback such as "You didn't look for the biggest piece first" was higher for girls. Fathers made more specific attributions than mothers. Mothers and fathers both made more specific attributions to boys than to girls. These findings support the notion that a major difference of attribution style observed between boys and girls is related to these different socialization patterns (Levine & Conway, 2010).

The tendency toward a particular attribution style for failure can also be learned or further consolidated at school. During the elementary school years, teachers are likely to exert considerable influence on children's attribution styles, particularly around achievement. How teachers describe and react to children's actions contributes to their emerging styles and likely influences many of the sex differences observed in achievement-related attributions in later childhood. At least in some studies, most of the criticism that teachers direct at elementary school boys refers to specific instances of misbehavior or lack of effort—that is, to task-specific factors, rather than to negative personality traits or lack of ability. Such feedback patterns promote specific and controllable attributions. In girls, the opposite pattern can be observed. Despite the fact that girls, on average, do better in elementary school than boys, girls are more likely to attribute failures to lack of ability, a global factor. Teachers' use of evaluative feedback can be a direct cause of either learned helplessness or mastery orientation in children. Once it appears, teachers' criticisms of girls, in contrast to their criticisms of boys, almost always indicated that the girls lacked general competence or did not understand the work, which are both global attributions. Thus, there is ample reason to expect sex differences in attribution styles based on the consistent pattern of sex differences observed during early socialization and the school years (Lewis, 1976; Witkin, 1965).

Although information on sex differences constitutes much of what we know about the socialization of attribution styles at home and in school, biological factors that covary with sex cannot be completely ruled out in accounting for some of these differences. For example, H. B. Lewis has linked a global attribution style to the perceptual and cognitive style of field dependency, which may be related to biological differences. "Field dependence" refers to the ability to separate a perceived object from the context in which it is embedded, with girls more field dependent than boys (Lewis, 1976; Witkin, 1965)

Learning SRGs

In order for success and failure to elicit self-conscious emotions, the child has to internalize SRGs. Several studies have found that around 3 years of age children seem to have acquired some SRGs that they appear to have incorporated into their knowledge system. Stipek as well as Heckhausen have shown that independent of an adult's praise or punishment, 3-year-old children seem to know about their performance and even make self-judgments about whether they have succeeded or failed at a task. Kagan has also shown that by this age, children can identify which pictures they drew at an earlier time (Heckhausen, 1984; Nolan, Adams, & Kagan, 1980; Stipek et al., 1992). While there is sufficient data to show that children by age 3 years have SRGs, exactly how these are acquired remains relatively unstudied. What is clear, however, is that what constitutes success or failure varies among children. While we talk about this topic in more detail later, our data also indicate that children this age are likely to show more shame when they fail an easy task than when they fail a difficult task. Moreover, they are likely to show more pride when they succeed in a difficult task rather than in an easy task. When I ask adults when they would feel more shame, it is clear that they would feel more shame if they failed an easy rather than a difficult task. Likewise, they would feel more pride if they solved a difficult rather than easy task. It seems clear from a variety of data that children by age 3 years have already incorporated some SRGs into their repertoire. Of course the growth of SRGs as a function of socialization and greater cognitive ability is likely to continue.

Evaluative Style

Individual differences in evaluative style have been observed in young children. Somewhere between 3 and 6 years, differences in perceptions of personal performance emerge and appear consistent over age. Once learned, these early motivational dispositions may become entrenched as a personality or attribution style, especially in response to negative events. Strong negative events occurring early in children's lives seem to push children toward a global attribution style in a kind of one-trial learning—that is, children exposed to such events will more consistently make global attributions under most conditions of failure. Their attributions made in response to success are less likely to be predictable. The intensity and power of negative events acting on a child with still limited coping skills may promote this development. Strong negative emotion swamps any cognitive processing that might override the child's egocentric perceptions about the event. Because children cannot separate themselves from the failure, they focus on the global self. The range of negative life events that lead to global attributions is in need of further investigation. These events may include negative experiences with parents, with others in the immediate social environment, or with general calamities that impact the self, family, or others. However, a reasonable working hypothesis is that the performance or self-attribution style of failure is created in the cauldron of stress. This topic has been discussed in more detail in Lewis (2014).

As we have shown, some attribution can be seen in 3- and 4-year-olds' display of shame and pride as a function of success and failure to easy and difficult tasks. That they behave as we adults do suggests that they evaluate difficult task failures as less their fault than easy task failures, thus exhibiting more shame to the failure of easy tasks. Likewise, success on a difficult task leads to more pride than success on an easy one. In the failure tasks, they attribute the failure of an easy task to themselves, thinking something like "After all, anyone should have passed it," but at the same time attribute their failure at a difficult task to the task parameters. Such data lead us to believe that they are even at this age already able to evaluate as internally or externally their action response to SRGs.

Other individual differences in attributions may affect the child's emotional behavior. While we have shown that particular evaluative patterns have an impact on children's emotional life, it has also been shown that children's beliefs influence their achievement behaviors and motivation even though they may not yet make adult-like attributions. How, then, can individual young children's evaluative attribution styles be assessed? Paper-and-pencil methods developed for older children and adults are not appropriate with young children. However, there are measurement procedures useful in obtaining individual differences in children's focus either as performance- or task oriented, how such differences are related to other kinds of evaluative judgments, and how they affect the display of some self-conscious evaluative emotions.

Dweck has obtained performance or task orientations by asking children to work on both solvable and unsolvable tasks, and afterward to assess their choice to avoid or return to the unsolved task (Elliot & Dweck, 2005). Children who choose to avoid the unsolved task and choose instead a task on which they know they have succeeded are considered to be performance oriented. Their choice of a sure success suggests a motive to avoid a display of incompetence. In order to explore this question further, we have used some of the techniques developed by Dweck (Dweck, 1991; Dweck, Chiu, & Hong, 1995; Smiley & Dweck, 1995) but added several others. After each task we ask the children as young as 3–4 years a series of questions including whether they would like to do the task again and how they feel about how they did, which they answer by matching their feelings to a series of picture faces going from very sad to very happy. We then score the spontaneous negative or positive statements they make after each task. We also have developed a measure of whether they are task- or performance oriented.

After each task, children are asked whether the task was easy or difficult. Our focus was on an easy task that they failed. Their response of "easy" or "hard" in the easy-failed task informs us about whether they are making a performance- or a task-based evaluation. If they state that it was "hard"—even though in reality it was easy—they are focusing on their performance, which was a failure. If they say "easy," they are focusing on the task despite their own performance. Thus, the easy-failed task presents the child with a discrepancy between what the child expects, that is, to do well when it is easy, and the outcome of their behavior, which is a failure. We have found children's responses reveal whether children focus their attention globally on their personal performance, or specifically on the nature of the task. Our hypothesis is that these judgments in response to the failure at an easy task should predict other self-related evaluations as well as the expression of the self-conscious evaluative emotions.

When we compare the questions we asked the children, we find an interesting coherence between them. The task versus performance measures of easy or difficult were related to whether they wanted to try to do another task. The children who were task oriented—that is, those who said the task was easy, were significantly more likely to want to try again than were the children who were performance oriented—that is, those who said the task was hard. These data support the idea that performance and task orientation can be measured in 3- to 4-year-olds (Matthews, Sullivan, & Lewis, 2013).

Certain self-attributions lead to more self-conscious emotions. According to our theory, children who are performance focused should display more shame following failure than children who are task focused, and they should also display more pride following success, although this prediction is more tentative because it is not possible to distinguish between hubris and pride at this age. The effect of performance focus on self-conscious evaluative emotions was observed in two studies. A greater percentage of children who are performance focused as opposed to children who are task focused showed shame and evaluative embarrassment following failure. While the children showed more shame and embarrassment if they were performance oriented, they did not show more sadness than the children who are task oriented. We also looked at anger in response to failure and here found that children who are performance oriented showed more anger than the children who are task oriented. Performance orientation is likely to lead to more shame, which in some cases leads to the outward deflection of shame into blaming others. Finally, performance orientation affects all the self-conscious emotions more than the early emotions of sadness and joy.

This set of studies reveals that children's task and performance focus following failure on an easy task is related to other evaluative judgments about their performance and to the overt display of their self-conscious evaluative emotions. The consistency of children's answers to questions about an easy-failed task can be examined to determine the degree to which they focus on the self when thinking about the failure. A performance focus, as opposed to a task focus following failure, is related to thinking poorly about oneself, to being unwilling to try again, and to being more likely to show shame and evaluative embarrassment following failure. This pattern of negative self-judgments might represent the early precursors of the internal, stable, global attribution styles observed in older children and adults. Such attribution styles for negative events promote shame and thus constitute a risk factor for subsequent maladjustment. While space does not allow us, the relationship between shame and psychopathology has been examined; a brief list of some of the more recent ones include Bennett, Sullivan, and Lewis (2005, 2010); Feiring, Taska, and Lewis (2002); Gold and Lewis (2010); Gold, Sullivan, and Lewis (2011); Stuewig et al. (2015); and Tracy et al. (2009).

More work on the normal and pathological development of the self-conscious emotions is needed. The structural model we have proposed provides the base for the self-conscious emotions. Without a more accurate or agreed-upon taxonomy, the harder it will be to study these emotions. Given the interest in emotional life, and in the relation between emotions and health, it seems increasingly necessary to study these emotions, rather than only the more "primary" or "basic" ones. Given the place of self-evaluation in adult life, it seems clear that the self-conscious evaluative emotions are likely to stand in the center of our emotional and social lives.

CHAPTER 46

Disgust

Paul Rozin, Jonathan Haidt, and Clark McCauley

If there were a stock market in emotion research, you would have been wise to put your money on disgust back in the 1970s. According to PsycInfo,[1] the number of articles with the word "disgust" in the title or key-phrase fields has increased 80fold since then. "Anger," in contrast, increased only eightfold, and "happiness" grew only 13fold.

The first full book devoted to disgust, William Miller's *The Anatomy of Disgust*, was not published until 1997, well over 100 years after Darwin's (1872/1998) first chapter on disgust. In contrast, in the first 13 years of the 21st century, eight books devoted to disgust were published (Menninghaus, 2003; Miller, 2004; Olatunji & McKay, 2009; Korsmeyer, 2011; Kelly, 2011; McGinn, 2011; Herz, 2012; Curtis, 2013). The most comprehensive overall scholarly source is the edited book *Disgust and Its Disorders* (Olatunji & McKay, 2009). Furthermore, books with broad intellectual agendas have devoted substantial attention to disgust in recent years (Pinker, 1997; Bloom, 2004; Nussbaum, 2004; Haidt, 2012), with one additional book clearly related to disgust (Haslam, 2012). In addition, more than a few significant general theoretical/review articles have been written (e.g., Tybur, Lieberman, Kurzban, & DeScioli, 2013; Strohminger, 2014).

What accounts for this explosion of interest in disgust? First, there is the evolutionary perspective, focusing on pathogen avoidance (e.g., Tybur, Lieberman, Kurzban, & DeScioli, 2013; Curtis, 2013). Second, there is the cognitive neuroscience perspective (Schienele, 2009). Third, there is the psychopathology perspective, with disgust taking its place beside fear in the understanding of anxiety disorders (Olatunji & McKay, 2009).

Most of the major current theories of disgust (Tybur et al., 2013; Kelly, 2011; Rozin, Haidt, & McCauley, 2008) agree on four points: (1) disgust originates in part or whole as a food rejection system; (2) pathogen avoidance has some fundamental role in explaining the origins and expansion of disgust; (3) a process like preadapation (recruitment of something already present for a new function) is involved in the expansion of disgust elicitors; and (4) the disgust emotion program (facial and bodily expression, psychophysiological events, behavioral withdrawal, and feeling of revulsion) is relatively conservative as disgust expands, while the class of elicitors and their meanings is more plastic. We organize much of this chapter around attempts to make sense of the full range of disgust elicitors.

Definitions, Origins, and Expansions

There are two classic papers describing disgust, published some 70 years apart. The first, by Darwin (1872/1998), defined disgust as referring to "something revolting, primarily in relation to the sense of taste, as actually perceived or vividly imagined; and secondarily to anything which causes a similar feeling, through the sense of smell, touch and even of eyesight" (p. 253). Darwin related disgust not only to the experience of revulsion but to a characteristic facial expression. The second paper, by psychoanalyst Andras Angyal (1941, p. 395), held that disgust is "Revulsion at the prospect of oral incorporation of an offensive object." He identified body waste products as a focus of disgust, and related the strength of disgust to the degree of intimacy of contact. Our own description of what we call "core disgust" follows Angyal's definition, adding the sentence "The offensive objects are contaminants; that is, if they even briefly contact an acceptable food, they tend to render that food unacceptable" (Rozin & Fallon, 1987, p. 23). Most definitions focus on the mouth and real or imagined ingestion. Tomkins (1963, 1982) held that, of all the emotions, disgust has the clearest linkage to a specific motivation (hunger), and functions to oppose this motive. Ekman and Friesen (1975) see disgust as an aversion that centers on oral rejection.

The food origin of disgust is probably linked to minimizing the risk of consuming pathogens contained in food (Curtis & Biran, 2001; Curtis, 2013). The English term "disgust" literally means "bad taste," and one of the facial expressions of disgust (the gape and tongue protrusion; Rozin, Lowery, & Ebert, 1994; Widen, Pochedly, Pieloch, & Russell, 2013) serves functionally in rejecting unwanted foods. The most distinct physiological concomitant of disgust—nausea—is a gastrointestinal, food-related sensation that inhibits ingestion. Finally, the brain region most often activated in studies of disgust is the anterior insula (Vytal & Hamann, 2010), which, among its other functions, is the gustatory cortex in primates (Rolls, 1994).

Most scholars recognize the innate aversion to bitter (and its face) as the origin of disgust, although the rejection of bitterness itself is not disgust. All agree as well that a process like preadaptation (sometimes referred to as co-opting or exaptation) is responsible for the first full form of disgust, core disgust (or pathogen avoidance disgust), and the expansion of disgust to a wide range of elicitors. Preadaptation is the co-opting of an existing system for a new function (Mayr, 1960). It is a major force in biological evolution, and even more important in cultural evolution where adaptation is easier and faster. Kelly (2011), in particular, notes that a first step in disgust is a linkage of the innate bitter rejection system to a pathogen avoidance system. He calls this the entanglement hypothesis. We do not yet know how or when disgust originated in human history, or how or when any of the later expansions actually occurred.

The Components of Disgust and the Disgust Program

Paul Ekman (1992) has provided the clearest articulation of the characteristics of an emotion, and disgust meets seven or eight of his nine criteria. Scholars disagree about whether disgust qualifies for Ekman's criterion of presence in nonhuman primates, or in relation to that, whether disgust is uniquely human.

Behavioral Component

Disgust is manifested as a distancing from some object, event, or situation, and can be characterized as a rejection or withdrawal.

Physiological Component

Disgust is associated with a *specific* physiological state—nausea—that is typically measured by self-report. Disgust is the only "basic" emotion that has such a specific visceral signature. Visceral/autonomic correlates of disgust are reviewed by Vrana (2009) and Kreibig (2010). Meissner, Muth, and Herbert (2011) report relationships between the electrophysiological measures of nausea (the electrogastrogram) and both disgust sensitivity and the degree of disgust reported in response to disgust-eliciting pictures. Nausea may be manifested more in response to food and other core disgust elicitors, and less in response to pain-related blood and injury elicitors (Shenhav & Mendes, 2014).

There is some dispute about whether disgust involves net parasympathetic activation (Kreibig, 2010; Vrana, 2009), but it is clearly not a strong sympathetic activator, like anger and fear.

Expressive Component

Although the ability to recognize the expression of disgust has been studied extensively, almost the entire literature uses still (as opposed to dynamic) stimuli, and is focused on the faces made by individuals from Western cultures. The Natyashastra (Masson & Patwardhan, 1970), an ancient Hindu treatise on drama, treats disgust as a basic emotion and designates multiple dynamic displays of disgust, including the hands, face, and body. Americans as well as Indians are able to identify these dynamic disgust expressions remarkably well (Hejmadi, Davidson, & Rozin, 2000).

The characteristics of the "disgust face" have received particular attention from Darwin

(1872/1998); Izard (1971); Ekman (1972; Ekman & Friesen, 1975); Rozin, Lowery, et al. (1994); and Widen and Russell (2013). Four main components seem to be the gape, tongue extension, retraction of the upper lip, and the nose wrinkle. Contraction of the muscles around the eye typically occurs as well, but is not diagnostic because it tends to occur with other negative emotions (Vrana, 2009).

Darwin (1872/1998) described the disgust face in some detail:

> Extreme disgust is expressed by movements round the mouth identical with those preparatory to the act of vomiting. The mouth is opened widely, with the upper lip strongly retracted, which wrinkles the sides of the nose, and the lower lip protruded and everted as much as possible. (1998, p. 256)

Ekman, however, disagreed to some extent with Darwin:

> There are two disgust expressions. Darwin described one, but not the best one—in terms of people of various cultures agreeing that disgust, not contempt, is being shown. In this disgust expression the nose is wrinkled, the nostrils raised, and the inner corners of the brow lowered. (note by Ekman in Darwin, 1998, pp. 256–257)

Ekman and Friesen's (1978) celebrated work on facial expressions of emotion included all four components we have mentioned, but the upper lip retraction and nose wrinkle are almost exclusively used in disgust research. However, the most distinctive features of infant facial expressions in response to bitter tastes, taken by most scholars to be the precursor of adult disgust, are a gape and a tongue protrusion, actions serving to rid the mouth of a distasteful substance.

The gape face is typically selected by Western adults as related to food- and body-related disgusts, while the upper lip raise disgust becomes more commonly selected in response to moral offenses that are called disgusting (Rozin, Lowery, et al., 1994; Rozin, Lowery, Imada, & Haidt, 1999). Recently, Widen et al. (2013) have identified a "sick" face, which also centers on the oral rejection muscles as the principal face associated with disgusting objects (as opposed to people), and have shown that the gape-centered face is more reliably assigned to core disgust elicitors.

The upper lip raise is used as the standard indicator of disgust, but it is also part of one of two anger expressions. Functionally, it represents a baring of the teeth in the upper jaw. When both disgust faces and both anger faces are used in facial recognition studies (Rozin, Lowery, et al., 1994, 1999), it is clear that there is overlap in elicitors between (especially moral) disgust and anger faces that include the upper lip raise. Since the differentiation of disgust and anger as moral emotions is a matter of current concern, future research may need to give more attention to the gape or sick versions of the disgust face.

Qualia

Qualia, the mental or feeling component of emotion, may be at once the most central component of disgust and the most difficult to study. The qualia of disgust is often described as revulsion. In comparison to other emotions, the experience of disgust appears to be rather short in duration (Scherer & Wallbott, 1994).

Core (or Pathogen Avoidance) Disgust

We conceive of core disgust (Rozin, Haidt, & McCauley, 1993) as one of four categories of food rejection, the others being distaste (motivated by bad sensory properties), danger (motivated by fear of bodily harm), and inappropriateness (culturally classified as not edible; Fallon & Rozin, 1983). Like inappropriateness, disgust is defined by ideational factors, rather than by perceptual qualities: beliefs about the nature or origin of a potential food. Unlike inappropriate entities, disgusting entities are presumed to be both distasteful and dangerous. On this view, the appraisal that elicits core disgust requires (1) a sense of potential oral incorporation (and hence a linkage with food or eating), (2) a sense of offensiveness, and (3) contamination potency (Angyal, 1941; Rozin & Fallon, 1987).

Oral Incorporation

Rozin and Fallon (1987) noted that the mouth is the principal route of entry of material things into the body, and hence can be thought of as the gateway to the body. Aversion to an offensive entity in the mouth is usually stronger than aversion to the same entity on the body surface near but not inside the mouth, or inside the stomach (Rozin, Nemeroff, Horowitz, Gordon, & Voet, 1995).

The threat of oral incorporation is framed by a widespread belief that one takes on the properties of the food one eats ("You are what you eat"). In *The Golden Bough*, Frazer (1890/1922) noted:

"The savage commonly believes that by eating the flesh of an animal or man, he acquires not only the physical but even the moral and intellectual qualities which are characteristic of that animal or man" (p. 573). This belief is consistent with our general experience that when two things combine (in this case, a food and a person), the product resembles both. Nemeroff and Rozin (1989) found evidence for an implicit belief that "You are what you eat" in American college students.

Offensive Entities: Animals and Their Products

Angyal (1941) held that the center of disgust is animal (including human) waste products, which he saw as debasing. Body products are a focus of disgust, and are central to the related anthropological concept of pollution (Douglas, 1966; Meigs, 1978, 1984). There is widespread historical and cultural evidence for aversion and disgust to virtually all body products, including feces, vomit, saliva, mucus, sweat, urine, and blood (especially menstrual blood), but typically not tears or milk. In accord with Angyal's (1941) suggestion of an animal focus for disgust, Rozin and Fallon (1987) proposed that the elicitor category for core disgust is *all animals* and their products as potential foods. Martins and Pliner (2006) report a dimension of livingness/animalness emerging from multidimensional scaling of ratings of the disgustingness of a wide range of novel foods.

Almost all cultures eat only a small subset of potential animal foods. For example, with well over 4,000 species of mammals, Americans only regularly consume three (pig, cow, and sheep), and then consume only the muscle. Angyal (1941) pointed out that in many cultures some care is taken to disguise the animal origin of animal food by cutting, chopping, and other culinary preparations, as well as by having names for animal foods (e.g., "pork," "beef," in English) that are distinct from the corresponding animal names.

Animals and their products seem, cross-culturally, to be both the most favored of foods and the most tabooed (Tambiah, 1969). Most food taboos involve animals (Fessler & Navarette, 2003), and are very often backed up by disgust (Meigs, 1984). Some animals are disgusting because they bear some resemblance to body products such as mucus (e.g., slugs), or because they are commonly in contact with rotting animal flesh, feces, or other human wastes (e.g., flies, cockroaches, rats, vultures). Carnivorous land animals eat raw, often decaying animal flesh, and produce putrid feces; they are disgusting at both ends. Herbivores are much less likely to be prohibited cross-culturally.

Two other categories of animal food prohibitions deserve mention. Animals that are close to humans, either in appearance (e.g., other primates) or by virtue of a relationship with humans as pets, are rarely eaten and elicit disgust as food. And finally, there is a group of anomalous animals that seem to produce a mixture of fear (danger) and disgust (e.g., spiders and snakes). Davey and his colleagues (Davey, 1993; Matchett & Davey, 1991) offer evidence that the aversion to these animals is based more on disgust than fear.

Contamination

The contamination response—rejection of a potential food if it even briefly contacted a disgusting entity—appears to be powerful and universal among adults. American college students reject liked beverages after they have briefly contacted a dead cockroach (Rozin, Millman, & Nemeroff, 1986). Virtually all Americans reject foods that have been handled or bitten by either unsavory or disliked persons (Rozin, Nemeroff, Wane, & Sherrod, 1989). Although this aversion is typically justified as an avoidance of disease, removal of this justification (e.g., by sterilizing the offending dead cockroach) typically has only a small effect. Contamination seems likely to have been shaped as an adaptation for disease avoidance, but it is often expressed even when an individual realizes that there is no disease threat.

Contamination effects may be instances of the sympathetic magical law of contagion (Tylor, 1871/1974; Frazer, 1890/1922; Mauss, 1902/1972), which essentially holds that "once in contact, always in contact" (Rozin & Fallon, 1987; Rozin & Nemeroff, 1990).

Core Disgust or Pathogen Avoidance Disgust

If core disgust is an oral defense, then the most obvious thing it is defending the mouth against is pathogens. Pathogen avoidance as an origin for disgust has been suggested a number of times (Renner, 1944; Plutchik, 1980; Haidt, Rozin, McCauley, & Imada, 1997).

In the last decade, several scholars have made a much stronger case for the evolutionary origins of disgust as a pathogen avoidance mechanism (Curtis, de Barra, & Aunger, 2011; Curtis, 2013; Tybur et al., 2013; Oaten, Stevenson, & Case, 2009; Kelly, 2011). Pathogens are a major problem for animals, and there are many adaptations in nonhuman animals to reduce the risk of pathogens (Hart, 2011). The pathogen threat to humans may be especially high because of the high density of human habitation consequent on domestication of plants and animals, and the intimate contact between humans and animal vectors of infection due to the domestication of animals (Wolfe, Dunavan, & Diamond, 2007). Infectious diseases were likely the major causes of death to humans in the ancestral environment, and remain a major cause of death today in tropical Africa. The pathogen avoidance theory of disgust (PAT; Curtis et al., 2011; Curtis, 2013; see Oaten et al., 2009; Tybur, et al., 2013, for similar conclusions) is forwarded by Valerie Curtis, who is an infectious disease epidemiologist and field worker.

Oaten et al. (2009) examined 14 predictions that would follow from linking core disgust and pathogen avoidance, and find evidence for all of them. For example, (1) objects that elicit disgust are likely to be infection risks; (2) the focus of core disgust is on food, almost always food of animal origin, which is more likely to harbor pathogens than are plant foods; and (3) contamination sensitivity is exactly what one would predict for a pathogen avoidance system. Human groups are vulnerable to epidemics, so pathogen threats have been linked to cultural institutions and negative attitudes toward strangers or outsiders (Fincher & Thornhill, 2012; Schaller & Murray, 2008). Indeed, pathogen avoidance may constitute a basic feature of human life (Curtis, 2013).

Nevertheless, we think that biologically evolved pathogen avoidance is unlikely to provide a complete account of core disgust elicitors. Examples of problems with this exclusive approach are (1) infants do not show avoidance of feces and decay odors, (2) contamination sensitivity does not appear until 4–5 years of age, (3) toilet training is an often difficult and extended task, and (4) it is often difficult to convince people to use sanitary practices. Curtis (2013) notes that perhaps one in five humans alive today regularly washes his or her hands after defecation. If disgust were an innate pathogen avoidance system, we would expect that desires for hygiene and washing would be innate, or at least that there would be an evolutionary predisposition to learn such behaviors easily. Furthermore, the identification of a current human practice as adaptive in preventing infection is only a first step in making a biological evolutionary argument. Cooking, water purification, and antibiotics are probably the most powerful antipathogen adaptations for modern humans, and we know that these evolved culturally.

Animal–Nature Reminder Disgust

When we asked American and Japanese respondents to list the things they thought were disgusting, less than 25% of examples came from the core disgust domains of food, animals, and body products (Haidt et al., 1997). Many of the other examples could be classified into four additional domains: inappropriate sexual acts, poor hygiene, death, and violations of the ideal body "envelope" or exterior form (e.g., gore, deformity, obesity). In these additional domains, the focus of threat has spread from the mouth to the body in general. We described this set of disgust elicitors as reminders of our animal nature (Rozin et al., 1993).

Contact with death and corpses is a particularly potent elicitor of disgust. Two of the items in our 32-item disgust scale that correlate most highly with the total score are about contact with dead bodies (Haidt, McCauley, & Rozin, 1994). The prototypical odor of disgust is the odor of decay, which is the odor of death. The centrality of death in disgust suggests that disgust may be linked to existential threats beyond the threat of pathogens.

Becker (1973) has argued that the most important threat to the psyche is the certainty of death. Humans are the only animals that know they will die. In this framework, Becker's "denial of death" is served in part by disgust, which helps to suppress thoughts or experiences that suggest human mortality. Research on "terror management theory" has shown a connection between disgust and the fear of death: death reminders prime disgust sensitivity (Goldenberg et al., 2001). Conversely, exposure to disgusting stimuli, under some conditions, increases implicit death-related ideation (Cox, Goldenberg, Pyszczynski, & Weise, 2007).

The centrality of death in disgust led us to posit that anything that reminds us that we are animals is a potential elicitor of disgust (Rozin & Fallon, 1987; Rozin et al., 1993). Humans must eat, excrete, clean the body surface, and have sex, just like other animals. Each culture prescribes the proper way to perform these actions—for example, by placing most animals off limits as potential foods, and all animals and most people off limits as potential sexual partners. People who ignore these prescriptions are reviled as disgusting and animal-like. Furthermore, humans are like animals in having fragile body envelopes that, when breached, reveal blood and soft viscera that display our commonalities with animals. Human bodies, like animal bodies, die. On this view, envelope violations and death are disgusting in part because they are uncomfortable reminders of our animal vulnerability.

Plato offers us a vivid illustration of this concern. In *The Republic* Socrates distinguishes between the kind of man who pursues higher (intellectual) pleasures and the common man, who indulges his lower, more carnal and animal-like nature: "They bend over their tables, like sheep with heads bent over their pasture and eyes on the ground, they stuff themselves and copulate. . . . " (Plato, 1987/4th-century B.C.E., Book IX, 586a).

Elias (1939/1978), in *The History of Manners*, concluded that "people, in the course of the civilizing process, seek to suppress in themselves every characteristic that they feel to be 'animal' " (p. 120; see also Miller, 1997). Tambiah (1969) emphasized the importance of this distinction for humans, and pointed to the paradox of human fascination with and aversion to animals. Ortner (1973) noted that the one body product that does not reliably elicit disgust is tears, and these are seen as uniquely human. And Leach (1964) pointed out that animal words are used as insults in many cultures.

We note, however, that gods in many polytheistic societies often take animal forms, or are represented as being part human, part animal, which is a complication for our story. Furthermore, incest is almost universally prohibited to humans but widely attributed to some gods (and sometimes permitted for royalty). Such patterns show that humans can hold negative (disgust) and positive attitudes to the same object. They also show how disgust can be elaborated culturally and woven into the moral order.

Tybur et al. (2013) and Curtis (2013) are clearly correct in pointing out that corpses, sexuality, hygiene, and violations of the body envelope are all potential avenues of infection. This connection argues in favor of a pathogen avoidance alternative to reminders of our animal nature. Yet the many connections between the "animal nature" elicitors and concerns about mortality are not easy to dismiss. Whether or not disgust *originated* as a pathogen avoidance system, disgust as we now experience it, far into the civilizing process, may reflect and give rise to many concerns beyond disease avoidance (see Goldenberg, Pyszczynski, Greenberg, & Solomon, 2000, for a review).

Interpersonal Disgust

In our original formulation, we proposed an additional expansion of disgust into what we described as the interpersonal domain; most other people, including strangers, or individuals with some types of negative properties (e.g., membership in despised groups), elicit disgust (Rozin, Markwith, & McCauley, 1994). However, with the elaboration of the disgust-as-pathogen avoidance model, much of what we called interpersonal disgust could be included as examples of responses to pathogen threats represented by other humans (Curtis, 2013; Tybur et al., 2013; Schaller & Park, 2011). Other people become disgusting not just to the extent that they show signs of infectiousness, but to the extent that anything about them makes us want to avoid associating with them, and this is the key to understanding the social functions of disgust.

Sexual Disgust

There is little doubt that some sexual acts can trigger disgust. This can be accounted for as either a pathogen risk or an animal–nature reminder. But recently Tybur et al. (2013) proposed that core disgust was preadapted to help human beings optimize their mating choices. They point out that core disgust is already involved in sexuality, in that disgust must be down-regulated during sexual acts to enable contact with bodily parts and fluids that pose a pathogen threat and that would—in the absence of sexual arousal—trigger a core-disgust response.

Tybur et al. (2013) propose that sexual disgust "is just the felt output of computational procedures estimating expected sexual value" (by which Tybur et al. mean reproductive value).

This account makes good sense of sexual disgust as experienced by a woman facing an unwanted sexual advance, because she is the person whose body will be entered and she will have to live with the consequences of a successful mating. Less clear is how a reproductive value for sexual disgust could encompass male disgust toward sex with an unattractive but fertile woman. For third-party judgments of sexual acts, the mate-value account is even less clear and symbolic concerns about animality and degradation seem to become more relevant. For example, Plato's (1987/4th-century B.C.E.) disgust at wanton sexuality seems to be more a revulsion about animality than an expression of concern about maximizing mate value. It may be that sexual disgust involves multiple concerns about pathogens, mates, animality, and morality.

Moral Disgust

Many cultures conceive of human beings as falling along an explicitly vertical dimension in which God, divinity, spirit, goodness, and purity are at the top; demons, animals, evil, and impurity are at the bottom; and humans rise and fall in a range in the middle. This idea is evident in the quotation from Plato (1987/4th-century B.C.E.) above, in the Christian conception of a *scala natura* or great chain of being, and in Hindu notions of reincarnation. We hypothesized that moral disgust was a reaction not just to any moral violation, but to actions that made a person seem to be moving downward on this vertical dimension—actions that made us see the person as degraded, base, or subhuman (Rozin, Lowery, Imada, & Haidt, 1999).

Morality is multifaceted. Richard Shweder and colleagues proposed a theory of three modes of moral discourse (Shweder, Much, Mahapatra, & Park, 1997). The "ethics of autonomy" is dominant when we think about people as autonomous preference structures: we want to maximize the individual's ability to act freely, without interference or harm from others. The "ethics of community" is dominant when we think about people as having roles to play within a social structure; we talk about duty, hierarchy, and interdependence. The "ethic of divinity" is dominant when we think about people as spiritual beings created by God, who contain a soul or some other element of divinity inside, which must be protected from acts or contact with things that are degrading. The ethic of divinity underlies the frequent moralization and regulation of eating, hygienic practices, and sexuality in many of the world's religious scriptures.

We saw a rough match between Shweder et al.'s (1997) three ethics and three moral emotions: community/contempt, autonomy/anger, and divinity/disgust. Taking advantage of the coincidence that the first letters of the ethics and emotions match up, we called this the CAD triad hypothesis, and found empirical evidence for these linkages (Rozin et al., 1999), as did Horberg, Oveis, Keltner, and Cohen (2009). However, our conception of moral disgust and its relationship to the ethic of divinity has been controversial.

The Critique: Moral Disgust as Just a Metaphor for Anger

Royzman and Kurzban (2011) point out that when we say that we are "hungry for knowledge" or have a "lust for adventure" we are not actually hungry or sexually aroused. We are simply using evocative metaphors. They argue that moral disgust is the same sort of thing. It is a way of using words (and sometimes facial expressions) to *communicate* one's condemnation of an act, but the disgust program is not really activated, and no disgust is actually felt (see also Royzman & Sabini, 2001). Bloom (2004) made a similar argument, and Nabi (2002) showed that for speakers of English, the word "disgust" overlaps greatly with anger with respect to immoral disgust elicitors, whereas core disgust elicitors align more with the English expression "grossed out."

The "metaphor" critique has been reinforced by empirical research showing that cases of apparent moral disgust are usually intertwined with anger and perceptions of harm (Gray, Schein, & Ward, 2014). This view is supported by Royzman, Atanasov, Landy, Parks, and Gepty (2014), who noted a flaw in the original CAD research. The vignettes used as exemplars of divinity violations involved body-related events. When they ran their own version of the CAD study using vignettes that involved mistreating sacred objects but with no bodily component (e.g., using a crucifix as a doorstop), they found that anger (the word and the facial expression, along with desires for retaliation) was the dominant response, not disgust.

We believe that Gray et al. (2014) are correct in arguing that harm (broadly conceived) encompasses most moral violations and that Royzman and his colleagues (Royzman et al., 2014) are correct in nominating anger as the primary moral emotion. Nevertheless, we think that there is considerable evidence that disgust plays a unique and important role in moral judgment. Chapman and Anderson (2013) offer a comprehensive review of the studies of moral disgust. We briefly summarize the literature using their three categories of evidence.

Many Moral Transgressions Elicit Disgust

People usually report that moral violations, including pure violations of the ethics of autonomy (e.g., stealing and lying) cause them to feel some degree of disgust, and this has been found for children as well as adults (Danovitch & Bloom, 2009). But such self-reports on their own are easily explained by the metaphor critique.

There is one set of results that is not easily explained by either the metaphor or animal nature critiques. Rottman, Keleman, and Young (2014) asked participants to read suicide obituaries that did not mention anything disgusting. People varied in their moralization of suicide. Disgust ratings predicted these judgments, whereas anger ratings did not. Ratings of the "impurity" of the act predicted condemnation, whereas ratings of the harmfulness did not.

Eliciting Disgust Makes Moral Judgments More Severe

If disgust is involved in moral judgments, then activating feelings of incidental disgust might amplify moral judgments. Wheatley and Haidt (2005) found such an effect using disgust induced by posthypnotic suggestion, and others have replicated the effect using a variety of other means, including bad smells, bad tastes, and disgusting film clips (Schnall, Haidt, Clore, & Jordan, 2008; Eskine, Kacinik, & Prinz, 2011; Moretti & di Pellegrino, 2010; but see Landy & Goodwin, 2015).

Disgust Sensitivity Predicts Moral Judgment

Social conservatives have repeatedly been found to score higher than liberals and libertarians on the disgust scale (Inbar, Pizarro, & Bloom, 2009; Iyer, Koleva, Graham, Ditto, & Haidt, 2012). Furthermore, even after partialing out political ideology, disgust sensitivity predicts increased moralization primarily on divinity topics such as abortion and homosexuality (Inbar et al., 2009).

Koleva, Graham, Iyer, Ditto, and Haidt (2012) found that the "sanctity" subscale (roughly equivalent to divinity) of the Moral Foundations Questionnaire (Graham et al., 2011) was a strong predictor of many "culture-war" attitudes, even after partialing out religiosity and conservatism, and even for some issues that involved no physical disgust (such as flag burning). The care/harm foundation was a poor predictor. The key to understanding the role of the sanctity foundation is Shweder et al.'s (1997) idea that some objects (such as flags) carry an invisible essence that must be protected from desecration.

Moral Disgust Reconsidered

Several lines of evidence therefore indicate that disgust sometimes serves—among its many other functions—as a moral emotion. There is no question that moral violations that involve some degree of core, animal–nature, or sexual elicitors produce disgust. A major review paper by Russell and Giner-Sorolla (2013) calls this emotion "bodily moral disgust." On the other hand, repeated demonstrations that cheating, lying, and unfair treatment produce disgust falsify our strong view of a tight and exclusive link between divinity violations and disgust. Furthermore, clear divinity violations (such as when American servicemen burned Korans) produce more anger than disgust (Royzman et al., 2014).

A possible resolution may be found in the social–functionalist account of moral emotions offered by Hutcherson and Gross (2011), who analyzed the appraisals and action tendencies associated with anger, contempt, and disgust. They found that anger and disgust were both frequent responses to moral violations, and that the key differentiator was not the Shweder et al. (1997) ethic of the violation, but the nature of the most adaptive response to the violation. Anger is an approach-oriented emotion, and when a moral violation involved some offense to the self for which attack might be an appropriate response, then anger was generally selected by participants as the most relevant emotion. However, when a moral violation was not committed against the self, but the violation indicated that a third party was not trustworthy (e.g., the person lied or cheated), then moral disgust became much more important. This is consistent with disgust's role as an emotion of withdrawal or avoidance.

In sum, there is continuing controversy, but emerging evidence indicates that moral disgust is not just a metaphor. Or, as Chapman and Anderson (2013) suggest, disgust may be a metaphor in a deeper and more substantive sense: "theories of embodied cognition propose that abstract concepts or knowledge are grounded in modality-specific perceptual and motor systems" (p. 310). Disgust is an ancient perceptual and motor system, rooted originally in distaste and localized partly in the anterior insula, which may serve as the embodied grounding of at least some of our higher-level cognition about morality.

The Development of Disgust and Contamination Sensitivity

For adults, feces seems to be a universal disgust substance (Angyal, 1941; Rozin & Fallon, 1987), with the odor of decay as perhaps the most potent sensory attribute associated with disgust. It is also possible that vomit is a primary substance for disgust. Since feces, vomit, and decay are associated with disease vectors, it would be reasonable to suppose that there would be an innate rejection of such things. However, none of these seems to be reliably rejected by nonhuman animals or young children (Rozin, Hammer, Oster, Horowitz, & Marmara, 1986). Rather, it appears that the infant may be attracted to feces, and that many cultures use disgust during the process of toilet training, which turns this attraction into disgust/aversion (Freud, 1910/1957; Jones, 1912/1948). The preponderance of evidence suggests that there are no negative nonirritant odors that are clearly aversive to infants, and that a rejection of decay odors (with or without a referent object present) appears somewhere between 3 and 7 years of age (Petó, 1936; Schmidt & Beauchamp, 1988; Stein, Ottenberg, & Roulet, 1958). Disgust seems to require enculturation—a supposition confirmed by Malson's (1964/1972) review of some 50 feral humans, none of whom showed any sign of disgust.

Toilet training may be the initial disgust-generating experience. Expansion of disgust elicitors may occur either by generalization from existing disgusting entities (Ferenczi, 1952) or by evaluative conditioning (Schienle, Stark, & Vaitl, 2001). There may be a predisposition or expectancy to associate certain entities, such as certain types of animals, with already disgusting entities (Davey, Cavanagh, & Lamb, 2003). Disgust may also be acquired by witnessing facial displays of emotions that elicit the experience of those emotions (Tomkins, 1963), perhaps engaging processes that involve mirror neurons (Gallese, Keysers, & Rizzolatti, 2004; Wicker et al., 2003). A recent study provides evidence for a link between parents' displays of disgust and their children's exhibitions of disgust responses (Stevenson, Oaten, Case, Repacholi, & Wagland, 2010).

Locating the onset of true disgust in development depends on subtle measures of "offensiveness" or "ideational rejection" and the appearance of contamination sensitivity. Contamination sensitivity is not present in children under 3–5 years of age (Fallon, Rozin, & Pliner, 1984; Siegal & Share, 1990; Hejmadi, Rozin, & Siegal, 2004).

Contamination sensitivity is a sophisticated ability requiring a separation of appearance and reality. There is no sensory residue of past contamination in a contaminated entity; it is the history of contact that is critical (Rozin & Nemeroff, 1990; Nemeroff & Rozin, 2000).

Adult contamination sensitivity is a mixture of at least two types of conceptions. One involves transfer of invisible material through contact, and hence is often sensitive to manipulations like washing (material essence). A second is more indelible, and involves the passing of what is felt to be some type of nonmaterial force that is not subject to removal by chemical and physical treatments ("spiritual essence"; Nemeroff & Rozin, 1994). There is evidence that at its first appearance in children, the essence producing contamination sensitivity is more like the indelible, "spiritual" than material form (Hejmadi et al., 2004), and appears somewhat earlier and in greater intensity in Hindu Indians as opposed to American children.

A particularly thorough study of the development of different types of disgust used parent interviews as well as direct testing of children's (ages 2–16 years) responses to a wide range of disgust elicitors (Stevenson et al., 2010). The findings indicate that in most cases, the order of appearance of disgust responses across years is core first, then animal reminder, then moral.

The picture of the development of disgust, particularly the recognition of disgust faces over the childhood years, has changed owing to a suite of studies by Widen and Russell, and others, summarized in a review by Widen and Russell (2013). They suggest that in development, the first stage is that disgust elicitors produce a general, nonspecific unhappy state, later elicited specifically by bad tastes or smells. Then a verbal label ("disgust," "yucky," "gross") is acquired, then rejection, and finally the disgust facial expression.

Widen and Russell (2013) note consistent confusion between assignment of the standard (upper lip raise and nose wrinkle) disgust face to "anger" versus "disgust," in adults as well as children. Widen and Russell suggest that part of the reason for the reported delayed onset of disgust face recognition may be that the primal and unambiguous disgust face involves the gape that is not part of the most frequently studied disgust faces. The developmental trajectory of disgust recognition may have to be reassessed using the "sick face" (Rozin, Lowery, et al., 1994; Widen et al., 2013). The only study that assesses "moral disgust" in children used the "standard" disgust face and verbal "disgust" responses (Danovitch & Bloom, 2009). A minority of 5- to 9-year-old American children endorsed disgust for moral autonomy violations. On both measures, disgust responses were much higher for core disgust scenarios.

In brief, it appears that social learning and increasing cognitive ability may both be needed for the appearance of full core disgust, including contamination, by approximately 5 years of age. In the absence of any socializing agents, it seems that core disgust might not emerge on its own. Disgust might therefore be like snake phobia (Mineka & Cook, 1988): easy to acquire because of an evolved predisposition.

Individual Differences

The paper-and-pencil Disgust Scale (DS) introduced by Haidt et al. (1994) had eight subscales: seven domains of disgust elicitors (food, animals, body products, sex, death, body envelope violations, and hygiene violations) and one domain of magical thinking (disgust by similarity and contagion that cut across the domains of elicitors). Half of the items asked how disgusting (not, slightly, very) a particular experience was; half presented a disgusting experience and asked (true/false) whether the respondent would be bothered by or try to avoid this experience. The 32-item DS had alpha reliability in the .80s in several samples, although the alphas for each of the eight short subscales (.40–.60) were adequate only for group comparisons. In a follow-up study Rozin et al. (1999) found a correlation of .57 between the DS and willingness to engage in disgusting tasks in a laboratory.

Structure of Disgust

More recent research on individual differences in disgust has moved toward reducing the number of domains and increasing the number of items in each domain, in search of more reliable domain scores. Following psychometric analyses of the DS by Olatunji, Williams, et al. (2007), a revised Disgust Scale (DS-R) dropped seven items (including all four sex items) and reduced the number of domains to three: core disgust (12 items from the old food, animals, and body product categories), animal-reminder disgust (eight items from the old death and envelope violation categories), and contamination disgust (five items from the hygiene and magical thinking categories). Using a Dutch version of the DS-R, van Overveld, de Jong, Peters, and Schouten (2011) confirmed the three-factor model, but other studies have reported numbers of factors ranging from one to six (Kang et al., 2012; Melli, Chiorri, & Smurra, 2013; Sand'in et al., 2013).

Moving in a different direction from the original DS, Tybur, Lieberman, and Griskevicius (2009) have introduced the Three-Domain Disgust Scale (TDDS) with separate scores for pathogen, sexual, and moral disgust. Seven items for each domain are assessed on a 7-point scale ("not at all disgusting" to "extremely disgusting"). The domain scores have alpha reliability in the .80s but intercorrelate only in the .30s (Tybur & de Vries, 2013). The pathogen subscale corresponds in content to the core disgust subscale of the DS-R, but the other subscales are quite different. The sex subscale of the TDDS combines moralization of sexual acts (e.g., using pornography, sex with strangers) with perceptions of sexual threat (a stranger rubs your thigh in an elevator), and both first- and third-party framings (your thigh vs. someone's thigh). The moral subscale focuses exclusively on violations of the ethics of autonomy (e.g., cheating, stealing) and hence may be more of a measure of anger as opposed to disgust sensitivity (Olatunji et al., 2012). The TDDS items are all in the disgust-rating format, leaving open the possibility mentioned earlier that, especially for moral items, some respondents use "disgust" metaphorically to mean only "bad."

Another innovation in assessing individual differences in disgust (van Overveld, de Jong, Peters, Cavanagh, & Davey, 2006) has been to distinguish propensity (frequency of experiencing disgust) from sensitivity (unpleasantness of the experience). Olatunji, Cisler, Deacon, Connolly, and Lohr (2007) report psychometric results for an eight-item propensity scale and an eight-item sensitivity scale: propensity and sensitivity factors were correlated (.66) and showed similar and small correlations (.07–.34) with anxiety-disorder symptoms, including fear of spiders, spider avoidance, injection phobia anxiety, injection fainting, injection avoidance, and contamination fear.

In short, different studies have used different rating scales (disgust vs. true/false, frequency vs. unpleasantness) and produced different numbers of factors or domains (ranging from one to eight). The source of this variability clearly includes differing theories and measurement instruments, and may also include cultural variation. Metaphoric use of disgust to signal simply "bad" argues against scales that rely only on ratings of disgustingness. Finally, we suspect that there is no single answer to the question of the structure of disgust. How to cluster items from the array of disgust-item intercorrelations, and the number of items per scale, will depend on the goals of the investigator.

Perhaps the strongest correlate of sensitivity to disgust is gender: females consistently score about a half standard deviation higher on disgust than males. We believe that this difference is real, although some portion of the measured effect may be due to a male reluctance to admit disgust. (Facing down disgust is sometimes used as a test of machismo, as in some college fraternity initiation rites.) Many other correlates of disgust sensitivity have been reported; too many for systematic review here. Positive correlates include political conservatism, blood phobia, neuroticism, low self-esteem, food disorders, posttraumatic stress disorder (PTSD), and behavioral inhibition. Notable negative correlates include openness to experience in the Big Five personality system and the thrill and adventure seeking and experience seeking subscales of Zuckerman's sensation seeking system (Olatunji, Haidt, McKay, & David, 2008; Terrizzi, Shook, & McDaniel, 2013). In general, this network of correlations is consistent with seeing disgust as a defensive emotion that is positively related to a more general sensitivity to negative feelings and events, and negatively related to attraction to what is new and risky.

Disgust and the Brain

Disgust has received considerable attention in the last decade from cognitive and affective neuroscientists. Studies using imaging techniques (principally functional magnetic resonance imaging [fMRI]) have suggested that three interconnected brain areas are characteristically activated when there is exposure to disgust faces, disgust eliciting images, disgust-related odors, or thoughts about disgusting entities (Phillips et al., 1997; Wicker et al., 2003; Wright, He, Shapira, Goodman, & Liu, 2004). The areas are the anterior insula, the basal ganglia, and parts of the prefrontal cortex (see Husted, Shapira, & Goodman, 2006, for a review). A linkage between disgust and the anterior insula and basal ganglia is also demonstrated in the case of a patient with damage to both areas who showed a selective impairment in both the recognition and experience of disgust (Calder, Keane, Manes, Antoun, & Young, 2000). Wicker et al. (2003) have reported activation in the anterior insula from both disgusting odors and images of disgust faces in the same participants, opening up the possibility that the anterior insula can perhaps be a "mirror area" for disgust, and that there might be individual neurons activated by both the experience and observation of disgust.

The relation between disgust and activity in specific brain areas has been reviewed by Schienle (2009); Kurth, Zilles, Fox, Laird, and Eickhoff (2010); and Vytal and Hamann (2010). The Vytal and Hamann meta-analysis of 83 studies implicates two brain areas—the anterior insula and the inferior frontal gyrus—as specifically involved with disgust, as opposed to emotions in general. The anterior insula link is particularly appropriate for core/pathogen disgust because the insula is the primary cortical projection area for both taste inputs and visceral inputs, notably nausea (Stern, Koch, & Andrews, 2011). The analysis of insula activity by Kurth et al. (2010) suggests differentiation within the insula with respect to activation involving, for example, sensory versus sociomoral inputs, and makes suggestions about the integration of these inputs. Also, Rolls (1994) noted excitation of the insula in nonhuman primates in response to unpleasant tastes and odors. This is consistent with the food basis of core disgust.

It is also clear that the pathology of Huntington's disease, which involves primarily basal ganglia degeneration, is associated with a fairly specific deficit in disgust recognition in the absence of any measured expressive or experiential deficit (Sprengelmeyer et al., 1996; Sprengelmeyer, Rausch, Eysel, & Przuntek, 1998). Disgust-recognition deficits are also seen in people who have the Huntington genotype but are still too young to show any of the classical symptoms (Gray, Young, Barker, Curtis, & Gibson, 1997). In addition, Kipps, Duggins, McCusker, and Calder (2007) have shown a link between Huntington's disease and the anterior insula.

Despite numerous positive findings, there is one line of research that questions whether insula and basal ganglia activation distinguishes disgust from fear (e.g., Stark et al., 2003; Schienle, Schafer, Stark, Walter, & Vaitl, 2005). Another issue is that most of the brain imaging work on disgust has used the standard disgust face (upper lip raise) that is often associated with anger rather than disgust (Rozin, Lowery, et al., 1994; Widen & Russell, 2013), and frequently uses harm-based autonomy violations, which we think are not prototypical elicitors of moral disgust. There are good prospects that further research on the neural basis of disgust will inform disgust theory in important ways. In particular, the relations among core disgust, moral disgust, and moral violations in general could be enlightened by increased understanding of the neural pathways and processing of the relevant elicitors. There are suggestions of both common and different areas activated by moral and core disgust elicitors (Moll et al., 2005). Using event-related potential (ERP) technology, there are differences between core disgust and moral violations that emerge at the earliest stages of processing, with evidence that distinct brain responses to moral violations may occur earlier than responses to core disgust (Yang, Li, Xiao, Zhang, & Tian, 2014). However, up to this time, the neural data has primarily served the important purpose of designating the appropriate neural structures and circuits.

Disgust and Psychopathology

Disgust has been linked with several kinds of psychopathology: obsessive–compulsive disorder (OCD), animal phobias, blood–injury–injection (BII) phobia, eating disorders, and sexual dysfunction. A key reference for these linkages is the book *Disgust and Its Disorders*, edited by Olatunji and McKay (2009; see also Rachman, 2006).

Obsessive–Compulsive Disorder

Disgust and individual differences in disgust have been associated with contamination fear, a common symptom of OCD that is particularly related to compulsive washing (Rachman, 2006). A question raised in this literature is whether the various aspects of OCD are differentially associated with various subtypes of disgust, as measured by the DS-R. Symptoms of OCD related to contamination and germs have been found to be more strongly correlated with the core and contamination subscales of the DS-R than with the animal-reminder subscale; the reverse is true for fears of death, injury, injections, and blood. These results support the utility of distinguishing animal-reminder concerns from pathogen-focused concerns (Olatunji et al., 2008; see also Olatunji, Williams, Lohr, & Sawchuk, 2005). A later study found that all three subscales were equally correlated with willingness to touch bathroom fixtures, although only contamination disgust emerged as a significant predictor in a regression analysis (Olatunji, Ebesutani, Haidt, & Sawchuk, 2014).

Animal Phobias

Davey and his colleagues have linked disgust with anxiety disorders. Individuals with animal phobias are about half of all individuals reporting any phobia (Davey & Marzillier, 2009). Animals that commonly trigger phobias include spiders, snakes, lizards, rats, mice, cockroaches, beetles, moths, maggots, slugs, snails, and worms. Individual differences in disgust measured by various scales (including the DS and DS-R) are correlated with fear of these animals but not with fear of predatory animals (e.g., lions). This literature has accorded special attention to spider phobia. Comparing individuals who are spider phobic with nonphobics shows the expected higher scores on disgust sensitivity for the phobics (Davey & Marzillier, 2009).

Blood–Injury–Injection Phobia

Persistent and excessive fear and avoidance of blood, injury, and injections (BII) is a problem for about 3% of the U.S. population (Page & Tan, 2009). As with animal phobias, both disgust and fear are high for individuals with BII phobia, but it appears that BII phobics show greater disgust reactions than fear reactions to BII stimuli (Page & Tan, 2009).

As with animal phobics, an open question is whether disgust is part of the origin of BII phobia or only a multiplier. Perhaps some individuals respond to BII stimuli with fear, others respond with disgust, and a third group responds with both fear and disgust (Woody & Teachman, 2000).

Eating Disorders and Sexual Dysfunction

Disgust seems to be involved in both of the major eating disorders (anorexia nervosa and bulimia nervosa), which are often accompanied by fat or fatness phobias (Troop & Baker, 2009). Similarly, disgust may be involved in understanding sexual dysfunction (DeJong & Peters, 2009). In both cases, there is a complex mixture of fear and disgust that has to be analyzed, and in both cases, there is an involvement of shame. Shame relates to eating in public or perceived fatness for eating disorders, and to poor performance or nonstandard preferences in the sexual domain.

Disgust in Intergroup Relations

Hodson et al. (2013) have introduced a new individual differences measure of intergroup disgust sensitivity (ITG-DS) that assesses disgust toward encounters with ethnic outgroups, including beliefs in stigma transfer and social superiority. This measure is related to previous measures of disgust sensitivity, authoritarianism, and sensitivity to negative affect, and it predicts negative attitudes toward outgroups, including Muslims in Western nations.

Schaller and Park (2011) review research indicating that disgust is more easily triggered when individuals are, or believe themselves to be, more vulnerable to pathogen infection. They find that disgust in reaction to people and events—even without pathogen risk—can contribute to negative attitudes toward outgroups and to cultural differences more broadly. Consistent with Schaller's suggestion, Terrizzi et al. (2013) review 24 studies to show that fear of contamination and disgust sensitivity are positively related to social conservatism (i.e., right-wing authoritarianism, social dominance orientation, religious fundamentalism, ethnocentrism, collectivism, and political conservatism).

Disgust may be a predictor of violent intergroup conflict. Taylor (2007) found that ideological hate speech expressed more disgust than fear. Matsumoto, Hwang, and Frank (2014) compared emotions expressed by leaders before attacking a rival group (e.g., JFK before the 1961 Bay of Pigs invasion) with emotions expressed by leaders before nonviolent resistance (e.g., Martin Luther King, Jr., before the 1963 March on Washington). Videos of leaders' speeches were coded for anger, contempt, and disgust, both when the leader was talking about the rival group and when the leader was talking about something else. Before an attack, leaders expressed more anger, contempt, and disgust when talking about the rival than when talking about something else; this difference was not found for leaders of nonviolent resistance.

Research in intergroup conflict has sometimes averaged ratings of disgust and contempt to produce an index labeled *contempt* (Cuddy, Fiske, & Glick, 2007) or *dehumanization* (Maoz & McCauley, 2008). A possible link between contempt and disgust is that both include the idea that the target group has a bad essence (Haslam, 2006). For instance, Petersen (2011) defines contempt as "cognition that a group or object is inherently inferior or defective; action tendency toward avoidance" (p. 43). Hutcherson and Gross (2011) found both overlap and distinctions among contempt, anger, and disgust (CAD) in reactions to individual bad behaviors, but additional research will be required to test these distinctions in reactions to events in intergroup conflict.

The perception of bad essence is often reflected in descriptions of an enemy as a disgusting animal, as Tutsi were described by Hutu, as cockroaches in the Rwanda genocide and as Jews were described by Nazis as lice, cockroaches, and vermin. It may be that disgust and contamination fear are highest in genocides where perpetrators and victims are most similar (Chirot & McCauley, 2006). As rational choice models of intergroup conflict are broadened to take account of emotions, disgust and contempt will join anger and fear in research aimed at understanding extreme forms of intergroup violence.

Cultural Differences in Disgust

Almost the entire literature on disgust comes from the approximately 6% of the world in which English is *the* native language. We believe that the cultural evolution of disgust has made few changes on the output side, but has created substantial cultural variation on the input side. For example, most cultures value some kind of decayed/fermented food that is disgusting in most other cultures, but that food varies quite a bit (e.g., cheese for Europeans, decayed meat for Inuit, fermented fish sauce for Southeast Asians). Similarly, cultures differ about whether dogs are best friends or dirty scavengers, or about whether or not corpses should be touched during mourning, or about whether mouth-to-mouth kissing is erotic or disgusting.

It is in the expansion of disgust into the social world that cultural differences seem to be greatest. Interpersonal disgust is particularly elaborated in Hindu India, compared with Western nations in which people rarely worry about the social status (caste) or background of the people cooking their food. Purity is a moral virtue to be protected in India, and in this respect, food is a "biomoral" substance (Appadurai, 1981). When reporting instances in which they had experienced disgust, Japanese often talked about situations in which there had been a failure to achieve a good fit in social relationships, such as when somebody else ignored them, or criticized them unfairly. Americans never mentioned such situations; instead they talked about racism, cruelty, and violence, especially toward people or animals who are weak or defenseless (Haidt et al., 1997). Cultures are social constructions, but as Lakoff and Johnson (1980) pointed out, embodied experience (including disgust) is one of the richest sources of building materials for those constructions.

Disgust in Humor, Sex, and Aesthetics

Given that our body is a repository of disgusting entities and that we live in a contaminated environment, humans are frequently poised on the edge of potential disgust. While we manage, by habituation or framing, to ignore most of the disgust elicitors around us, there are some situations in which we seek out and enjoy disgust. The powerful negativity of disgust seems perversely to encourage its involvement and enjoyment in at least three domains: humor, romantic attachment, and art (Strohminger, 2014).

Disgust plays a significant role in humor via jokes, cartoons, and casual word play. Boys and adolescent males use disgust to tease, question or confront adult norms, and to establish status within their peer groups (Fine, 1988). Bloom (2004) emphasizes the dignity-destroying aspect of disgust, and sees disgust humor as taking advantage of the fact that the human body is disgusting. The enjoyment of disgust has been documented among American adults, and has been described as an example of "benign masochism": enjoyment of a normally negative experience when it is not threatening and is at some distance from the self, perhaps as an exercise of mind over body (Rozin et al., 2013).

In intimate, often romantic, sexual encounters, body substances that are normally disgusting in others may become neutral or even attractive in a loved one. In many ways, enjoying the odors and/or body substances of a lover can be viewed as a statement of devotion, attraction, and the dissolution of the normal boundary between the self and another person.

Finally, some aspects of visual art, especially horror movies, depend on elaborate and disgusting images or sequences to appeal to mass audiences (McCauley, 1998). This appeal may again be an example of benign masochism.

Disgust as a Barrier to Progress

Recycled water is available with efficient technology that converts sewage water directly to tap water. Disgust has retarded the adoption of this "toilet to tap" technology despite water shortages in the U.S. Southwest (Rozin, Haddad, Nemeroff, & Slovic, 2015).

Food for a growing world population could come from increased consumption of insects; they provide excellent nutrition and make a minimal ecological footprint. Although about one billion humans eat them regularly, with no ill effects, they are rejected by almost everyone in the developed world. A major reason for this is disgust (Ruby, Rozin, & Chan, 2015). Similarly, much of the opposition to genetically modified foods is morally based, and is fueled by disgust at these products (Scott, Inbar, & Rozin, in press).

Disgust in Relation to Other Emotions

There is a special relation between disgust and contempt: the facial expressions are similar and there is a sense of looking down on, in both cases. The richest discussion of contempt is in Miller's (1997) *Anatomy of Disgust*. Both Miller (1997) and Hutcherson and Gross (2011) identify a strong theme of looking down on someone as incompetent, rather than immoral.

Disgust, particularly when it is framed as contamination, pathogen, or death risk, can be understood as a subcategory of fear. However, although both are withdrawal emotions, their expressions, physiological manifestations, and neural substrates are very different.

In the moral domain, there is substantial similarity in elicitors for disgust and anger. Both emotions share one aspect of facial expression (upper lip raise), but anger involves approach and disgust is accompanied by withdrawal. While moral disgust seems closely related to anger, core and animal-reminder disgust (or pathogen avoidance disgust) seem to be most related to fear (Lee & Ellsworth, 2013).

Both shame and disgust often involve moral censure, but in disgust it is oriented to others, and in shame it is oriented to the self. Lewis (1995) elaborates another important shame–disgust link: shame is often established by disgust responses of others to the self.

Conclusion

The rapid growth in the disgust literature has increased empirical knowledge and produced valuable theoretical advances. It has engaged social, cultural, evolutionary and clinical psychologists, epidemiologists, biologists, and philosophers. It has raised issues both specific (What is the best disgust face?) and general (How do emotions relate to the nature and structure of morality?).

The particularly wide range of disgust elicitors—as varied as dog feces, body sores, cremated ashes, unfamiliar humans, incest, axe murderers, and swindlers—has presented a theoretical challenge for which at least three solutions have been offered. One is that almost all references to and expressions of disgust for nonbodily elicitors are metaphoric. Another is that almost the entire range can be accounted for as responses to one or two evolutionary selection pressures. A third view—our view—is that some uses of disgust in the social and moral domain are metaphoric, and some really are built on core disgust (see figure in Rozin, Haidt, & Fincher, 2009). We do not know when and how social and moral elicitors of disgust came to be part of the human repertoire, but we believe that both biological and cultural evolution must be invoked to understand the current range of human disgust reactions.

Most generally, our view (to some degree also subscribed to by Tybur et al., 2013, and Kelly, 2011) is that a broadening array of disgust elicitors arose by a process of preadaptation, and amount to a "cultural wastebasket." The only theory that would explain what people in developed nations throw in the garbage is "things they want to get rid of." Rotted food, old newspapers, expired batteries, and printed advertisements have nothing in common except that they are not wanted. This view fits well with the social functionalist view of disgust proposed by Hutcherson and Gross (2011).

The breadth and complexity of disgust in human affairs mean that disgust research is likely to remain a growth stock for at least another decade.

Note

1. Analysis carried out by authors in July of 2014. We compared the number of hits in the PsycInfo database that had "disgust" or "anger" in the keyword or title fields, in 5-year blocks, specifically, 2009–2013 as a multiple of 1979–1983.

CHAPTER 47

Gratitude and Compassion

David DeSteno, Paul Condon, and Leah Dickens

Gratitude and compassion stand as some of the best exemplars of affective states tied to sociality. Unlike many other emotions, their evocation and intensity require interaction with another. The other need not be human, of course, as individuals can feel grateful to a divine entity or compassion for an animal in pain. Such others, however, must be perceived as sentient (or at least usually so). This close tie to social interaction marks these emotions as somewhat special in terms of their functionality, as at base they primarily function to build social capital and well-being over the long run (Bartlett & DeSteno, 2006; DeSteno, 2009; Valdesolo & DeSteno, 2011).

Although many dilemmas faced in social life might be framed as decisions between selfish and selfless behaviors (e.g., choosing to help another at some cost to oneself), most may also be understood as a tradeoff between immediate and long-term gain. For example, refusing to repay a debt to someone might leave one with more financial or hedonic rewards in the moment, but long term, it bodes ill for the development or continuation of a relationship that would likely offer greater rewards aggregated over time. Accordingly, many social dilemmas fit within an intertemporal choice framework (DeSteno, 2009). As its name implies, intertemporal choice refers to a situation where decisions hold different consequences as time unfolds. Combine this framework with the fact that the mind tends to overly discount the value of future rewards, and one readily recognizes the fact that humans possess something of a built-in bias for immediate gratification (Ainslie, 1975).

Within the realm of social interaction, gratitude and compassion appear to motivate decisions and behaviors meant to build resources, and thus well-being, for the long term—that is, they increase the probability that individuals will act in ways that tend to increase the strength and stability of interpersonal relationships and well-being over time, even though such acts require immediate costs to oneself in terms of effort, time, or money. Of import, the benefits of these emotions likely derive not only from their influence on an experiencer's choices, but also from the impact their expression has on others witnessing it—that is, the expression of these emotions may serve as markers to others of an individual's motive to behave in a manner meant to benefit relationship development (e.g., Williams & Bartlett, 2015). One, gratitude, functions to do so by nudging individuals to pay back benefits that have been given to them by others, while simultaneously suggesting to observers that grateful individuals are worthwhile relationship partners. The other, compassion, often motivates the initial impulse to offer assistance in the first place. Together, they get and keep the wheels of social exchange greased. In what follows, we examine each state individually.

Gratitude

Gratitude is a positive emotion one feels with the receipt of a gift from another person or entity (i.e., a higher power). The gift can be tangible in nature or intangible—like help in a time of need—

but must be perceived by the recipient as positive, intentional, and beneficial, for gratitude to result (McCullough, Kilpatrick, Emmons, & Larson, 2001). Phenomenologically, gratitude, unlike indebtedness, is experienced as a positive state, but one that is differentiable both cognitively and behaviorally from a more general feeling of positive affect (Bartlett & DeSteno, 2006; Emmons & McCullough, 2003; Watkins, 2007). As noted above, a primary purpose of gratitude is to build long-term well-being through directly or indirectly enhancing the value placed on decisions and behaviors that maximize virtue and its associated increases in social capital. Here, we first review gratitude's role in shaping relationships, and then examine its benefits for personal well-being.

Benefits for Relationships

Helping

Much of the recent literature has considered how gratitude acts to build and maintain relationships. It helps people accept short-term costs (e.g., spending time or money to help someone else) in exchange for long-term gains (e.g., building a strong relationship one can rely on in the future). In particular, gratitude seems to promote helping behavior, which likely bolsters feelings of trust within a relationship that subsequently strengthen cooperation. In support of this notion, Bartlett and DeSteno (2006) conducted a series of experiments that induced gratitude by confronting participants with a problem and then having them receive the assistance of another to fix it. They found that grateful individuals were not only more willing to agree to help their benefactor or a complete stranger subsequently, but also devoted more effort to doing so than did individuals who were experiencing a neutral affective state. Of import, this effect of gratitude on helping clearly diverged from that of a more general positive state. Individuals who were induced to experience happiness as opposed to gratitude did not engage in any increased helping behavior. Additionally, Bartlett and DeSteno (2006) ruled out the possibility that increased helping derived from simple awareness of norms for reciprocity or "paying it forward" by using a paradigm to correct for affective misattribution (cf. Schwarz & Clore, 1996). When individuals feeling grateful were reminded to whom those feelings applied, increased efforts to aid the stranger disappeared. Binding the feeling of gratitude to its source prevented its use as an informational cue to acquiesce to the requests of aid of another.

Attesting to the link of gratitude and prosocial helping, several other researchers have reported similar findings. For example, grateful individuals reported increased motives to give back to others (Algoe & Haidt, 2009), and expressions of gratitude by one person motivated receivers of that expression to work harder to assist him or her (Grant & Gino, 2010). Thus, it appears that gratitude can serve both to (1) motivate people to reciprocate helping, which, over time, could potentially inspire a cycle of mutual give-and-take that would strengthen the relationship; as well as (2) pay it forward, using gratitude toward one individual to inspire prosociality in the general social sphere. These provisions of assistance, although requiring an initial cost in terms of hedonic, temporal, or physical resources, function to foster social capital, which will be of future benefit.

Forming Relationships

For individuals to receive the benefits associated with social relationships, they must first meet the challenge of forming a bond with others. Here, gratitude has clearly been shown to play a supportive role. For example, work by Algoe, Haidt, and Gable (2008) examined the ways in which gratitude influenced the relationships between new members of a sorority and their assigned "big sisters." After new "little sisters" initially joined the sorority, big sisters would give them anonymous gifts for a week. The gratitude that little sisters felt during that first week predicted their feelings of relationship quality not only at that time but also 1 month later. In addition, little sisters' gratitude also predicted how their big sisters viewed the relationship. Stronger expressions of gratitude by gift recipients (i.e., little sisters) corresponded to more positive views of the relationships by their benefactors (i.e., big sisters). Thus, for both the benefactor and recipient, gratitude seemed to play a role in building a strong relationship—likely through inspiring a reciprocal relationship that would continue to grow.

In a similar vein, feelings of gratitude toward another stand as a primary predictor of intentions and desires to spend more time with a previously unknown benefactor in the future—a sign of a desire to attempt to construct a relationship from a single instance of gratitude toward a stranger (Bartlett, Condon, Cruz, Baumann, & DeSteno, 2012).

Maintaining and Strengthening Relationships

Once relationships have been formed, gratitude has also been shown to aid their maintenance. Participants instructed to think about a time when they were grateful to someone reported a motivation to repay this other, indicating a desire to maintain and continue the relationship (Algoe & Haidt, 2009). Other empirical findings demonstrated that expressing gratitude in relationships was associated with increasing relationship strength (Lambert, Clark, Durtschi, Fincham, & Graham, 2010). After controlling for variables including relationship length and relationship satisfaction, higher levels of gratitude expression significantly predicted higher levels of perceived relationship durability with regard to friendships and romantic relationships both immediately and after a 6-week lag. In addition, Lambert et al. (2010) confirmed that when controlling for relationship strength at outset, the act of expressing gratitude to a friend twice a week for 3 weeks significantly elevated the expressers' assessments of relationship quality at the end of this period.

In a reciprocal manner, receiving and experiencing gratitude within romantic relationships conveys important benefits as well (Gordon, Impett, Kogan, Oveis, & Keltner, 2012). Here, individuals who reported feeling more appreciated by their partners also reported feeling more appreciation for their partners. This effect occurred both at an overarching level, as well as in more micro, time-lagged situations. For example, feelings of appreciation and gratefulness on a given day were significantly associated with corresponding feelings on the next day. Moreover, attesting to the power of appearing grateful, gratitude expressed by one's partner predicted feelings of relationship commitment the next day. Finally, with regard to its impact on relationship stability, individuals who felt more grateful toward their partners at the start of the study were more likely to still be in the relationship 9 months later, as compared to those with lower levels of gratefulness at baseline.

Other studies have also found relationships between gratitude and positive relationship outcomes. For example, gratitude levels on one day were found to predict increases in reported relationship connection and satisfaction on the next day (Algoe, Gable, & Maisel, 2010). Expressions of gratitude led people to feel more comfortable talking about concerns they may have for the relationship—an important way to make sure concerns do not go unaddressed and result in the deterioration of the relationship—and also led them to perceive their partner in a more positive light (Lambert & Fincham, 2011). For partners in long-term marriages, an individual's felt gratitude and expressed gratitude positively covaried with his or her feelings of marital satisfaction (Gordon, Arnett, & Smith, 2011). Furthermore, felt gratitude (but not expressed gratitude) also predicted the spouse's reports of marital satisfaction (Gordon, Arnett, & Smith, 2011). Finally, higher levels of gratitude for one's partner assessed over a 1-week period predicted increases in relationship commitment 9 months later (Joel, Gordon, Impett, MacDonald, & Keltner, 2013).

Perceived responsiveness—acting in ways that show understanding, acceptance, and consideration of the other person's needs and thus evoke feelings of gratitude—also plays a central role in positive relationship outcomes. For example, Gordon and colleagues (2012) found that increased feelings of appreciation for one's partner on a given day strongly predicted increases in responsiveness to the partner on the next day. Employing a slightly different paradigm with a different sample, Gordon et al. (2012) also had third-party observers rate participants' responsiveness to their partners by watching a videotape of the couple interacting; here again, more appreciative participants were seen as being more responsive and committed to their partners and the relationship than those who were less appreciative. In a similar vein, Algoe and colleagues found that the intensity of expressions of gratitude witnessed during a moment of exchange predicted improvements in the quality of a relationship 6 months later (Algoe, Fredrickson, & Gable, 2013). Kubacka, Finkenauer, Rusbult, and Keijsers (2011) likewise found responsiveness to be an important component of the gratitude experience such that it suggests a cyclical relationship for couples: Person A feels grateful for something and then acts to maintain the relationship (i.e., working in some way to promote relationship cohesion), which is then noticed by Person B, who feels Person A is acting in a responsive manner, which then causes Person B to feel grateful to Person A, followed by Person B then continuing the cycle. Thus it appears that gratitude and perceived responsiveness are linked, with gratitude functioning to motivate behavioral responses that build and maintain relationships.

Promoting Social Inclusion

Gratitude works at times to inspire not only relationship formation and maintenance but also general social network development, spreading the effects of relationship building to larger social contexts by influencing social inclusion and cooperation. In the sorority study mentioned previously (Algoe et al., 2008), gratitude felt toward a particular sorority sister during 1 week predicted how integrated individuals felt within the sorority house as a whole at a later point, thus demonstrating that particular instances of gratitude can have far-reaching effects. Additionally, work by Bartlett and colleagues (2012) revealed that grateful individuals strove to include their previous benefactors in social situations in which they were being excluded. Perhaps more interesting was the fact that grateful individuals were willing to accept a financial cost to bring about this inclusion, thereby lending support to the idea that gratitude serves to promote social inclusion even at the cost of individual reward. Similarly, in a separate study, gratitude enhanced preferences for financial decisions that benefited communal interests as opposed to immediate profit accumulation (DeSteno, Bartlett, Baumann, Williams, & Dickens, 2010). That is, feelings of gratitude mediated decisions that favored the equal sharing of profits through cooperation than the asymmetric accumulation of profits for one individual at the cost of another.

Using more macro levels of social networks, Froh and colleagues found that gratitude directly and indirectly predicted social integration, which then, itself, functioned to increase subsequent experiences of gratitude (Froh, Bono, & Emmons, 2010). A similar finding within the context of a medical support group showed that women diagnosed with breast cancer who both expressed their emotions and also were likely to respond to situations in a grateful manner reported an increase in perceived social support, as compared to women who did not express their emotions or respond to help in a grateful manner (Algoe & Stanton, 2012).

Benefits for General Well-Being

Gratitude has been examined both as a trait (i.e., a grateful disposition) and a state. Although not substantively different from the state classification, the notion of a trait classification can be best understood in this case as reflecting a tendency to experience gratitude more frequently due to an increased readiness to bring reciprocity-relevant cognitions to bear on events of daily life (cf. Barrett, 2012). Attesting to the benefits of gratitude, much research has documented positive correlations between a grateful disposition and aspects of general well-being (e.g., Emmons & Kneezel, 2005; McCullough, Emmons, & Tsang, 2002; McCullough, Tsang, & Emmons, 2004; see Wood, Froh, & Geraghty, 2010, for a comprehensive review). More specifically, a tendency to experience gratitude has been found to positively covary with life satisfaction (Wood, Joseph, & Maltby, 2008), psychological well-being (Wood, Joseph, & Maltby, 2009), and a sense of "coherence" (a feeling that "life is manageable, meaningful and comprehensible"; Lambert, Graham, Fincham, & Stillman, 2009, p. 462). Moreover, in studies investigating gratitude's relation to health outcomes, evidence has linked more experiences of gratitude to fewer depressive symptoms (Krause, 2007; Lambert, Fincham, & Stillman, 2012), lower aggression (DeWall, Lambert, Pond, Kashdan, & Fincham, 2012), better physical health (Hill, Allemand, & Roberts, 2013), and even better sleep (Wood, Joseph, Lloyd, & Atkins, 2009).

Although a majority of these health-relevant findings are of a correlational nature, experimental evidence demonstrates that gratitude can be cultivated and produce benefits over time. These experiments usually involve "gratitude interventions" in which participants are randomly assigned to complete gratitude exercises (e.g., completing a diary entry to reflect on an event that made them feel grateful) as a way to foster this state in their daily lives. The results of such interventions have been examined in several populations, including schoolchildren (Froh, Kashdan, Ozimkowski, & Miller, 2009; Froh, Sefick, & Emmons, 2008), people experiencing depression (Mongrain & Anselmo-Matthews, 2012; Sergeant & Mongrain, 2011), and those with physical illness (e.g., neuromuscular disease; Emmons & McCullough, 2003). In all cases, individuals completing gratitude exercises generally demonstrate increased well-being, happiness, and life satisfaction as soon as 1 or 2 weeks following the start of the intervention. Of import, these beneficial changes reflected increases not only from preintervention levels of well-being, but also from extant levels of well-being among control group members (i.e., members of the same sample who were not assigned to complete gratitude exercises; e.g., Emmons & McCullough, 2003; Froh et al., 2008). Accordingly, it seems that experiencing gratitude frequently aids individuals in achieving self-improvement goals.

A relatively unique line of research concerns gratitude's effects on materialism and financial decision making. It appears that gratitude is related to decreased materialism (Polak & McCullough, 2006). Lambert, Fincham, Stillman, and Dean (2009) found that this relationship was mediated by life satisfaction. Feelings of gratitude led people to report higher satisfaction with life, which then led to reduced materialism (as compared with a condition that induced feelings of envy). In terms of financial decision making, inducing gratitude in individuals made them opt for delayed, larger rewards rather than immediate, smaller rewards, helping them overcome the human propensity to engage in temporal discounting (DeSteno, Li, Dickens, & Lerner, 2014). Here again we can see that a primary mechanism underlying gratitude's effects involves nudging people to forgo actions that—although bringing short-term gain—tend to inhibit the accumulation of long-term benefit.

Compassion

Scholars have long proposed that compassion, like gratitude, is a sentiment that stands at the foundation of morality and virtue (Darwin 1871/2004; Goetz, Keltner, & Simon-Thomas, 2010; Nussbaum, 1996; Smith, 1759/2009). Emerging scientific evidence has begun to echo this claim by demonstrating the role of compassion in promoting prosocial behavior, cooperative relationships, and physical and psychological well-being. Although compassion, like gratitude, is sometimes conceived of as a dispositional trait, recent findings stemming from both examinations of meditation practice and subtle environmental nudging provide evidence that compassion is itself quite variable within individuals and thus amenable to being manipulated or trained as a skill.

Historically, the term "compassion" has been used interchangeably with terms such as "empathy," "empathic concern," "sympathy," and "pity" (e.g., Batson, 1991, 2009; Wispé, 1986). Yet many authors now differentiate *compassion* from *empathy*. Empathy typically refers to processes that allow an individual to understand another person's mental state, either through perspective taking (sometimes called "cognitive empathy," "theory of mind," "mental state attribution," or "mentalizing") or through emotional contagion (sometimes called "affective empathy" or "experience sharing"; Zaki & Ochsner, 2012). Compassion can be differentiated from empathy based on the motivations that underlie one's resonance with another's mental state. We adopt the definition offered by Goetz and colleagues (2010), who define compassion as an other-oriented emotional state that arises in response to another's suffering and motivates one to act in a prosocial manner to alleviate another's suffering. In short, whereas compassion includes a motivational component to relieve another's suffering, empathy typically refers to processes that merely provide access to the content or experience of another's state.

Unlike the case with gratitude, a large, historical body of research has demonstrated that compassion promotes helping behavior aimed to alleviate another's suffering. This work, usually employing the term *empathic concern* as opposed to compassion, comprised much of the social psychological literature on helping behavior in the late 20th century and has received considerable attention in other reviews (Batson, 1991, 2011; Eisenberg & Miller, 1987). We do not review that work here, but note that compassion functions as an affective state that increases the probability of costly helping independent of other factors that increase helping, such as social recognition (Batson, 1991, 2011; Goetz et al., 2010). Instead, we focus on recent findings that provide additional insight into the role that compassion plays in promoting short-term costs in favor of long-term gain with respect to social systems, relationships, and psychological well-being.

Compassion and Stable Social Systems

As noted, a fundamental problem of human social living concerns the development of cooperative social relationships and communities—a task that often proves difficult because individuals must forgo short-term benefits for the self in favor of long-term benefits for the greater good. Compassion appears to function as an emotional experience that promotes the attainment of cooperative social relationships by supporting the development of emerging relationships and, thereby, the growth in one's social network.

Indeed, the impact of compassionate motives has been demonstrated to predict the development of novel relationships. Crocker and colleagues have studied the experiences of first-semester college freshmen who have been randomly assigned a roommate and demonstrated that people who care about the well-being of others (i.e., those motivated by "compassionate goals") are more likely to satisfy their own and others' needs compared with those who are motivated by self-interest (i.e., "self-image goals"; see Crocker & Canevello, 2012 for a review). Whereas pursuing self-esteem can have various short- and long-term costs, including a reduced sense of relatedness and increased anxiety and depression, caring for the well-being of others functions to indirectly promote one's own well-being through the building of social capital (Crocker & Canevello, 2008). Based on longitudinal data that tracked college freshmen over their first semester, Crocker and Canevello found that those who maintained compassionate goals, compared with those who prioritized self-image goals, provided more support to others in the context of new relationships. Furthermore, those individuals who simultaneously endorsed high-compassionate goals and low-self-image goals reported receiving greater social support and greater interpersonal trust among friends and significant others. Thus, compassionate dispositions appeared to support the development of emerging relationships. These findings also suggest a positive impact of compassion on overall well-being: compassionate goals predicted downstream psychological well-being as indicated by self-reported feelings of trust, closeness, and reduced loneliness and interpersonal conflict (Crocker & Canevello, 2008).

The effects of compassion on the development of cooperative relationships may also extend to larger groups beyond dyadic relationships. For example, emerging empirical evidence supports the notion that cooperative groups accumulate the largest amounts of resources over time compared with groups that engage in punitive action. Using simulated economic exchanges, Dreber and colleagues confirmed that groups that refrain from punitive action reap greater communal gains compared with groups characterized by punitive behavior (Dreber, Rand, Fudenberg, & Nowak, 2008). Cooperation, rather than punishment, promotes a flourishing community. It is therefore of great value to identify the factors that might promote cooperation despite uncertainty about potential losses of resources in the short run. In this vein, researchers have taken interest in the potential of compassion as a moral force that can extend prosocial behavior and forgiveness toward those who have committed social violations or transgressions.

Initial investigation in this realm has produced findings indicating that compassion can in fact promote a reduction in punishment directed at individuals who commit a transgression, even in cases where the transgression occurs against a third party and no forgiveness is sought (Condon & DeSteno, 2011). Using an orchestrated scenario, Condon and DeSteno had participants witness a confederate (i.e., an actor) cheat on a task to win money. Participants later had the opportunity to punish the transgressor by deciding the amount of hot sauce he would be forced to consume (cf. Lieberman, Solomon, Greenberg, & McGregor, 1999). Some participants were also exposed to the intense sadness of a nearby female confederate. As expected, the experience of compassion in response to the female confederate's state mediated a reduction in the amount of hot sauce administered to the transgressor. Compassion may therefore be an effective mechanism for reducing escalations of violence. Although unpunished transgressions could prove costly, the avoidance of aggressive action can result in less psychological stress and greater hedonic well-being in the long run (Bushman, 2002; Carlsmith, Wilson, & Gilbert, 2008), suggesting that compassionate action even toward transgressors may prove worthwhile. An emerging question concerns the manner in which compassion promotes cooperative behavior in contexts that involve such moral violations. The motivation to reduce suffering would likely lead individuals to endorse policies and values that protect the rights of others (Goetz et al., 2010), thus it is likely that compassion would motivate an individual to engage in action to correct the actions of a transgressor with the ultimate aim to reduce collective suffering, albeit in a nonviolent manner that minimizes the transgressor's suffering. This interpretation remains speculative, however, and awaits empirical investigation. In sum, compassion supports the development of novel relationships and communal interest, in part by nudging people to forgo short-term benefits for the self and by attenuating impulses to engage in third-party punishment.

Compassion and Individual Well-Being

Various researchers have suggested that compassion may serve as a nourishing, replenishing experience that can contribute to one's personal well-being (e.g., Klimecki & Singer, 2012). This is in stark contrast with the notion that people can become overburdened by "compassion fatigue" when providing care for others, such as in health care settings or among people who take on the role of a primary caregiver for a family member. Yet several authors have distinguished compassion from empathic distress or empathy fatigue by suggesting that compassion moves beyond the simulation of another's pain and includes feelings of concern and love for those who suffer (Condon & Barrett, 2013; Klimecki & Singer, 2012). In line with this suggestion, several scholars have provided evidence that compassion might indeed promote psychological and physical well-being to individuals, as opposed solely to larger social groups.

Not surprisingly, the impact of compassionate goals compared with self-image goals—as reviewed above—extends to one's personal well-being (Crocker, Canevello, Breines, & Flynn, 2010). As previously noted, Crocker and colleagues examined the effect of compassionate goals in college freshmen on experiences of anxiety, dysphoria, and distress throughout their first semester. Compassionate goals predicted social support given and received, but interestingly, social support given to others uniquely predicted participants' own changes in distress from the beginning to the end of the semester. Thus, caring for the well-being of others over time appears to benefit an individual's own psychological well-being.

Similar effects extend to physiological outcomes as well. Individual differences in self-reported compassion have been found to moderate the effect of social support on reactions to a stress-inducing public speech task (Cosley, McCoy, Saslow, & Epel, 2010). Specifically, high dispositional compassion was associated with reduced blood pressure, reduced cortisol, and higher high-frequency heart rate variability, suggesting reduced sympathetic and increased parasympathetic activity during a stress-inducing public speech (Cosley et al., 2010). Recent experimental work has also confirmed that manipulating compassionate goals can reduce stress reactivity to a stress-inducing public speech task (Abelson et al., 2014). Specifically, individuals who thought about ways to help others while in a job interview setting experienced less hypothalamic–pituitary–adrenal (HPA) axis reactivity, which acts as a primary contributor to the negative impacts of stress on health. Thus, compassion could play a fundamental role in promoting psychological and physical well-being in response to stress.

Similar findings have emerged with respect to caregiving behavior. Brown and colleagues have demonstrated across differing samples that giving support and providing care for others can contribute to one's own health and psychological well-being (Brown, Brown, House, & Smith, 2008; Brown, Nesse, Vinokur, & Smith, 2003; Brown et al., 2009). Large-scale prospective survey research of individuals over the age of 65 has demonstrated that giving instrumental support (e.g., help with work, tasks) and emotional support (e.g., offering love and care for one's spouse) reliably predicted reduced mortality risk over a 5-year period, even after controlling for relevant factors such as health, income, education, socioeconomic status, personality factors, social contact, and support received (Brown et al., 2003). Data from the same sample also confirmed that, among participants who recently lost a spouse, self-reported compassion-related helping behavior was associated with decreased depressive symptoms (Brown et al., 2008). Data from a separate sample revealed that caregiving for a spouse predicted reduced risk of mortality (Brown et al., 2009). Similarly, survey research has shown that volunteering rates among people who adopt positive views of others predict lower rates of mortality and psychological distress even when exposed to high levels of stress (Poulin, 2014). Although much research has documented the negative effects of a caregiving role, this newer body of work has shown that compassion-based caregiving can increase self-reported feelings of self-worth, meaning in life, a strengthening in one's relationships, feelings of uplift or elevation, and a reduction in anxiety and depression (see Schulz & Monin, 2012, for a review).

These benefits of compassion-related caregiving are consistent with other findings showing the impact of prosocial action on one's own feeling of happiness. In a recent field experiment, Dunn, Aknin, and Norton (2008) demonstrated that participants who were randomly assigned to spend the cash they were endowed with on other people reported greater levels of happiness compared with participants who were randomly assigned to spend similar amounts of money on themselves. Of import, this effect has been replicated across numerous cultures (Aknin et al., 2013). Such findings are also consistent with neuroimaging evidence suggesting that charitable and cooperative behavior is experienced as rewarding (Moll et al., 2006; Rilling et al., 2002). Although these findings do not specifically focus on compassion, they suggest that other-oriented costly behavior of the type associated with compassion can promote subjective experiences of well-being.

Modulating Compassion

Numerous factors have been documented that decrease compassionate responding to another's suffering, including outgroup membership (Stürmer, Snyder, & Omoto, 2005), the presence of nonresponsive bystanders in a social context (Darley & Latané, 1968), heightened time pressure (Darley & Batson, 1973), higher socioeconomic status

(Piff, Kraus, Côté, Cheng, & Keltner, 2010; Stellar, Manzo, Kraus, & Keltner, 2012), and an increased number of people suffering (Cameron & Payne, 2011). These factors all decrease the likelihood that one will respond in a prosocial manner to those in need. Yet emerging evidence is beginning to identify factors that increase compassion as well, including Buddhist-inspired meditation programs and subtle situational cues.

Much of the scientific activity on meditation has focused on the personal health and psychological benefits of meditation, such as decreased anxiety and depression (Hölzel et al., 2011) and enhanced cognitive performance (e.g., Slagter, Lutz, Greischar, Nieuwenhuis, & Davidson, 2009). Recently, scientists extended the meditation-based literature to the interpersonal domain by examining the role of meditation in promoting helping and cooperation. A handful of initial studies provided compelling evidence that different types of meditation increase prosocial and compassionate responses to another's suffering. Fredrickson and colleagues (Fredrickson, Cohn, Coffey, Pek, & Finkel, 2008; Kok et al., 2013) have demonstrated that short-term training in loving-kindness meditation (LKM) increases daily experiences of positive emotions throughout training and self-reported social resources measured at posttraining (e.g., greater self-reported social connection). More specifically, they showed that participants completing LKM, compared with those assigned to a wait-list control, reported increased positive emotion, which accounted for increases in a variety of personal resources, including self-reported positive relations with others and self-reported social connection (Fredrickson et al., 2008; Kok et al., 2013).

Several independent groups have demonstrated that compassion-based meditation—a technique similar to, but distinct from LKM—increases empathic responses to others' suffering (Klimecki, Leiberg, Ricard, & Singer, 2014; Lutz, Brefczynski-Lewis, Johnstone, & Davidson, 2008; Mascaro, Rilling, Tenzin Negi, & Raison, 2013). Of import, this increased empathic response has been shown to be predictive of subsequent prosocial acts. As one example, loving-kindness and compassion-based training have been shown to increase economic generosity in computer-based transactions (Leiberg, Klimecki, & Singer, 2011; Weng et al., 2013). In an effort to link meditation to compassionate responses to the suffering of others directly, work by Condon and colleagues has confirmed that just a few weeks of training in either compassion- or mindfulness-based meditation significantly enhances the likelihood that individuals will act to relieve the pain of others, even within the context of bystander situation in which others are ignoring the suffering (Condon, Desbordes, Miller, & DeSteno, 2013; Lim, Condon & DeSteno, 2015).

A variety of non-meditation–based techniques may also prove effective for increasing compassion. Experimental research indicates that increases in feelings of similarity (Valdesolo & DeSteno, 2011) and security (Mikulincer, Shaver, Gillath, & Nitzberg, 2005) enhance compassion and helping behavior. In both lines of research, subtle cues were sufficient to increase feelings of compassion and downstream helping behavior. With respect to similarity, a simple measure of motor synchrony resulted in magnified feelings of similarity to a stranger, which subsequently mediated the experience of compassion for the stranger's plight and behaviors meant to assist him (Valdesolo & DeSteno, 2011). Mikulincer and colleagues likewise demonstrated that subtle manipulations of felt security increase compassionate responding to the other's suffering (Mikulincer et al., 2005). Participants in these studies viewed subliminal primes of the names of secure attachment figures (e.g., the name a person who has provided care and responsiveness in times of need, such as the participant's mother, a close friend, or other relationship partner) and later reported greater willingness to help a woman in need, compared with participants who viewed subliminal primes of neutral content.

Interventions that incorporate these factors may stand as potential targets for interventions that do not require protracted efforts involving meditation-based training. As the field matures, it will be noteworthy to examine possible contextual factors that predict the degree to which meditation increases compassionate outcomes (e.g., social context, practice settings) and individual susceptibility to compassion-based enhancements via meditation training. At present, however, it is interesting to note a potential common element that may tie some of these relatively nascent findings together. The goal of many meditative techniques is to foster a state of equanimity: a state in which the social categories typically used to separate people are broken down (Desbordes et al., 2015). Such a state, by definition, increases the similarity seen between individuals. Accordingly, the ability of subtle similarity manipulation to increase compassion may represent an efficient "hack" to achieve similar benefits that come from more chronic training of the mind. This view is supported by work showing that inductions of compassion enhance feelings of similarity to others (Oveis, Horberg, & Keltner, 2010), thereby suggesting a possible reciprocal interaction between the relevant mechanisms. A sense of increased similarity to another individual, of course, stands as a marker that this individual is likely to be more willing to repay the favor by providing subsequent aid in the future (de Waal, 2008).

Conclusion

As the preceding review makes abundantly clear, gratitude and compassion share several commonalities. Both are intrinsically linked with building social relationships. Both motivate behaviors that, although costly in the moment—in terms of social, financial, temporal, or hedonic resources—typically lead to opportunities for greater accumulation of similar rewards when aggregated over time. As such, these emotions enhance well-being by nudging individuals to behave virtuously (DeSteno, 2009). For all their similarities, however, they do constitute unique states that also address distinct challenges. Gratitude primarily functions to motivate behaviors likely to maintain relationships (e.g., repayment of debts, offering of social support to previous benefactors). Although it has been shown that gratitude can result in pay-it-forward behavior to strangers, such acts likely stem from a misattribution of the feeling state to others and thus represent a highly beneficial spandrel as opposed to a central functional outcome (cf. Bartlett & DeSteno, 2006). A unique aspect of compassion, on the other hand, is its ability to motivate supportive behavior and diminish aggressive behavior in the absence of any preexisting relationship. Thus, compassion and gratitude may work together to build social capital, with compassion motivating the initial impulse to be a benefactor to a new individual and gratitude motivating subsequent repayments meant to continue the exchange.

CHAPTER 48

Love

Positivity Resonance as a Fresh, Evidence-Based Perspective on an Age-Old Topic

Barbara L. Fredrickson

What is love? Humans have pondered the meaning of this splendored phenomenon for millennia. Anything that so reliably stirs the human heart, preoccupies the mind, and ignites passionate action certainly merits this long-standing and continued inquiry. Artistic expressions of what love is and how it works abound—in poetry, books, songs, and movies. Scientific perspectives are less prevalent. Although scientific psychology began in the late 1800s, more than six decades into this collective endeavor, Harry Harlow (1958), then president of the American Psychological Association, decried that psychologists had "failed" to advance beyond poets and novelists in understanding the "wondrous state" of love, "deep, tender, and rewarding" (p. 673). In the nearly six decades since receiving this failing grade, two strands of psychological science have taken the love question seriously: Developmental science has investigated how love emerges between infants and their caregivers (e.g., Ainsworth, 1985; Stern, 2008), and relationship science has explored romantic love, including how early childhood attachment shapes adulthood love relationships (Hazan & Shaver, 1987; Bartholomew & Horowitz, 1991; Mikulincer, Shaver, Sapir-Lavid, & Avihou-Kanza, 2009).[1]

Neighboring emotion science lags behind. Although a few emotion scientists have devoted attention to the love question over the years (e.g., Fehr & Russell, 1991; Gonzaga, Keltner, Londahl, & Smith, 2001; Shaver, Morgan, & Wu, 1996), these efforts have not germinated a thriving study of love within affective science. As long-time love scholar, Elaine Berscheid (2010) recently noted, "emotion theorists have their own problems [in defining emotions] and are not yet in a position to help love scholars" (p. 8). For emotion scientists, who by definition favor the study of momentary phenomena, love may well seem too large, too all-encompassing, if not too pop culture.

The largeness of love is evident by the diverse set of psychological phenomena that fit under the umbrella term "love": the preoccupying and strong *desire* for further connection, the powerful *bonds* people hold with a select few and the *intimacy* that grows between them, the *commitments* to loyalty and faithfulness. Indeed, when one person says, "I love you" to another, it can point to any or all of the above—that is, this ubiquitous utterance may reflect a strong craving for physical contact or proximity, or serve as a means to invite or secure the other person into one's innermost circle of social ties, or it may signal a deep and abiding trust, or a commitment to be loyal. Yet, in addition to desire, bonds, intimacy, and commitment, love is an *emotion*—a phenomenon that arises to infuse both mind and body for a moment, and then dissipates.

This chapter puts forth a new perspective on love, one that emanates from emotion science. The goal is to provide a conceptual framework to support a fresh wave of empirical research on this revered emotional state. This new perspective holds that, at its core, love is a pleasant and momentary experience of connection with another person (or persons). In this framework, other constructs that are commonly taken as synonyms of "love"—such as desire, bonds, intimacy, and commitments—are cast as *products* of the accumulation of fleeting emotional states of love. As such, the range of other phenomena that go by the name "love," in both scientific and common language, may best be seen as part of a larger and dynamic "love system."

The hub concept that drives this dynamic system is a potent and pleasant emotional state. Like all positive emotions, the emotional state of love obeys the ancestral logic of the broaden-and-build theory (cf. Fredrickson, 1998, 2013a). Love-the-emotion broadens mind-sets by expanding people's awareness, particularly of self–other overlap (Aron, Aron, & Smollen, 1992; Waugh & Fredrickson, 2006), creating perceptions of togetherness, connection, unity, or oneness. Love-the-emotion builds resources for survival by forging and strengthening people's social desire, bonds, intimacy, and commitments. Each of these other concepts within the broader love system grows stronger as moments of love-the-emotion accumulate. Yet the causal arrows also run in the other direction. Each of these other concepts within the more encompassing love system—the desire, the bonds, the intimacy, the commitments—also facilitate subsequent moments of love-the-emotion, creating the dynamics of an upward spiral. Put simply, it is far easier for two or more people to connect when their desire, bonds, intimacy, or commitments are present and strong.

Perhaps it is no wonder that love has puzzled so many for so long. Part of the confusion is that the word "love" has been affixed to different parts of this larger, dynamic love system. A primary mission of science, however, is to peer into complex systems to discover the order therein. We are now equipped to use the lenses of emotion science to sharpen our appreciation of love. These lenses add to the understandings of love that neighboring relationship science and developmental science have offered by drawing particular attention to the momentary nature of love, its biological bases, and by offering the framework and logic of the broaden-and-build theory of positive emotions.

The sharper appreciation for love to be developed here also illuminates the value of mild or low-intensity forms of this consequential state. Mild forms of love-the-emotion are too often eclipsed by the overwhelming intensity of select love experiences, the ones that forge life's strongest bonds, such as those between an infant and his or her caregivers, or between two new romantic partners just now "falling in love." The study of positive emotions, however, cautions researchers not to be blinded by intensity: Ample empirical evidence reveals that the frequency of pleasant affective states is far more consequential than the intensity of those states (Diener, Sandvik, & Pavot, 1991; Folkman, 1997; Isen, 1993), and that the consequences of mild pleasant affective states for health and well-being are considerable (Cohn, Fredrickson, Brown, Mikels, & Conway, 2009; Moskowitz, 2003; Fredrickson, Cohn, Coffey, Pek, & Finkel, 2008). Love-the-emotion likely follows this same pattern. Mild yet consequential forms of love can infuse everyday positive connections between and among family, friends, acquaintances—even strangers—to forge and fortify bonds, alliances, meaning, and purpose, as well as community and collective health and well-being.

Toward a Formal Definition of Love-the-Emotion

Views from Emotion Science

Emotion scientists distinguish between love experiences and love relationships (Lazarus, 1991), and direct their focus to the former, the transient feeling states of love, rather than the latter, the long-standing social ties that are infused with, and supported by love-the-emotion. Even so, it bears underscoring that transient experiences of love are felt *toward* and *with* specific individuals (e.g., one's mother, friend, lover, or child), and are therefore contextualized by these interpersonal connections. Many theorists have pointed out that love is not actually a single emotional state, but rather comes in multiple forms, some more tender and low-key, and others more joyful and high energy. As Rempel and Burris (2005) put it, "love seems to be reflected in multiple emotions rather than one distinct emotion" (p. 298). Supporting this view, in examining 14 pleasant emotions, Ellsworth and Smith (1988) found that love was among the least differentiated.

Whereas Rempel and Burris (2005) use love's lack of specificity to argue that love is not, in fact, an emotion, other theorists, like Izard (1977) and Fredrickson (1998), use this same observation to support a different, contextualized view of love. This alternate view holds that experiences of love can be seen as the experience of any other positive emotion when that emotion is felt in the context of a safe, often close relationship. For Izard (1977), who at the time identified only interest and joy as among the other positive emotions he considered, love was taken to be the joy and interest that people feel in connection with others. In his words, "acquaintances or friends renew your interest by revealing new aspects of themselves and the resulting increase in familiarity (deeper knowledge of the person) brings joy. In lasting friendships or love relationships this cycle is repeated endlessly" (p. 243).

More recently, Fredrickson (2009) expanded on Izard's (1977) illustration to include eight additional positive emotions alongside the appraisal patterns associated with each, arguing that each of these moments might be equally described as love:

> In the early stages of a relationship, tied up with your initial attraction, you're deeply *interested* in anything and everything this new person says and does. You share *amusements* and laugh together, often as a result of the awkwardness of coming together for the first time. As your relationship builds and perhaps surpasses your expectations, it brings great *joy*. You begin to share your *hopes* and dreams for your future together. As the relationship becomes more solid, you sink back into the cozy *serenity* [contentment] that comes with the security of mutual love. You're *grateful* for the joys your beloved brings into your life, as *proud* of their achievements as you are of your own, *inspired* by their good qualities, and perhaps in *awe* of the forces of the universe that brought you two together. (p. 47)

Following Izard's (1977) footsteps, my earliest scholarly description of love-the-emotion took an "all of the above" approach, defining it as any positive emotion felt in the context of a safe, often close relationship (Fredrickson, 1998). Although I still hold that acknowledging the many different flavors of love-the-emotion is a vital step, for two reasons, I now see that this step is not nearly big enough. First and foremost, this earlier conceptualization remains a one-person psychology, positioning the other person as merely the "context" for the focal person's experience of love. A richer understanding of love-the-emotion emerges when we widen the lens to also include what the other person is, at that same moment, feeling. Stepping up to this two-person psychology,[2] I now more specifically position love-the-emotion as emerging any time a positive emotion is momentarily shared by two (or more) individuals. Second, I find the emphasis on established close relationships to be limiting and unjustifiable. Initial or one-time connections with novel interaction partners can also support the emergence of shared positive emotions. The differences between these connections and those that emerge within close relationships may be largely a matter of degree, rather than kind.

So, to expand the scope of past conceptualizations of love within emotion science, I posit here that one core element of love-the-emotion is shared positive emotions. To lay the foundation for two additional core elements, I outline views offered by relationship science and developmental science in turn.

Views from Relationship Science

A dominant approach within relationship science is to demark different types of love relationships. Berscheid (2010), for instance, identifies companionate, romantic, and compassionate, as well as attachment love relationships (see also Hatfield & Rapson, 1993; Sternberg, 1986; Fehr, Sprecher, & Underwood, 2008; Fisher, Aron, Mashek, Li, & Brown, 2002). Recent advances in understanding love, for instance, have explored the unique neural correlates of romantic versus companionate love (Acevedo, Aron, Fisher, & Brown, 2012).

Whereas these various forms of love certainly differ from one another, they also share certain family resemblances. In contrast to the dominant approach of defining love as a prototype (Fehr, 1988; Shaver, Schwartz, Kirson, & O'Connor, 1987), recent work by Hegi and Bergner (2010) attempts to articulate a formal definition of love, one that identifies necessary and sufficient conditions for using the word "love" correctly across a range of love relationships. Building on work by Clark and colleagues on communal relationships (Clark & Mills, 1979; Clark & Monin, 2006), as well as work by Singer (1984) and Rempel and Burris (2005), Hegi and Bergner (2010) hypothesize that essential to a range of love relationships—companionate, romantic, compassionate, and attachment—is "investment in the well-being of the other, for his or her own sake" (p. 621). They draw support for their hypothesis from surveys that capture respondents' schemas for what counts as love. Specifically, respondents consider hypothetical examples of different types of relationships in which a certain relationship characteristic is missing on the part of one individual in the relationship, and indicate the degree to which they would find it contradictory to say that this person loves the other under those circumstances. In examining relationship characteristics ranging from similarity and trust to exclusivity and enjoyment, they found that only the absence of "investment in the well-being of the other for his or her own sake" was deemed "very contradictory" to the presence of a love relationship by the vast majority of respondents (Hegi & Bergner, 2010). The authors use these data to argue that such investment is a necessary and essential feature of human love of various kinds. As such, love, by definition, conveys a caring orientation toward others.

The interpersonal counterpart to love's caring orientation toward the other appears to be the concept of "perceived partner responsiveness to the self," which reflects the extent to which the other person registers that he or she is being attentively cared for (e.g., Reis, Clark, & Holmes, 2004)—that is, to the extent that Person A invests in the well-being of Person B, for B's own sake, Person B may come to believe that Person A understands and values him or her, and responds supportively. Perceived partner responsiveness is positioned as "a cardinal process in closeness and intimacy" (Reis et al., 2004, p. 220; see also Laurenceau, Barrett, & Pietromonaco, 1998), particularly within communal relationships. Assessments of the degree to which another person understands, cares for, and validates you inform your overarching belief that this other person truly "gets you," and uses his or her privileged knowledge thoughtfully, for your benefit. Responsive parenting is also a cornerstone concept within attachment theory (Bowlby, 1969/1982), with studies showing that parental responsiveness to a child's needs is the root of secure attachment and the development of stable and positive internal models of self in relation to others (Bowlby, 1969/1982; Ainsworth, Blehar, Waters, & Wall, 1978), which in turn shape thoughts, emotions, and behavior throughout childhood and into adulthood (Mikulincer et al., 2009).

Research on perceived responsiveness underscores that love is not a unidirectional phenomenon, concerning one person's feelings toward another, but is instead a *bidirectional transaction*, in which each person's perceptions of the other's feelings toward the self are also vital to the emergence of intimacy. Responsiveness is known to be consequential across a range of emotional exchanges. For instance, when one member of a romantic couple thanks the other (Algoe, Fredrickson, & Gable, 2013), or reacts as the other shares some personal good fortune (Gable, Gonzaga, & Strachman, 2006), the extent to which the other person perceives that thanks or that reaction to be responsive forecasts future relational well-being, and even the longevity of the relationship. Responsiveness may also be consequential to physical health. A national U.S. survey of individuals who are married or cohabitating with a romantic partner found that high received emotional support from the partner is associated with increased mortality risk for those who rate their partners as lacking responsiveness, whereas this risk is absent among those who rate their partners as high in responsiveness (Selcuk & Ong, 2013).

Although most studied within communal relationships, responsiveness—and the perception of it—can also characterize exchange relationships, even one-time encounters with strangers. As a traveler to an unfamiliar city, for instance, you may come to appreciate that the barista who makes your morning brew is especially attuned to your wishes and mood, eager to please and connect. As you make your economic transaction, the two of you smile and chat with ease and openness. Walking away from this exchange, you might feel more uplifted and energized than you had felt just moments ago. Dutton and colleagues describe such encounters as *high-quality connections* (HQCs; Stephens, Heaphy, & Dutton, 2011; see also Heaphy & Dutton, 2008). HQCs are short-term, positive interactions that are experienced as enlivening, characterized by mutual perceived responsiveness. Although these positive encounters may be part of ongoing relationships, they need not be. They can also readily emerge within one-time encounters with shopkeepers or customers, health care providers or patients, or any time two or more people interact.

Rapport is also commonly used to describe the sorts of positive connections that emerge between and among people who are said to "click" or have "chemistry." Conceptually, rapport is an emergent, interpersonal phenomenon marked by mutual attentiveness, positivity, and coordination (Tickle-Degnen & Rosenthal, 1990), all the hallmarks of responsiveness. Nonverbally, rapport is embodied through mutual direct body orientation and gaze, accompanied by smiles, nods, and forward leans (Tickle-Degnen & Rosenthal, 1990), as well as behavioral synchrony (Vacharkulksemsuk & Fredrickson, 2012). Whereas the concept of "love," in its traditional usage, tends to imply long-standing intimate relationships, the concept of "rapport" all but implies a lack of intimacy and history. By contrast, I hold that the concepts of love and rapport may differ primarily in degree, rather in kind, and that it may be more generative to consider them as examples of the same underlying biopsychosocial phenomenon.

For the present purposes, I denote the reciprocal combination of "investment in the well-being of the other, for his or her own sake" and "perceived partner responsiveness to the self" by the shorthand phrase "mutual care." Although mutual care is perhaps most obvious within people's longstanding love relationships—with, for instance, romantic partners and other family members—it is not an exclusive property of these communal relationships. In milder, perhaps less obvious forms, mutual care can also infuse more casual encounters with friends, coworkers, acquaintances, and even strangers. Indeed, any time embodied rapport or HQCs emerge, mutual care is, by definition, present. Importantly, this care is neither heavy-handed nor role bound, as in being a caregiver. Rather it is as light, nonconscious, and momentary as the unbidden concern you would feel if the person with whom you were connecting suddenly had a heavy object fall on his or her foot: you would wince also, then quickly assess your companion's well-being. Mutual care describes a state in which each person would show this minimal level of engagement with, concern for, and investment in the well-being of the other. I posit that mutual care is a second core element of love-the-emotion.

Views from Developmental Science

If mutual care, with its hallmark mutual concern for the other's well-being and mutual perceived responsiveness, is taken as an additional core element of love-the-emotion, it might seem that encounters or relationships that involve dependence or asymmetry—as with an infant, or child (or an otherwise needy individual) with a parent or caregiver—are ruled out of such mutuality. While doting parents clearly love their newborns, can their newborns truly love them back? With their limited capacities, how can newborns muster up the selfless other-focus that defines love?

The way out of this seeming conundrum is to recognize that warmth-infused other-focus requires no mustering at all. Rather, it unfolds automatically and effortlessly, completely without higher symbolic or effortful mental processes. Indeed, developmental psychologists have argued that, from birth, infants are biologically prepared to perceive cross-modal correspondences between what they see on their interaction partners' faces and what they sense, proprioceptively, on their own faces (Meltzoff & Moore, 1989; Trevarthen, 1998). This ability is what enables infants to synchronize their movements—in form, tempo, and intensity—with those of others, to the extent that their motor control allows (Meltzoff & Moore, 1989).

Notably, behavioral synchrony goes beyond mimicry because matching often occurs across modalities, such as when the rhythm of an infant's movements sync up with the rhythm of his or her mother's vocalizations. Such cross-modal analogies point to a resonance between infants and their interaction partners at the level of subjective mind states and emotions, and not merely at the level of observable behaviors. Behavioral synchrony can thus be taken to reveal an intersubjectivity (Beebe, Sorter, Rustin, & Knoblauch, 2003), or affective attunement (Stern, 1985), described as an innate form of intimacy, a way to find and show delight in communing, connecting, or being with another. Through such affective sharing, an infant "experiences being experienced" (Beebe et al., 2003, p. 786) or "feel[s] felt" by the other (Siegel, 2001, p. 78), a momentary experience akin to what relationship scientists, as described above, have termed "perceived partner responsiveness to the self." Importantly, "feeling felt" is itself a positive emotional experience (Beebe et al., 2003).

Developmental science has also shown that the attentive dance of behavioral synchrony that emerges between infants and their responsive caregivers—a dance laced with smiles, coos, and other gestures of positivity—is absolutely vital to normal human development, as vital a good nutrition (Stern, 1985; Siegel, 2001). The classic "still-face paradigm," for instance, reveals how avidly infants seek it out. Researchers who use this paradigm invite parent–infant dyads to the laboratory to videotape them during typical face-to-face play, after a few minutes of which the researchers signal the parent to adopt a still, neutral face, while maintaining eye contact with his or her infant. The parent's still face sends a mixed message to the infant: the parent's gaze signals readiness to engage, yet his or her passive face conveys unavailability. Behavioral coding of infant responses to the still-face paradigm reveals that, in the first half minute or so, infants typically continue to gaze and smile at their parent, making "positive bids" for reengagement. These hopeful bids are destined to fail, however, because parents are instructed to maintain a passive face for 2 minutes. Faced with this failure, the infants' positivity typically wanes and gives way to negativity, marked by lowered brows and open-mouth cries (Ekas, Haltigan, & Messinger, 2013).

More sobering evidence for the developmental necessity of the positive intersubjectivity signaled by behavioral synchrony comes from caregivers who struggle with depression, who are far less likely to show the "dance" of behavioral synchrony with the infants in their care. Studies show that depression, which affects 10–12% of postpartum mothers, slows both speech and body movements, and disrupts parent–infant synchrony (Feldman, 2007). Widely viewed as a disorder of the positive emotion system (Davidson, 2000), depression stifles the emergence of intersubjectivity and shared positivity. Ample research confirms that maternal depression in infancy forecasts a child's impairments in cognitive and socioemotional skills even decades later (see Feldman, 2007, for a review).

More recent evidence suggests that positive behavioral synchrony—the degree to which an infant and a parent (through eye contact and affectionate touch) laugh, smile, and coo together—corresponds with oxytocin synchrony. Researchers have measured oxytocin levels in the saliva of dads, moms, and infants both before and after a videotaped, face-to-face parent–infant interaction. For parent–infant pairs that show mutual positive engagement, oxytocin levels also come into sync. Without such engagement, however, no oxytocin synchrony emerged (Feldman, Gordon, & Zagoory-Sharon, 2010).

Based on the aforementioned evidence from developmental science, I posit that biobehavioral synchrony is a third core element of love-the-emotion.

Pushing Emotion Science Further: A New Hybrid View

Distinct, albeit overlapping, views of love have emerged within the neighboring disciplines of emotion science, relationship science, and developmental science. Further integrating these views, I propose a new hybrid view that positions love as a momentary emotional phenomenon that is coexperienced by any two or more interacting people. Distilling to a formal definition, I define love-the-emotion as a *micro moment of positivity resonance*, during which three core elements—(1) shared positive emotion, (2) mutual care, and (3) biobehavioral synchrony—emerge with temporal coherence between and among people.

Departing from relationship science, love, as conceptualized here, is not an enduring or intimate relationship. In keeping, however, with the adaptationist logic of the broaden-and-build theory of positive emotions (Fredrickson, 1998, 2013b), micro moments of positivity resonance fertilize the growth of consequential personal and social resources, including enduring close and intimate relationships, as well as mental and physical health.

Taking a cue from relationship science, I also elevate micro moments of positivity resonance above the experiences of other positive emotions—that is, I hypothesize that positivity that resonates between and among people is particularly efficient for building consequential resources, relative to positive emotions that are experienced in isolation or absent the elements of mutual care and biobehavioral synchrony. Accordingly, I have called out love as "our supreme emotion" (Fredrickson, 2013a). This approach departs sharply from an unspoken tradition within emotion science, which implicitly take specific, discernable emotions—fear, anger, joy, and pride—as roughly equal-status categories, each holding value for human survival in its own way. Under this traditional logic, no emotion, love included, is set apart as on a different plane, or scale of importance. By contrast, relationship science unabashedly positions love relationships as distinct from other relationships and more consequential to human welfare. Likewise, for its ability to weave individuals into the social fabric of community, love-the-emotion may well be more consequential to human welfare than any other emotion.

Mileage Gained from the Concept of Positivity Resonance

Preconditions for Positivity Resonance

Micro moments of positivity resonance between and among people do not emerge at random, regardless of conditions. In this way, love is not unconditional. (I acknowledge that I deploy the term "unconditional" in a different manner than have humanistic psychologists.) Love's first precondition, I posit, is perceived safety. As for most positive emotions, momentary perceptions of safety appear to be an important prerequisite. When people appraise their current circumstances as somehow threatening or dangerous, the ability to share an experience of positivity resonance becomes highly improbable. Fortunately, true threats to safety are statistically rare: Most moments are benign (Oishi et al., 2007). Yet, unfortunately, many people do not experience the safety in which their lives are embedded. Those who suffer from anxiety, depression, loneliness, or low self-esteem, for instance, perceive threats far more often than their objective circumstances warrant (e.g., Cacioppo & Hawkley, 2009). This overalert state thwarts the emergence of all positive emotions, including love. More generally, the inability to experience safety in the company of others is a poignant obstacle to love.

Love's second precondition, I posit, is sensory connection. Neither abstract nor mediated, sensory connection is physical and unfolds in real time. It requires the copresence of bodies, through touch, voice, or visibly synchronized postures, gestures, or facial expressions. Arguably, however, the main mode of sensory connection is eye contact (Farroni, Csibra, Simion, & Johnson, 2002). Newborns, for instance, show an immediate preference for eye contact, as well as innate skills for establishing it with the adults who come into their visual range. Eye contact is also a gateway construct within the simulation of smiles (SIMS) model, articulated by Niedenthal and colleagues (Niedenthal, Mermillod, Maringer, & Hess, 2010). Making eye contact with someone who smiles, according to the SIMS model, triggers a rapid and nonconscious embodied simulation of that smile—through facial mimicry and neural activation—that implicitly functions to disambiguate the meaning of that smile. In support of the SIMS model, controlled laboratory experiments confirm that mutual eye gaze, relative to averted gaze, triggers facial mimicry to dynamic emotional stimuli (Schrammel, Pannasch, Graupner, Mojzisch, & Velichkovsky, 2009), and that facial mimicry enables more accurate decoding of the genuineness of dynamic smiles (Maringer, Krumhuber, Fischer, & Niedenthal, 2011). These processes may account infants' ability to detect inauthentic emotions (Walle & Campos, 2014). To the extent that eye contact during emotional episodes triggers embodied simulations, infants' prescient skills for making eye contact can be viewed as evolved adaptations that help infants wordlessly and accurately convey their evershifting emotional needs to engaged caregivers (Niedenthal et al., 2010). Through sensory connection, then, positive emotions "jump the gap" between people to become shared experiences of positivity resonance, marked biobehavioral synchrony, and mutual care.

Products of Positivity Resonance

Even though micro moments of positivity resonance are often mild and by definition fleeting, the accumulated frequency of these experiences over time builds a range of resources important to subjective, relational, and physical well-being. For instance, the experience of pleasure or "liking" precedes and lays the foundation for desire or "wanting" (Berridge, 2007). In the case of positivity resonance, the pleasure of feeling connected to a new romantic partner or "crush," assessed as self–other overlap (Aron et al., 1992), prospectively predicts the frequency of positive spontaneous thoughts about that person, which can serve to motivate subsequent efforts to reconnect (Rice, Schenker, & Fredrickson, 2014). Likewise, experiencing positivity resonance with the same person repeatedly over time builds trust and loyalty, social attitudes vital to successful friendships and community alliances. The recurrence of positivity resonance also seeds the motivation for secure attachments, social bonds, and more formal commitments to loyalty such as marriage (Cohn & Fredrickson, 2006; Brown & Brown, 2006). As stated previously, these enduring resources—desire, bonds, and commitments—are themselves identified as "love" in both scientific and lay writings. To increase scientific precision, I offer positivity resonance (love-the-emotion), as the recurrent biopsychosocial mechanisms, or "tiny engines," that drive a larger love system that also includes these more enduring products of positivity resonance.

Evidence for Positivity Resonance

A range of converging evidence inspired me to formulate the concept of positivity resonance and articulate key hypotheses about it. Within my own laboratory, the work of Tanya Vacharkulksemsuk has been foundational (Vacharkulksemsuk & Fredrickson, 2012). She and I studied pairs of previously unacquainted dyads that we had randomly assigned to complete one of two interaction tasks, which we videotaped: either a variant of Aron's self-disclosure induction paradigm (Aron, Melinat, Aron, Vallone, & Bator, 1997), or a neutral, collaborative proofreading task. Trained coders later viewed the muted video recordings and rated the extent of simultaneous movement, tempo similarity, and coordination and smoothness in the dyad's nonverbal behaviors, which we then summed into an aggregate index of behavioral synchrony. We learned that the physical and dynamic property of behavioral synchrony mediated the association between self-disclosure condition and subsequent reports of embodied rapport, even when controlling for reports of positive emotion (Vacharkulksemsuk & Fredrickson, 2012). Our evidence for the importance of naturally occurring behavioral synchrony complements research that has manipulated behavioral synchrony to show that it breeds affiliation (Hove & Risen, 2009), cooperation (Wiltermuth & Heath, 2009), and compassion (Valdesolo & DeSteno, 2011).

Going beyond behavioral synchrony—and unseen within ordinary interactions—is the biological synchrony that emerges when two or more people share a positive emotional state. As previously mentioned, oxytocin synchrony arises during positive interactions within parent–infant dyads (Feldman et al., 2010). More compelling still is evidence from recent neuroimaging studies that show widespread neural synchrony within dyads and groups sharing a positive emotional experience (Hasson, 2010; Hasson, Nir, Levy, Fuhrmann, & Malach, 2004; Stephens, Silbert, & Hasson, 2010). It appears, then, that when people share a positive emotional state, they also share gestural, biochemical, and neural patterns. This momentary biobehavioral synchrony unifies the interacting individuals within a shared experience of positive resonance.

Two additional streams of evidence also contributed to my theorizing on love. First, a longstanding body of prospective studies shows that having diverse and rewarding social relationships robustly forecasts better physical health and greater longevity. For instance, a recent meta-analysis of 148 studies concludes that the influence of social integration on mortality risk is on par with that of other, well-established health risk factors, including smoking, excessive alcohol intake, obesity, and lack of physical exercise (Holt-Lunstad, Smith, & Layton, 2010). Second, conspicuously similar prospective evidence links the frequent experience of positive emotions to living longer and healthier lives (see Chida & Steptoe, 2008; Howell, Kern, & Lyubomirsky, 2007, for meta-analytic reviews). Uniting these two streams of evidence, recent work from my laboratory shows that perceived positive social connections—a proxy measure of positivity resonance—accounts for the relationship between positive emotions and physical health (Kok et al., 2013). Specifically, people's daily experiences of feeling "close" and "in tune" with their social interaction partners mediated the effect of an experimental intervention that taught study participants how to self-generate positive emotions (via loving-kindness meditation; see also Fredrickson et al., 2008) on improvements in cardiac vagal tone, a proxy measure of physical health. Thus, it appears that when people's efforts to cultivate positive emotions culminate in experiences of day-to-day positivity resonance with others, they incur particular boosts to their physical health. Much like our day-to-day habits of being physically active and eating nutritious foods, our day-to-day habits of cultivating positivity resonance with others may well function as positive health behaviors.

Research Agenda

Research on the concept of positivity resonance remains scant, to be sure. As such, opportunities abound to test and refine this new definition of love. Key to the success of this work will be the development of valid and reliable measures of positivity resonance that honor its momentary and multifaceted nature. Although self-report measures may capture the phenomenological aspects of positivity resonance, nonverbal behavioral and biological measures with appropriate temporal resolution gathered from interacting dyads will also be essential. In addition, longitudinal research will be needed to test the claim that positivity resonance merits elevation above other positive emotions in its ability to augment well-being and physical health. Longitudinal and dynamic statistical modeling may be especially relevant tools as this research area matures.

Theoretical Implications

What good is a smile? What is it for? Although a range of past theorists have addressed these questions, the new concept of positivity resonance offers a fresh take on the evolved adaptive function of spontaneous and genuine smiles—what have been termed "Duchenne smiles" in the research literature. Following Charles Darwin (1872/1998), Ekman and colleagues contend that such smiles evolved as an outward expression or readout of a person's otherwise unseen inner subjective state (Ekman, Davidson, & Friesen, 1990). An opposing view shifts the focus onto the recipient of a smile, and proposes that smiles evolved not because they provided readouts of positive emotional states, but instead because they evoked positive emotions in those who meet a smiling person's gaze (Owren & Bachorowski, 2003; see also Gervais & Wilson, 2005). Maintaining the focus on the person who meets the smiler's gaze, the embodied cognition perspective of the SIMS model suggests that, through neural simulation, smiles tune an observer toward a better understanding the smiler's subjective experience and motives, so that the perceiver can, for instance, disambiguate sincere affiliative bids from domineering or self-absorbed smiles (Niedenthal et al., 2010). Each of these accounts of the function of genuine smiles seems viable, although each remains incomplete by remaining anchored too exclusively within a one-person psychology (focused *either* on the one person who smiles *or* the one person who witnesses a smile).

Stepping up to a two-person psychology, in which both the smiling individual and the smile recipient play equal and important roles, I propose that the function of at least a subset of Duchenne smiles is "all of the above" and then some. Specifically, the adaptive significance of a genuine, affiliative smile may be to create a momentarily unified mind-set between two people, or intersubjectivity, that is characterized by positivity resonance, as reflected by the trio of love's features: a now shared positive emotion, biobehavioral synchrony, and an orientation toward mutual care. Research documents that a smile draws our eye more than any other facial expression (Becker, Anderson, Mortensen, Neufeld, & Neel, 2011). As we have seen, eye contact nonconsciously triggers facial mimicry (Schrammel et al., 2009), which in turn triggers neural simulation (Niedenthal et al., 2010). When the original smile emanates from a sincere affiliative bid, the momentary intersubjectivity created by neural synchrony will include orientations toward mutual care and responsivity. In short, the evolved adaptive significance of genuine affiliative smiles may be to seed states of positivity resonance. Harkening back to the broaden-and-build theory (Fredrickson, 1998, 2013b), to the extent that positivity resonance builds consequential personal and social resources, genuine affiliative smiles may have evolved to spur positive psychosocial development and improved physical health in individuals, relationships, and indeed, whole communities. Casting love as a micro moment of positivity resonance, then, offers a detailed evolutionary perspective on how genuine smiles can seed the life-enhancing states of positivity resonance and thus do good, both within the body and within society.

Conclusions

Love, defined as micro moments of positivity resonance, may thus be the most generative and consequential of all positive emotions. By virtue of being a single state, distributed across and reverberating between two or more brains and bodies at once, love's ability to broaden mind-sets and build resources may have substantially greater reach. Love, then, is not simply another positive emotion. Rather, it is the momentary phenomenon through which we feel and become part of something larger than ourselves. Meaning in life may thus emerge not from the grand and unrealistic utopian ideals of "happily-ever-after" love, but from what art historian Nicholas Bourriaud (1998) calls the "day-to-day micro-utopias" of shared positivity.

Seeing love as positivity resonance also blurs the boundaries that surround the concept of emotion. Many, if not most, scientific descriptions of emotions locate these affective phenomena within individuals, confined within one person's mind and skin. By contrast, the concept of positivity resonance aligns with perspectives offered within cultural psychology that position emotions as unfolding between and among people as they interact (e.g., Mesquita, 2001). Seeing emotions as properties of individuals may indeed be a myopic by-product of the Western tendency to perceptually extract focal objects from their contextual surround (e.g., Masuda & Nisbett, 2001). By contrast, positioning love as a dynamic process that unfurls across and unifies two or more interacting individuals offers parsimony to accounts of the social and societal functions of positive emotions.

Seeing love as positivity resonance also holds practical implications for how people might strengthen their relationships, families, and communities. Striving to improve these directly can be like telling a complete stranger "trust me" in the absence of any trustworthy actions. By contrast, knowing that relationships, families, and communities grow stronger to the extent that positivity resonates between and among people reveals the value of planning for and prioritizing positivity. Creating activities and safe contexts that allow real-time sensory connection and support the emergence of shared positive emotions becomes the pathway to build social bonds and community. This guidance may be especially valuable within contemporary urban cultures that propel people toward multitasking and technology-mediated social connections. As novelist Ursula Le Guin (1971) put it, "Love doesn't just sit there, like a stone; it has to be made, like bread; remade all the time, made new."

NOTES

1. Even so, scientific investigations of love have been stifled by controversy. It took courage and creativity, for instance, for social psychologists Ellen Berscheid and Elaine Hatfield to sustain their pioneering efforts to study romantic love in the face of what has come to be called "l'affaire Proxmire" (Reis, 2012). This refers to the 1974 debacle in which Wisconsin senator William Proxmire singled out Berscheid and Hatfield's NSF-sponsored research on love for his first of many Golden Fleece Awards, bestowed to highlight what he deemed to be outrageous and shamefully wasteful uses of federal tax dollars.
2. For simplicity I describe love-the-emotion as a property of dyads. Importantly, I see it as equally able to account for communal experiences of shared positivity, or what Haidt and colleagues refer to as an innate *hive psychology* that periodically propels humans to lose themselves enjoyably in a much larger social organism, like the crowd at a football game, music festival, or religious revival (Haidt, Seder, & Kesebir, 2008). Through physical copresence and behavioral synchrony, love-the-emotion can thus also spread from dyads to whole crowds or communities (e.g., Fowler & Christakis, 2008).

CHAPTER 49

Sadness and Depression

Christian A. Webb and Diego A. Pizzagalli

Differentiating Sadness and Depression

The term "depression," in common parlance, is frequently used to describe the emotional experience of sadness. However, *clinical depression* refers to a specific psychiatric disorder (i.e., major depressive disorder [MDD]) characterized by a constellation of affective, behavioral, and cognitive symptoms, as well as significant impairments in functioning. According to the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5; American Psychiatric Association, 2013, pp. 160–161), a major depressive episode (MDE) is defined as experiencing at least five of the following symptoms for a minimum of 2 weeks (either symptom 1 or 2 must be present): (1) depressed mood; (2) diminished pleasure or interest (i.e., *anhedonia*); (3) significant change in weight or appetite; (4) insomnia or hypersomnia; (5) psychomotor agitation or retardation; (6) fatigue or loss of energy; (7) feelings of worthlessness or excessive or inappropriate guilt; (8) difficulties thinking, concentrating, or indecisiveness; and (9) recurrent thoughts of death, or suicidal ideation or actions.

As noted in the DSM-5 (American Psychiatric Association, 2013), "the mood in a major depressive episode is often described by the person as depressed, sad, hopeless, discouraged, or 'down in the dumps'" (p. 163). Although it may overlap with the depressed mood symptom of MDD, sadness—even if intense and prolonged—is not sufficient, in and of itself, to warrant a DSM diagnosis of depression. Indeed, sadness is a normative human emotion, typically experienced in response to the perception of loss or defeat (Beck & Alford, 2009; Ekman, 2007). Moreover, DSM criteria do not require sadness or a depressed mood to be present for a diagnosis of MDD. Like sadness, most MDEs are associated with stressful life events (often with themes of loss or defeat) as preceding, and arguably triggering, the onset of the episode (Hammen, 2005).

Evolutionary Accounts of Sadness and Depression

The apparent universality of basic emotions—including fear, anger, sadness, disgust, surprise, and joy/happiness—have led a number of scholars and evolutionary psychologists to theorize about the adaptive function of these emotions. According to Tooby and Cosmides (2008), emotions function as a "superordinate program" that

> direct the activities and interactions of the subprograms governing perception; attention; inference; learning; memory; goal choice; motivational priorities; categorization and conceptual frameworks; physiological reactions (such as heart rate, endocrine function, immune function); . . . affective coloration of events and stimuli; recalibration of probability estimates, situation assessments, values, and regulatory variables (e.g., self-esteem, . . . , relative value of alternative goal states, efficacy discount rate); and so on (p. 118)

The adaptive function of fear, for example, has been extensively discussed (e.g., see Sapolsky, 2004). Fear is typically triggered by the perception of imminent threat and is associated with a cascade of adaptive physiological "fight-or-flight" reactions (e.g., pupil dilation, increased heart rate, vasoconstriction). Ultimately, these biological processes facilitate and culminate in a survival-increasing behavioral, fight-or-flight response to the threat.

In contrast to the case of fear, a clear-cut evolutionary account of the adaptive function of sadness has proved more elusive. A consideration of the common situational triggers of sadness has informed ideas about what may be its adaptive function(s). The emotion of sadness is commonly triggered by perceptions of loss or defeat (Beck & Alford, 2009; Ekman, 2007). It has been argued that the state of sadness may facilitate deliberation, aid in the reevaluation of goals, and motivate individuals to change their life circumstances in adaptive ways in the face of such stressful or negative life events (Carver, 2004; Keller & Nesse, 2006; Tiedens & Linton, 2001). Moreover, the visible manifestation of sadness, in particular crying, may elicit compassion and aid from others (Nettle, 2004; Vingerhoets & Cornelius, 2001).

A bolder, and perhaps more controversial, claim is that depression itself is an evolutionary adaptation. The relatively high prevalence rate of MDD (see the section "Epidemiology of Depression") raises the following question: Given the myriad ways depression seems to reduce Darwinian fitness, why is it so prevalent and heritable? A number of researchers have argued that depression does serve an adaptive function, and that many diagnoses of MDD are erroneous and overpathologizing an adaptive state (e.g., see Andrews & Thomson, 2009; Horwitz & Wakefield, 2007). Indeed, the relatively high prevalence rate of DSM-defined MDD reported in nationally representative epidemiological studies is striking, and has inspired arguments regarding the adaptive function of what is currently classified as a disorder.

A range of theories have been proposed regarding the adaptive function of depression, including that depressive symptomatology (1) helps to promote the conservation of energy and resources, in particular reducing unproductive investment in unrealistic goals (e.g., Engel, 1980; Nesse, 2000); (2) facilitates the sustained analysis of the precipitant problem(s) (*analytical rumination hypothesis*; Andrews & Thomson, 2009) or aids in the analysis of complex social problems (*social navigation hypothesis*; Watson & Andrews, 2002); (3) reduces the risk of social losses and exclusion (*social risk hypothesis*; Allen & Badcock, 2003); (4) signals submissiveness in the face of a loss of status and facilitates the de-escalation of conflict (*social competition hypothesis*; Price, Sloman, Gardner, Gilbert, & Rohde, 1994); and (5) is associated with a suite of immunological and behavioral responses that reduce immune system vulnerability and risk of infection (Anders, Tanaka, & Kinney, 2013).

Depression is a complex and heterogeneous syndrome, and it is not always clear whether evolutionary theories are referring to sadness or clinical depression, and if the latter, what specific symptoms of depression. Indeed, distinctions have been made in the clinical literature between different subtypes of depressive symptom profiles (e.g., melancholic and atypical depression) and differences in the categories of stressors or events that trigger the episode (e.g., bereavement, seasonal affective disorder), as well as in vulnerability to different kinds of life stressors (e.g., sociotropic vs. autonomous individuals; Liu & Alloy, 2010). Yet, evolutionary accounts of depression often treat the disorder as a seemingly unitary construct. Some evolutionary theorists have attempted to parse the heterogeneity of depressive symptom profiles. For example, Keller and Nesse (2006) provided data indicating that different categories of negative events (e.g., social losses vs. failed efforts) trigger distinct patterns of depressive symptoms, which may be uniquely suited to the adaptive challenges specific to those triggering events (i.e., the *situation–symptom congruence hypothesis*).

Of course, the cognitive (e.g., distorted and entrenched pessimistic cognitions, consuming rumination, suicidal ideation), behavioral (e.g., suicidal actions, poor hygiene, social isolation, and withdrawal from daily activities), and affective (e.g., extreme anhedonia) symptoms associated with higher-severity cases of depressive symptomatology seem more challenging to label as adaptive. However, these may be exceptions to the rule—that is, sadness, and perhaps many cases of DSM-defined MDD, may indeed serve adaptive functions. However, more extreme cases may represent evolved mechanisms that have become dysregulated, as any evolved bodily system or organ is susceptible to malfunction. It will be important for future investigations of the possible adaptive function of depression to carefully consider the heterogeneity of depressive symptom presentations, and to devise meaningful tests of the various above-mentioned hypotheses.

Epidemiology of Depression

Prevalence

Epidemiological studies over the past three decades indicate that the point prevalence (i.e., the prevalence of the disorder at any one point in time) of MDD is approximately 2% in childhood and 5–8% in adulthood (Costello, Erkanli, & Angold, 2006; Kessler, Birnbaum, Shahly, Bromet, Hwang, et al., 2010). With regard to 12-month prevalence, the large, nationally representative National Comorbidity Survey—Replication (NCS-R) study reported that 6.7% of Americans met criteria for at least one MDE in the 12 months preceding the survey (Kessler, Chiu, Demler, & Walters, 2005). Estimates of the lifetime prevalence of MDD vary widely across studies, ranging from 6 (Weissman, Bruce, Leaf, Florio, & Holzer, 1991) to 25% (Lewinsohn, Hops, Roberts, Seeley, & Andrews, 1993). The NCS-R estimated the lifetime prevalence rate of MDD to be 16.6% (Kessler, Berglund, Demler, Jin, Merikangas, & Walters, 2005).

Age of Onset and Gender Differences

One of the striking findings regarding depression is the extent to which depression rates surge during adolescence. Cross-sectional studies suggest that the lifetime prevalence rate of depression is quite low in preadolescent school-age children (< 3%; e.g., Costello, Angold, Burns, Erkanli, Stangl, et al., 1996). However, the prevalence rate in older adolescents (15- to 18-year-olds) is significantly higher and similar to those found in adults (approximately 14%; Kessler, McGonagle, Zhao, et al., 1994). Of course, it is challenging to draw strong conclusions from cross-sectional studies regarding whether depression rates increase as a function of age (i.e., an *age effect*). Fortunately, prospective, longitudinal studies have been conducted that have tracked the prevalence rates of depression within the same sample as they age. Several longitudinal studies have confirmed that the prevalence rate of clinical depression is relatively low in childhood (i.e., 1–3%), but begins to increase during the transition from early to middle adolescence (i.e., ages 12–15) and rises significantly from middle to late adolescence (i.e., ages 15–18), reaching levels similar to those observed throughout adulthood (i.e., approximately 17%; e.g., Costello, Mustillo, Erkanli, Keller, & Angold, 2003; Hankin, Abramson, Moffitt, Silva, McGee et al., 1998; Reinherz, Giaconia, Lefkowitz, & Pakiz, 1993). In addition, during the transition from early to middle adolescence (i.e., ages 12–15), gender differences in depression rates emerge, with females beginning to report increasingly higher levels of depression than males (e.g., Hankin et al., 1998). By middle adolescence, females are twice as likely as males to report clinically significant depressive episodes and this 2:1 female-to-male ratio persists throughout adulthood.

Course

The course of depressive episodes is highly variable. However, the majority of individuals do recover within the first year (e.g., Keller, Lavori, Mueller, Endicott, Coryell, et al., 1992), with one study finding a median time to recovery of 6 weeks (Kendler, Walters, & Kessler, 1997). At the same time, a proportion of patients experience chronic, longer-term episodes. For example, the large, prospective National Institute of Mental Health's (NIMH) Collaborative Depression Study (CDS; Katz & Klerman, 1979) found that 12% of depressed individuals had not yet recovered at the 5-year follow-up (Keller et al., 1992), 7% were deemed unrecovered at the 10-year follow-up (Mueller, Keller, Leon, Solomon, Shea, et al., 1996), and 6% had yet to recover at the 15-year follow-up (Keller & Boland, 1998). In addition, among those who have experienced an MDE, rates of recurrence are exceedingly common, with approximately 80% having a recurrent episode (Kessler, Berglund, Demler, Jin, Koretz, et al., 2003). Moreover, data suggest that the risk of recurrence increases (by approximately 16%) with each successive episode (Boland & Keller, 2009). These findings highlight the importance of treatments not only reducing current depressive symptoms but also the risk of future depression relapse.

Cognitive Biases in Depression and Sadness

A growing body of research has uncovered a range of *cognitive biases* in depression, which influence various phases of information processing (e.g., biases in attention, interpretation, memory; Gotlib & Joormann, 2010). Indeed, cognitive-behavioral therapy (CBT), an empirically validated treatment for depression, is rooted in the cognitive model of depression (Beck, Rush, Shaw, & Emery, 1979), and in teaching patients the skills to identify and modify depressogenic biases in thinking and maladaptive information processing strategies. Below we review several of the major domains of cognitive biases in depression, and discuss the extent to which these biases are also observed in naturally occuring or induced sadness in nondepressed individuals.

Attentional Biases

Biased attention toward depressogenic stimuli represents one of the core elements of Beck's (2008) cognitive model of depression. A number of different paradigms have been employed to test whether depressed inviduals exhibit greater attentional biases toward negative information relative to healthy, nondepressed individuals. The most common paradigms are attentional allocation paradigms, such as the dot-probe task, the "emotional" Stroop task, and eye-tracking paradigms.

In the typical dot-probe task, pairs of stimuli (words or faces) are presented simultaneously. One of the stimuli is neutral, whereas the other is emotional (e.g., a sad or threat-related stimuli). A dot probe then replaces one of the preceding stimuli. Participants are asked to indicate the spatial location of the probe via button press. Response latencies to the probe are used as a measure of attentional bias. Specifically, a briefer latency in identifying the probe replacing the depressotypic stimuli is typically interpreted as reflecting early (automatic) attentional allocation to such stimuli. For example, Mogg, Bradley, and Williams (1995) administered a dot-probe task involving word pairs, half of which were presented supraliminally and half subliminally. The study found that depressed participants, relative to healthy participants, exhibited an attentional bias toward negative words, but only if the words were presented supraliminally. Subsequently, Bradley, Mogg, and Lee (1997) reported a similar mood-congruent attentional bias on the dot-probe task for both induced and naturally occuring dysphoria, but only when words were presented for 500 or 1,000 milliseconds (not in the 14 milliseconds masked exposure condition). The latter findings suggest that mood-congruent attentional biases may not be restricted to those who meet MDD criteria, but can be observed following sad mood induction in nondepressed individuals (but see Chepenik, Cornew, & Farah, 2007).

Attentional biases in depression are not restricted to word stimuli but also emerge for emotional faces. For example, Gotlib, Krasnoperova, Yue, and Joormann (2004) administered a pictorial variant of the dot-probe task involving the presentation of pairs of faces (sad, angry, happy, and neutral expressions) for 1,000 milliseconds. The authors found that depressed individuals displayed a specific attentional bias toward the sad—but not the happy or angry—faces. In summary, attentional bias findings in depression seem to typically emerge only under conditions in which the stimuli are presented supraliminally and for relatively longer periods of time.

In the emotional Stroop task, partipants are asked to name, as quickly as possible, the ink color of presented words, while ignoring the affectively laden meaning of the words (e.g., "sad," "down," "unworthy," "hopeless"). It is hypothesized that depressed invididuals will evidence greater response latency to depressotypic words compared with neutral words. Such effects have been argued to reflect the fact that attention is "grabbed" by the emotional word and thus distracts depressed participants from the task at hand (i.e., naming the ink color of the word).

A meta-analysis (Epp, Dobson, Dozois, & Frewen, 2012) revealed large emotional Stroop effects for negative stimuli in depressed participants compared to their nondepressed counterparts (Hedges's g = .98). It should be noted, however, that, although the largest group differences emerged for the negative stimuli, significant effects were also observed for neutral and even *positive* stimuli (i.e., a larger Stroop effect for depressed participants), arguing against a strong emotion-congruent bias (see Gotlib & Joorman, 2010; Williams, Mathews, & MacLeod, 1996). Fewer studies have examined the effect of naturally occurring or induced sadness on emotional Stroop performance, and findings are mixed. Although some studies have reported Stroop interference for sad words following sad mood induction (Gilboa-Schechtman, Revelle, & Gotlib, 2000), others have not (Perez, Rivera, Fuster, & Rodríguez, 1999).

Finally, eye-tracking technology has also been used in studies examining mood-congruent attentional biases in depression. For example, Eizenman et al. (2003) found that depressed individuals spent significantly more time attending to images with dysphoric themes (loss and sadness) in comparison to nondepressed controls. Interestingly, the study also found that the average glance duration for the dysphoric images was significantly longer for the depressed, relative to the healthy, group. Similarly, a subsequent study (Kellough, Beevers, Ellis, & Wells, 2008) found that depressed participants, relative to their nondepressed counterparts, spent more time attending to dysphoric images, as well as less time attending to pleasant images (see also Caseras, Garner, Bradley, & Mogg, 2007). A recent meta-analytic review of the eye-tracking literature reported that depressed individuals indeed display an increased maintenance of gaze on dysphoric (but not threat-related) stimuli in comparison to nondepressed participants (Armstrong & Olatunji, 2012). The latter findings suggest that depressed individuals may struggle to disengage from negative stimuli. In addition to preferential attention toward dyphoric stimuli, the results of the above meta-analysis also supported an "anhedonic" bias in depression, such that depressed participants were characterized by reduced orienting toward positive stimuli, as well as decreased maintenance of gaze toward positive stimuli. Future studies will be required to examine attential biases via eye tracking in nondepressed individuals undergoing a sad mood induction.

One important question is whether these attentional biases are simply correlates or consequences of depression, or if they index vulnerability and thus precede the onset of depressive episodes. According to Beck's model (Beck et al., 1979), biased attention toward negative, and away from positive, information fuels depressogenic cognitions and maladaptive schemas, which in turn render one vulnerable to depressive symptoms (particularly in the face of stressors). Interestingly, Joormann and colleagues found that individuals at risk of experiencing a future depressive episode by virtue of either having a history of depression (Joormann & Gotlib, 2007) or a mother with MDD (Joorman, Talbot, & Gotlib, 2007) exhibited attentional biases toward negative facial expressions. These findings suggest that attentional biases may be more than a mere symptom or "scar" of depression, and may reflect a risk factor for future depressive episodes and serve as a potential target of interventions aimed at improving attentional control and, ultimately, alleviating depressive symptoms (Siegle, Ghinassi, & Thase, 2007).

Memory Biases

Negative Information

Among the most consistently observed biases in depression are memory biases for mood-congruent information (Gotlib & Joormann, 2010; Mathews & MacLeod, 2005). A common pattern of findings is that nondepressed individuals exhibit a memory bias for positive stimuli (e.g., affectively valenced words), relative to negative (or neutral) stimuli. In contrast, depressed individuals typically show a recall bias for negatively valenced information (e.g., Bradley, Mogg, Millar, & White, 1995; Denny & Hunt, 1992). The effect also extends to memory for faces that differ in affective expression. For example, in a facial recognition task, Ridout, Astell, Reid, Glen, and O'Carroll (2003) found that depressed individuals displayed enhanced memory for sad faces relative to neutral or happy faces. In contrast, nondepressed individuals displayed the opposite memory bias, such that they had superior memory for happy, relative to sad or neutral, faces. It is important to note that there is also evidence of memory biases for mood-congruent information in healthy individuals following sad mood induction (e.g., Forgas, 2001; Chepenik et al., 2007). Indeed, Chepenik et al. (2007) assessed the effect of a sad mood induction in healthy individuals on performance on a range of cognitive tasks, and the strongest mood-congruent effect emerged on their memory bias task (no significant mood induction effects emerged on tasks tapping attentional biases or executive function).

More recently, Dillon, Dobbins, and Pizzagalli (2014) found that only healthy individuals showed significantly enhanced memory for rewarded stimuli relative to nonrewarded stimuli; depressed individuals show no such recall differences. Moreover, using experience sampling methodology to assess recall biases for mood states, Wenze, Gunthert, and German (2012) found that individuals with higher levels of depressive symptoms tended to have more negative mood recall bias and had *less* positive (i.e., more realistic) mood recall bias relative to those with lower levels of depressive symptoms.

Overgeneral Autobiographical Information

In addition to memory biases for negative information, studies indicate that depressed individuals have a tendency to recall overgeneral autobiographical memories, even when instructed to recall specific memories (see Williams et al., 2007, for a review). These results have emerged from a series of studies that have typically used the Autobiographical Memory Test (AMT; Williams & Broadbent, 1986; Williams et al., 2007) to assess the specificity of memory retrieval. Accordingly, when presented with positive and negative valenced words and asked to recall thematically related specific episodic memories, depressed individuals are more likely to recall generic summaries of events than healthy controls. This bias toward overgeneral memory retrieval in depression has been associated with deficits in problem solving and prolonged depressive episodes, as well as difficulties in imagining specific *future* events (Williams et al., 2007). It has been argued that overgeneral memory bias in depression may be related to functional avoidance (i.e., avoiding the threat of negative affect aroused from the recall of specific events), ruminative processes, and deficits in executive function (Williams et al., 2007). Interestingly, a study that trained dysphoric participants to be more concrete and specific in their thinking resulted in reductions in overgeneral thinking and, critically, in improvements in depressive syptoms and rumination (Watkins, Baeyens, & Read, 2009).

Biases in Predicting the Future

Event Forecasting

Not only is depression associated with biases in remembering the past, but there is also evidence linking depression to pessimistic biases in predicting both *future* events and affect. In his early writings, Aaron Beck argued that depressed individuals are characterized by pessimistic cognitions about one's future, as well as the self and world (Beck et al., 1979). Studies have found that depressed adults (e.g., Pyszczynski, Holt, & Greenberg, 1987; Strunk, Lopez, & DeRubeis, 2006) and children (e.g., Muris & van der Heiden, 2006) do indeed report more pessimistic cognitions about the future relative to their nondepressed counterparts. For example, in a sample of children, Muris and van der Heiden (2006) found that depressive symptoms were negatively associated with probability estimates of future positive events, but only when these events were about the self. Similarly, in an undergraduate sample, Pyszczynski et al. (1987) found that depressed participants expected fewer positive events and greater levels of negative events for themselves relative to others.

The latter findings are generally consistent with Beck's cognitive model of depression (Beck et al., 1979). However, the fact that depressed individuals hold pessimistic views of their future does not address whether these cognitions are *biased* relative to objective reality. One could argue, for example, that the reason depressed individuals predict greater negative, and fewer positive, outcomes in the future is not a cognitive bias or distortion per se, but rather reflects the simple fact that depressed individuals do indeed *experience* more negative, and fewer positive, events relative to their nondepressed peers. However, later studies found that pessimistic predictions about the future are biased relative to reality (e.g., Strunk & Adler, 2009; Strunk et al., 2006; Wenze et al., 2012). For example, Strunk et al. (2006) recruited a group of 153 subjects with a broad range of depressive symptoms and had them complete a battery of questionnaires at two time points, 1 month apart. At the first assessment, participants were asked to review a list of 40 varied life events: 20 desirable (e.g., "Will be invited to a party") and 20 undesirable (e.g., "Will get a parking or speeding ticket"). Participants were then asked to estimate the probability that each event would occur to them in the next 30 days. In order to assess predictive bias, at the end of the 30-day period, participants were asked to review the event list and report which of the events occurred to them. Individuals with relatively higher levels of depressive symptoms predicted that they would experience fewer positive outcomes during the study period. However, and most relevant to the question of predictive bias, higher levels of depressive symptoms were associated with greater pessimistic bias and inaccuracy in predicting future live events (see Strunk & Adler, 2009, for a replication). In contrast, research indicates that nondepressed individuals typically display an *optimistic bias* (i.e., a tendency to overestimate the likelihood of positive outcomes and downplay the likelihood of negative outcomes in the future; see Sharot, 2012). To our knowledge, no study has experimentally tested the effect of a sad mood induction on event forecasting.

Affective Forecasting

Evidence also indicates that pessimistic predictive biases may extend to other domains, including the prediction of future affective states (i.e., *affective forecasting*). Using experience sampling methodology, Wenze et al. (2012) found that individuals with greater levels of depression evidenced a more pessimistic negative mood prediction bias, but a less optimistic (i.e., more realistic) positive mood prediction bias. However, in contrast to the findings of Strunk and colleagues (Strunk & Adler, 2009; Strunk et al., 2006), depressive symptoms were not significantly associated with biases in future event prediction. The extent to which attentional and memory biases may fuel biases in the prediction of one's future (e.g., future events and affective states), and vice versa (e.g., pessimistic predictions of the future contributing to biased attention toward negative events and stimuli), is an interesting question needing research.

Neurobiology of Depression and Sadness: Functional Abnormalities

A burgeoning body of literature has described functional abnormalities in MDD, particularly in brain regions linked to reward processing and emotion processing/regulation. (Due to space limitation, we are unable to summarize other domains, and do not discuss structural abnormalities in depression, but see Bora, Fornito, Pantelis, & Yücel, 2012, for a review.)

Hyperreactivity to Negative Stimuli

In a recent meta-analytic review, Hamilton et al. (2012) aggregated studies comparing neural response to negative stimuli (e.g., sad faces and pictures) in depressed versus healthy participants. Relative to healthy individuals, those diagnosed with MDD exhibited greater neural response to negative stimuli in the amygdala, insula, and dorsal anterior cingulate cortex (dACC). These regions are prominent nodes within the so-called salience network, believed to play an important role in assessing the relevance of internal and external stimuli (Seeley et al., 2007). In addition, depressed individuals exhibited *decreased* response to negative stimuli in the dorsolateral prefrontal cortex (DLPFC), a hub of executive control. Taken together, increased reactivity in the salience network coupled with difficulties down-regulating negative affect (due to DLPFC hypoactivation) may reflect hyperreactivity to negative stimuli. Of note, activity in several of the above-mentioned regions normalizes following antidepressant treatment (i.e., decreased activity in the amygdala and insula, and increased activity in the DLPFC; see Delaveau et al., 2011).

Hyporeactivity to Positive Stimuli

Depression is also characterized by blunted reactivity to positive stimuli. Indeed, as noted above, one of the cardinal symptoms of depression is anhedonia (i.e., diminished pleasure or interest), and recent neuroimaging studies have revealed abnormalities across different temporal phases of reward processing, including the anticipation (*anticipatory phase*) and receipt (*consummatory phase*) of rewarding stimuli (Pizzagalli, 2014). MDD has been linked to reduced activity in reward-related brain regions in response to monetary rewards, positive words, and happy facial expressions, in particular in ventral (i.e., nucleus accumbens) and dorsal striatal (i.e., caudate, putamen) regions (Epstein, Pan, Kocsis, Yang, Butler et al., 2006; Forbes, Hariri, Martin, Silk, Moyles, et al., 2009; Pizzagalli, Holmes, Dillon, Goetz, Birk, et al., 2009; Surguladze, Brammer, Keedwell, Giampietro, Young, Travis, et al., 2005).

In addition to these consummatory deficits, blunted ventral and dorsal striatal activation has been observed during reward anticipation in MDD (Pizzagalli et al., 2009; Stoy et al., 2012). Interestingly, Stoy et al. (2012) found that ventral striatal hyporeactivity normalized following successful antidepressant treatment (see Dichter, Felder, Petty, Bizzell, Ernst, et al., 2009, for similar findings following successful psychotherapy). An important task for future research will be to elucidate whether such neural correlates are linked to depressed individuals' tendency to exhibit attentional biases toward negative, and away from positive, stimuli.

Sadness versus Depression

Overall, research indicates that there is partial overlap between the patterns of brain activation observed in MDD versus induced (or naturally occurring) sadness in healthy subjects, in particular, the presence of shared functional abnormalities in prefrontal and limbic regions (Aalto et al., 2002; Davidson, Pizzagalli, Nitschke, & Putnam, 2002; Mayberg et al., 1999). Paralleling findings in MDD, relatively reduced activity in the DLPFC has been observed in healthy participants following a sad mood induction (Mayberg et al., 1999). Moreover, as in depression, sadness in healthy participants has been associated with functional abnormalities in the ACC (Phan, Wager, Taylor, & Liberzon, 2002). Interestingly, in their meta-analysis of the functional neuroanatomy of emotions in healthy subjects, Phan et al. (2002) observed that, relative to other emotions, sadness was more strongly linked to modulation in the subgenual PFC (BA 25)—a region that has been strongly implicated in MDD and its treatment (Mayberg et al., 1999; Johansen-Berg, Gutman, Behrens, Matthews, Rushworth, et al., 2008).

Default Mode Network

In the above-mentioned neuroimaging studies, group comparisons were typically performed in response to emotional stimuli. Recent studies have revealed that an interconnected network of brain regions—including the medial prefrontal cortex (MPFC), posterior cingulate/retrosplenial cortex, and inferior parietal lobules, which have been collectively labeled the *default mode network* (DMN; Buckner, Andrews-Hanna, & Schacter, 2008; Whitfield-Gabrieli & Ford, 2012)—is *more* active during rest than during attention-demanding tasks. Relatively higher DMN activity has been linked to self-referential processes, including thinking about oneself, remembering one's past, and thoughts regarding one's future. Intriguingly, depressed individuals exhibit increased synchronicity within the DMN (Greicius, Flores, Menon, Glover, Solvason, et al., 2007) as well as reduced DMN suppression during task performance (Grimm et al., 2008; Pizzagalli, 2011; Sheline et al., 2009), suggesting potentiated (negative) self-referential processing as well as difficulty inhibiting spontaneous internal cognitions (e.g., rumination), which might prevent full engagement in the task at hand. Critically, relative dominance of DMN activity has been associated with higher levels of maladaptive rumination in MDD (Hamilton, Furman, Chang, Thomason, Dennis, et al., 2011). These findings are consistent with the notion that depression is characterized by preoccupation with spontaneous internal cognitions (rumination; "negative automatic thoughts" regarding self, future, and the world), and that individuals with MDD struggle to down-regulate these depressogenic and distracting thoughts during daily tasks that require their attention and focus.

Future Directions

Important progress has taken place over the last several decades in our understanding of depression. However, in comparison to the relatively less complex phenomenon of sadness, depression is a highly heterogeneous disorder, and is currently defined based on a cluster of symptoms and clinical course, rather than etiology or pathophysiology, which remain poorly understood. For example, it is still not entirely clear to what extent clinically significant MDD differs from normative sadness at the neurobiological level. MDD, as currently classified, likely encompasses a heterogeneous set of disorders with differing pathophysiologies (Pizzagalli, 2014), which consequently complicates efforts to uncover its etiology and underlying neurobiology. One promising approach to parsing this heterogeneity and gaining a better understanding of the etiology and pathophysiology of depression is to focus research on the examination of distinct, and more narrowly defined, endophenotypes of depression, such as anhedonia and, particularly relevant to the present review, cognitive (e.g., attentional and memory) biases (Hasler, Drevets, Manji, & Charney, 2004; Webb, Dillon, Pechtel, Goer, Murray, et al., 2016).

In addition, as evidenced in this review, the bulk of previous research in depression has been based on categorical comparisons of individuals meeting DSM criteria for MDD versus healthy controls. The NIMH, through its Research Domain Criteria (RDoC) initiative, is encouraging dimensional conceptual and analytic approaches to the investigation of MDD, as opposed to an overreliance on DSM-based categorical comparisons. Such a dimensional approach, which entails the consideration of the full range of depressive symptomatology (i.e., from no symptoms to high-severity cases), may yield important insights regarding the nature and etiology of the disorder. Moreover, such research may generate fruitful findings delineating the overlap and distinction between MDD and normative sadness. Although MDD, as currently defined (i.e., according to the DSM), shares minimal similarities with sadness, the empirical literature reviewed above suggests that there are important areas of overlap (e.g., with regard to functional neuroanatomy, cognitive biases and, arguably, evolutionary roots). Informative findings would likely emerge from additional research aimed at parsing the differences between sadness and MDD across different domains or "levels of analysis," including psychosocial (e.g., distinctions and overlap in cognitive biases/deficits and triggering events/stressors), behavioral (e.g., maladaptive patterns of behavior), and neurobiological (e.g., similarities and important differences in brain function and functional connectivity) levels.

With regard to clinical implications, a more in-depth understanding of the etiology of depression may ultimately inform efforts to improve treatment outcomes. For example, research on cognitive biases and the neural underpinning of depression can inform the development and testing of novel and targeted interventions for depression (e.g., see Siegle et al., 2007; Watkins et al., 2009, for the targeting of cognitive biases; see Holtzheimer et al., 2012, for deep brain stimulation of the subgenual PFC). Moreover, in an effort to minimize treatment nonresponse and maximize the efficacy of interventions for depression, it is also important for researchers to identify factors that contribute to worse outcomes. In addition to factors that predict better or poorer prognosis across treatments (i.e., a *prognostic* variable), it is particularly important to identify factors that predict better treatment response in one treatment versus another (i.e., a *prescriptive* variable), thus informing treatment selection. In other words, some patients may be better suited to a particular treatment based on their unique psychosocial, demographic, neurobiological, or clinical profile. For example, Fournier, DeRubeis, Shelton, Hollon, Amsterdam, et al. (2009) found that CBT was more effective than antidepressant medication for patients who were experiencing a relatively large number of life stressors, were married (or cohabitating), or unemployed. With regard to neural markers of differential treatment response, McGrath et al. (2013) recently found that glucose hypometabolism in the insula at pretreatment was associated with remission in the CBT but not the selective serotonin reuptake inhibitor (SSRI) escitalopram condition, whereas insula hypermetabolism was associated with the reverse pattern (i.e., better outcomes for escitalopram). Thus, in line with the pursuit of personalized medicine in psychiatry, future research on prescriptive predictors of symptom change may ultimately lead to critical information regarding which depression treatment is best suited for whom.

CHAPTER 50

EMPATHY

Jamil Zaki and Kevin Ochsner

In *The Western Illusion of Human Nature*, the anthropologist Marshall Sahlins (2008) chronicles a common idea uniting philosophers including Thucydides, Thomas Hobbes, and John Adams. According to Sahlins, these thinkers believed that social contracts are needed to restrain humans from expressing their antisocial "natural state," under which self-interest trumps all other concerns. This view of human nature has made its way into popular culture—via, for instance, the proclamation of *Wall Street*'s Gordon Gekko that "greed is good"—but it is not universal. Traditions throughout the world instead hold that people's identities are distributed, not only in their physical bodies but also across the persons about whom they care. Sahlins (2008) sums up the challenge these traditions pose to a self-oriented view of human nature: "What means 'self-interest' when both selves and interests are transpersonal relationships rather than the predicate of individuals?" (p. 43).

Increasingly, behavioral and neuroscientific research has weighed in on the side of this "transpersonal" view. Although people are physical islands, at a psychological level we are deeply intertwined. People commonly and powerfully share one another's internal states, and spend inordinate amounts of time thinking about others' experiences. The term "empathy" captures these phenomena, and more broadly describes the porous nature of emotions shared across interpersonal boundaries.

Defining Empathy and Its Components

We operationalize empathy as *the ability and tendency to share and understand others' internal states* (Zaki & Ochsner, 2012). This definition highlights the idea that empathy is a multifaceted construct comprising related but distinct components. Two of these processes have attracted the lion's share of empirical and theoretical attention over the last decades. The first of these is *experience sharing*, or the tendency of *perceivers* (individuals focusing on someone else) to take on the sensorimotor, visceral, and affective states of *targets* (individuals on whom perceivers focus). Early philosophical definitions often describe empathy solely in terms of experience sharing (Lipps, 1903; Smith, 1790/2002), and many theoretical models hold that this phenomenon constitutes empathy's central component (Gallese, 2007; Preston & de Waal, 2002). Regardless of one's stance on the centrality of experience sharing, a raft of empirical work demonstrates that people take on various kinds of states that they observe in others. For example, perceivers mimic others' bodily postures and facial movements (Chartrand & Lakin, 2013; Dimberg & Thunberg, 1998), experience autonomic arousal when they observe it in targets (Levenson & Ruef, 1992; Vaughan & Lanzetta, 1980), and take on targets' moods (Neumann & Strack, 2000).

Though experience sharing is a powerful empathic process, it is not the only one. A second, known as *mentalizing*, describes perceivers' explicit reasoning about targets' internal states using lay "theories" about how situations produce internal states (Gopnik & Wellman, 1992). For instance, most of us know that people can see things that are in front of, but not behind, them; we likewise generally believe that eating ice cream makes people happier than having a cavity drilled. When perceivers mentalize, they combine these intuitions with outward signs targets display (e.g., their facial expressions or actions) to draw inferences about targets' underlying emotions, intentions, and beliefs. Importantly, this form of mentalizing—the use of lay theories to decipher target cues—differs from the simpler process of merely accessing information about targets' states or traits, which can occur rapidly and spontaneously (Gilbert, Pelham, & Krull, 1989; Todorov & Uleman, 2002). The study of mentalizing finds its roots in developmental, ethological, and philosophical work on "theory of mind" (Flavell, 1999; Leslie, 1994; Premack & Woodruff, 1978). Since then, it has expanded to include social psychological investigations of the mechanisms underlying mentalizing (Ames, 2004; Epley, Keysar, Van Boven, & Gilovich, 2004) and computational models that specify the structure of perceivers' lay theories about targets (Baker, Saxe, & Tenenbaum, 2009; Ong, Zaki, & Goodman, 2015; Zaki, 2013).

Mentalizing and experience sharing relate to a third key component of empathy: *prosocial motivation*, through which individuals who share and understand targets' states often are compelled to help those targets (Batson, 2011; Zaki & Ochsner, 2012). We discuss this motivational component of empathy in more detail below.

TABLE 50.1. Comparison of Key Empathic Components

Experience sharing	Mentalizing
Development	
Rudimentary experience sharing in first weeks of life	Early signs toward end of first year/beginning of second year
Stable through first years of life	Develops over the course of early childhood, potentially in conjunction with other cognitive processes
Cognitive features	
Occurs rapidly and outside of awareness, and in the presence of concurrent tasks	Requires time, effort, and attention
Brain systems	
Neural resonance in regions associated with sensorimotor processing, visceral sensation, and affect	Regions of the so-called default network, including MPFC, TPJ, and STS
Disorders	
Psychopathy, conduct disorder, frontotemporal dementia	Autism spectrum disorders

Note. MPFC, medial prefrontal cortex; TPJ, temporoparietal junction; STS, superior temporal sulcus.

Independence of Empathic Processes

Many theories of empathy posit a strong boundary between experience sharing and mentalizing (Davis, 1994; Decety & Jackson, 2004; Hoffman, 1984; Singer, 2006; Uddin, Iacoboni, Lange, & Keenan, 2007), which often go by different but aligned terms such as "cognitive and affective empathy" (Shamay-Tsoory, Aharon-Peretz, & Perry, 2009) or "empathic concern" and "perspective taking" (Davis, 1983). As we (Zaki, 2013; Zaki & Ochsner, 2011b, 2012) have pointed out, these processes are impressively dissociable along a number of dimensions, which can be used to organize research on empathy from various psychological subdisciplines (see Table 50.1 for a summary of these dissociations).

Development

The first "wedge" that separates experience sharing and mentalizing is each process's developmental trajectory. Although somewhat sparse, existing evidence suggests that experience sharing, as compared with mentalizing, (1) comes online earlier in ontogeny and (2) remains more stable over the course of development.

Almost immediately after birth, neonates mimic facial movements such as tongue protrusions (Anisfeld, 1991; Meltzoff & Moore, 1977), consistent with a readily triggered link between perception of an action and the "sharing" of that action through imitation. Soon thereafter, infants display other signs of experience sharing. For instance, in the first week of life, infants express distress upon hearing the sound of another infant's cries (Sagi & Hoffman, 1976), but not when played the sound of their own cries (Martin & Clark, 1982). Ten-week-old infants broaden their imitative palette, responding congruently to adults' emotional facial expressions (Haviland &

Lelwica, 1987). Theorists such as Hoffman (2001) frame this type of experience sharing as the most primitive beginnings of later-developing concern for others. Interestingly, affect sharing also appears relatively stable in early development, as assessed through a small but growing number of longitudinal studies of children's naturalistic responses to feigned or videotaped pain in others (Davidov, Zahn-Waxler, Roth-Hanania, & Knafo, 2013). For instance, Knafo, Zahn-Waxler, Van Hulle, Robinson, and Rhee (2008) documented stable levels of experience sharing in the second year of life, and more recently Roth-Hanania, Davidov, and Zahn-Waxler (2011) demonstrated that this stability stretches even into the first year of life.

By comparison, mentalizing appears a more hard-fought developmental prize. Until a decade or so ago, research on theory of mind—which focused largely on children's understanding of targets' false beliefs—suggested that mentalizing came online between children's third and fourth birthday (Flavell, 1999). This trajectory was so consistent that some theorists assumed that it reflected the activation of a neurodevelopmental "module" for understanding others (Leslie, Friedman, & German, 2004). A major problem with this work, however, is that it often relied on children's verbal reports about their understanding of social targets, thus artificially constraining mentalizing to postverbal children. Removing this constraint, for instance, by using looking time to assess preverbal children's expectations about others' beliefs, has revealed mentalizing capacity much earlier in development, near children's first birthday (Onishi & Baillargeon, 2005; Surian, Caldi, & Sperber, 2007). Critically, however, there remains no evidence that mentalizing comes online as early as experience sharing.

Mentalizing also exhibits a more continuous trajectory across early development than experience sharing. For instance, although Roth-Hanania et al. (2011) documented stable levels of experience sharing between the ages of 6 and 18 months, they found that "hypothesis testing," or children's cognitive assessment of the reason for a target's pain, continued developing over that period. Further, the development of mentalizing abilities coincides with the advent of other "top-down" cognitive abilities such as response inhibition (Carlson & Moses, 2001; Wellman, Cross, & Watson, 2001), again suggesting that—unlike experience sharing—mentalizing develops only after some of its basic psychological "building blocks" fall into place.

Automaticity

A second difference between experience sharing and mentalizing is their level of behavioral automaticity. Experience sharing and mimicry can occur rapidly (Dimberg & Thunberg, 1998) and outside of awareness (Neumann & Strack, 2000). By contrast, mentalizing can be disrupted by the absence of attention and time. Interestingly, failures in mentalizing often reflect perceivers' incorrect assumption that their experiences are shared by social targets. For instance, when distracted or placed under time pressure, perceivers often wrongly infer that targets share their (perceivers') knowledge, beliefs, and emotions (Gilovich, Medvec, & Savitsky, 2000; Keysar, Barr, Balin, & Brauner, 2000). Under this model, mentalizing requires an "anchoring and adjustment" process in which perceivers begin with the egocentric assumption that they share states with targets, and effortfully correct that assumption in order to properly understand targets through mentalizing.[1]

Brain Systems

Experience sharing and mentalizing also diverge based on the neural systems underlying each process. Since the discovery of so-called mirror neurons over two decades ago (di Pellegrino, Fadiga, Fogassi, Gallese, & Rizzolatti, 1992; Rizzolatti & Sinigaglia, 2010), the neuroscience of experience sharing has been dominated by a simple but powerful insight: When observing targets experiencing motor, sensory, and affective states, perceivers exhibit patterns of brain activity similar to those they would evince if experiencing those states themselves. This property—which we term "neural resonance"—characterizes activity across a number of brain regions, including those involved in motor actions (Iacoboni et al., 1999), somatosensation (Keysers, Kaas, & Gazzola, 2010), and affective states such as pain, disgust, and reward (Lamm, Decety, & Singer, 2011; Morelli, Sacchet, & Zaki, 2015; Wicker et al., 2003; Zaki, Lopez, & Mitchell, 2014; Zaki & Ochsner, 2011a).

In our view, neural resonance reflects a more general property of the brain: embodied, or "grounded" cognition. Numerous demonstrations suggest that cognitive representations and linguistic descriptions of internal states produce patterns of brain activity consistent with sensorimotor and visceral representations (Barrett & Satpute, 2013; Barsalou, 2008). For instance, remembering or imagining visual percepts produces activity in the visual cortex (Kosslyn & Ochsner, 1994; Wheeler, Petersen, & Buckner, 2000). Likewise, linguistic terms associated with movements (e.g., "bite" or "kick") produces activity in patches of the motor cortex associated with those movements. It stands to reason, then, that such mechanisms should also apply to the observation of states in others. Such "perception–action coupling" (Dijksterhuis & Bargh, 2001; Preston & de Waal, 2002) thus likely connects experience sharing to other forms of grounded cognition.

Mentalizing exhibits a very different neural profile: typically engaging midline cortical structures such as the medial prefrontal cortex (MPFC) and posterior cingulate cortex, as well as the lateral temporal and inferior parietal cortex, and the temporoparietal junction (TPJ; Mitchell, 2009; Saxe, 2006; Zaki & Ochsner, 2012). At least some evidence indicates that regions within this network are engaged by dissociable features of mentalizing. For instance, the MPFC appears broadly responsive to information about mental states, whereas the TPJ responds more selectively to inferences about others' false beliefs (Saxe & Powell, 2006). This could reflect the TPJ's broader role in orienting to new and unexpected information (Corbetta, Patel, & Shulman, 2008; Mitchell, 2008), or holding multiple representations in mind simultaneously.

Interestingly, brain activity related to mentalizing also characterizes a number of other psychological phenomena, including autobiographical memory, prospection into the future, and mental navigation (Spreng, Mar, & Kim, 2009). These data speak to common mechanisms, such as the need to project one's self out of the "here and now" and imagine distal times, places, or perspectives. These phenomena likely share common psychological features—for instance, the need to reason about probabilistic or "fuzzy" outcomes—that unite them with mentalizing (Buckner & Carroll, 2007).

Further, the set of brain regions associated with mentalizing and other forms of self-projection differs from other systems in the brain in that it is stably active at rest. As such, this system is often referred to as the brain's "default network" (Raichle et al., 2001). The default network comprises multiple subsystems, some of which appear maximally relevant to mentalizing (Andrews-Hanna, Reidler, Sepulcre, Poulin, & Buckner, 2010). However, the overlap of this network with regions implicated in mentalizing and self-projections provides intriguing evidence that individuals at rest might tend to engage in these forms of thinking, including consideration of others' minds (Mason et al., 2007).

Critically, the systems of brain regions engaged by experience sharing and mentalizing are almost entirely nonoverlapping. This dissociation is evident not just across studies but also within studies. For instance, orienting perceivers toward lower-level motor and sensory features of targets' experience engages areas associated with experience sharing, whereas orienting them toward targets' high-level intentions produces engagement in brain areas associated with mentalizing (Spunt, Falk, & Lieberman, 2010; Spunt & Lieberman, 2012; Wheatley, Milleville, & Martin, 2007). Likewise, damage to structures associated with neural resonance produces impairments in experience sharing, whereas damage to regions associated with self-projection (such as the MPFC) produce impairments in mentalizing (Shamay-Tsoory et al., 2009). Together, these data once again suggest a powerful separation among empathic subprocesses.

Disorders

A final way in which mentalizing and experience sharing dissociate is through their differing profiles of dysfunction in psychiatric illness. The most famous such dissociation, highlighted by Blair (2005, 2008), separates autism spectrum disorders (ASDs) from psychopathy. Individuals with ASD exhibit circumscribed difficulties in mentalizing, accompanied by altered patterns of activity in brain systems associated with this empathic subprocess (Philip et al., 2011). They also exhibit reduced spontaneous mimicry, blunted engagement of relevant musculature, reduced mu-supression (an electroencephalogram [EEG] signal associated with motor resonance), and reduced mirror neuron system activity when observing target actions (Dapretto et al., 2006; McIntosh, Reichmann-Decker, Winkielman, & Wilbarger, 2006; Oberman, Ramachandran, & Pineda, 2008), indicating a reduction in low-level sharing of motor intentions. Interestingly, however, these abnormalities are not consistently accompanied by deficits in affect sharing. Instead, children and adults with ASD often exhibit typical levels of distress and concern in the presence of target suffering, and demonstrate typical levels of neural resonance for affective states such as pain (Hadjikhani et al., 2014).

By contrast, individuals with psychopathy are often able to understand others' states, but fail to share those states or exhibit typical levels of neural resonance (Meffert, Gazzola, den Boer, Bartels, & Keysers, 2013), producing a behavioral pattern of callous disregard for others' well-being. In fact, the ability to mentalize while unfettered by experience sharing can be a recipe for socially manipulative behavior. For instance, individuals high in "narcissistic exploitativeness," who self-report a tendency to use others for personal gain, exhibit higher than average levels of interpersonal accuracy, consistent with intact and even superior mentalizing ability (Konrath, Corneille, Bushman, & Luminet, 2013).

Summary

These data support the idea that empathy, rather than being a monolithic phenomenon, instead constitutes a constellation of psychological processes, including mentalizing and experience sharing. These processes are impressively separable, based on their developmental trajectories, cognitive features, underlying neural systems, and pattern of dysfunction in disordered populations. That said, the holistic experience of empathy, and the behavior it produces, likely involves a densely intermingled deployment of both processes. It is to this idea that we now turn.

Nonindependence of Empathic Processes

Cases in which psychological processes *can be* dissociated can tempt readers into the inference that those processes are *always* independent. This type of logic is often wrong, however, and the case of empathy is no different. Despite the splits between experience sharing and mentalizing we describe above, measuring empathy in realistic contexts and examining its most important "downstream" consequences reveals that these processes are deeply interconnected.

Naturalism

As with so much of psychology (Neisser, 1976; Rozin, 2001), the study of empathy reflects a tension between experimental control and naturalism (see also Zaki, 2013; Zaki & Ochsner, 2009, 2012). On the one hand, elucidating empathy's structure requires employing paradigms in which the different facets of empathy can be elicited and studied as cleanly and independently as possible. For instance, neuroscientists examining experience sharing often present subjects with decontextualized nonverbal displays of target affect (e.g., images of targets experiencing pain), and do not ask perceivers to draw explicit inferences about targets' experiences based on those cues. By contrast, studies of mentalizing typically ask perceivers to draw just such inferences, often based on "higher-level" social cues, such as written descriptions of the situation in which a target finds him- or herself. These methodological disparities make it unsurprising when previous studies isolate nonoverlapping areas associated with each empathic process. To wit, they are designed to do so.

However, the vast majority of empathic episodes outside the narrow context of the laboratory do not feature isolated "pieces" of social information. Instead, perceivers most often encounter cues that are multimodal (occurring over multiple informational channels), dynamic (changing over time), and contextually embedded (such that interpreting one cue requires processing of other, concurrent or temporally antecedent, social information). Recently, a spate of neuroscientific studies of empathy has employed more *naturalistic* social stimuli that contain these features (e.g., videos of targets explaining their experiences or live interactions between perceivers and targets). These studies have consistently revealed concurrent engagement of brain regions associated with both mentalizing and experience sharing (Redcay et al., 2010; Schilbach et al., 2013; Zaki, Weber, Bolger, & Ochsner, 2009), as well as connectivity across the brain networks supporting both processes (Lombardo et al., 2010; Zaki, Ochsner, Hanelin, Wager, & Mackey, 2007). Together, such data suggest that although empathic processes are separable, in everyday situations empathy likely comprises an interactive deployment of both processes (Keysers & Gazzola, 2007; Shamay-Tsoory, 2011; Uddin et al., 2007).

Accuracy

Another way to probe interactions between empathic subprocesses is by examining the predictors of empathy's "downstream" consequences. Here, we discuss one such consequence: perceivers' ability to accurately infer targets' internal states (Funder, 1995; Ickes, 1997). Accuracy in social contexts allows individuals to effectively interact with others—whether those interactions entail coordinated cooperation or outsmarting others in competitive settings (Byrne & Whiten, 1988; Tomasello, 2000)—and predicts adaptive outcomes in a number of contexts, such as the success of close relationships and positive adjustment in adolescents (Gleason, Jensen-Campbell, & Ickes, 2009; Verhofstadt, Buysse, Ickes, Davis, & Devoldre, 2008).

As with naturalistic empathic settings, accuracy appears not to be scaffolded by *either* experience sharing or mentalizing, but rather by a combination of both processes (Zaki & Ochsner, 2011b). Intuitively, the connection between mentalizing and accurate social inferences appears clear; after all, accuracy often requires "thinking through" what a perceiver likely feels given his or her displays and context, given sufficient time and attentional resources (Epley et al., 2004; Keysar et al., 2000). Neuroimaging investigations likewise reveal that brain areas associated with mentalizing track the complexity (Hampton, Bossaerts, & O'Doherty, 2008) and accuracy (Zaki et al., 2009) of inferences about others.

However, intuitive processes, including experience sharing, also scaffold interpersonal accuracy, in some cases more quickly and efficiently than mentalizing. As discussed above, perceivers quickly take on targets' facial expressions, postures, and moods. Such sharing, in turn, allows perceivers to "read out" their own internal states as cues about what targets might be feeling. And indeed, mimicry—whether it is measured or manipulated across individuals—tracks reaction time and accuracy in interpreting nonverbal emotion cues such as facial expressions (Blairy, Herrerea, & Hess, 1999; Hess & Blairy, 2001; Neal & Chartrand, 2011).

We have used neuroimaging to further examine the role of experience sharing and mentalizing in supporting accurate inferences, using an empathic accuracy paradigm (Ickes, 1997; Zaki & Ochsner, 2011b). In our protocol, perceivers were scanned using functional magnetic resonance imaging (fMRI) while they viewed videos of targets describing emotional autobiographical events. Critically, targets had previously viewed videos of themselves describing these events and used a rating dial to continuously report how positively or negatively they had felt at each moment while talking. Perceivers then used the same rating scale to infer how they believed targets felt, allowing us to use time series correlations between perceiver guesses and target self-reports as quantitative measures of accuracy. This approach revealed that areas in the so-called mirror neuron system, associated with mimicry and shared experience, as well as areas classically associated with mentalizing, both tracked the accuracy of perceivers' inferences on a video-by-video basis (Zaki et al., 2009).

It is important to note that although both mentalizing and experience sharing both support accuracy, they might do so more or less depending on the context. For instance, experience sharing affords a powerful window into targets' internal states, but only to the extent that perceivers believe their own minds are reasonable templates through which to understand targets. Similarity often determines whether or not this is the case. For instance, if a Bostonian perceiver and a New Yorker target both attend the Democratic National Convention, the perceiver's own states are probably useful in understanding how the target will feel about politics, but not about baseball (where the vicious Yankees–Red Sox rivalry likely divides them).

Both behavioral and neuroimaging approaches confirm the bounded nature of perceivers' tendency to deploy experience sharing, and the utility of doing so. For instance, perceivers who are similar to targets along important dimensions (e.g., political orientation) or share relatively minimal group assignments (e.g., based on preference for a television show) assume that their own preferences and mental states track targets' own (Ames & Kammrath, 2004). Likewise, perceivers who are similar to, but not dissimilar from, targets deploy neural resonance when watching targets perform movements (Aziz-Zadeh, Sheng, Liew, & Damasio, 2011), thinking about target preferences (Jenkins, Macrae, & Mitchell, 2008; Mitchell, Macrae, & Banaji, 2006), and observing targets' affective states (Mobbs et al., 2009; Singer et al., 2006; Xu, Zuo, Wang, & Han, 2009). Perceivers' "tuning" of experience sharing based on similarity further appears to be an adaptive strategy: perceivers' use of their own states to understand targets improves accuracy only when overall perceiver–target similarity is high (Hodges, Kiel, Kramer, Veach, & Villanueva, 2010; Neyer, Banse, & Asendorpf, 1999).

Overall, these data support two key points: (1) accuracy demonstrates the joint utility of both experience sharing and mentalizing in accurately understanding others; and (2) each of these processes' relationship to accuracy depends on contextual factors, such as overall similarity between targets and perceivers.

Prosocial Motivation as Both a Component and a Consequence of Empathy

Psychological phenomena are typically not idle, but rather serve important adaptive behaviors. Put more succinctly, thinking is for doing (Fiske, 1992). Empathy is no exception, and instead supports humans' vital cooperative and generous behavior through *prosocial motivation*, or perceivers' desire to help one another. Interestingly, researchers have described prosocial motivation both as a *component* of empathy, akin to experience sharing and mentalizing (Davis, 1994; Batson, 2011; Zaki & Ochsner, 2012, and as a *consequence* of these other two processes (Tomasello, Carpenter, Call, Behne, & Moll, 2005). We believe these two approaches dovetail nicely: prosocial motivation can be considered a component of empathy that flows from mentalizing and experience sharing. This is because individuals who vicariously share and also understand others' states should naturally come to care about targets' states. Interestingly, experience sharing and mentalizing might comprise dissociable routes to prosocial behavior, and it is to this idea that we now turn.

As has been recognized at least since Adam Smith's (1790/2002) *The Theory of Moral Sentiments*, experience sharing can produce powerful and even instinctive prosocial motivation (Zaki & Mitchell, 2013). Consider a perceiver who witnesses a friend in pain and has the option of helping that friend through a personally costly prosocial act. To the extent that the perceiver experiences self–other overlap with that target, the target's pain will produce vicarious distress in the perceiver. In many cases, such shared affect renders the psychological burden (in the form of shared pain) of *not helping* the target greater than that of helping.

Classic and contemporary work has leveraged knowledge about conditioning to demonstrate that (1) perceivers can be conditioned to fear or enjoy neutral stimuli that are paired with punishment or rewards delivered not to the perceiver him- or herself, but to a social target (Berger, 1962; Olsson & Phelps, 2007; Vaughan & Lanzetta, 1980); and (2) both humans and monkeys can be instrumentally conditioned to repeat a response simply because it decreases a target's suffering (Wechkin, Masserman, & Terris, 1964; Weiss, Buchanan, Altstatt, & Lombardo, 1971). Connecting these two ideas, Krebs (1975) demonstrated that individuals who displayed the strongest physiological reactions to others' distress (a proxy for the experience of shared affect) also were most willing to provide costly help to those targets. Cialdini and colleagues built on this model by documenting cases in which perceivers' sense of overlap with social targets predicts the costs they are willing to incur to help those targets (Cialdini, Brown, Lewis, Luce, & Neuberg, 1997; Cialdini & Kenrick, 1976; Cialdini et al., 1987). More recently, neuroscientists have documented cases in which self–other overlap measured through neural resonance predicts prosocial behavior. For instance, perceivers' engagement of brain areas associated with distress while seeing targets' misfortune (Hein, Silani, Preuschoff, Batson, & Singer, 2010), and with reward while observing targets' gains (Harbaugh, Mayr, & Burghart, 2007; Hare, Camerer, Knoepfle, & Rangel, 2010; Zaki et al., 2013), both predict individuals' willingness to later help those targets.

Mentalizing has also long been connected with prosocial motivation. Batson and others (Batson, 1991, 2011; Tomasello et al., 2005) have argued that prosociality fundamentally relies not only on individuals' sense of psychological overlap with each other, but also on perceivers' ability to represent the content of targets' minds through mentalizing. This idea is supported by evidence that explicit instructions to mentalize about targets increases perceivers' subsequent prosocial behaviors (Batson, Early, & Salvarani, 1997; Sturmer, Snyder, & Omoto, 2005). By contrast, dehumanization—people's unfortunate tendency to deny complex mental states to targets from other social groups—results in "sparse" inferences about outgroup targets' minds (Waytz, Gray, Epley, & Wegner, 2010), reductions in brain activity associated with mentalizing (Harris & Fiske, 2007), and reduced prosociality (Cuddy, Rock, & Norton, 2007). Finally, mentalizing-related brain activity during an impression formation task predicts later prosociality toward targets (Waytz, Zaki, & Mitchell, 2012), further suggesting that explicit consideration of targets' minds scaffolds our tendency to help.

The foregoing evidence thus points to two mechanisms underlying prosociality, which connect with experience sharing and mentalizing, respectively. As with accuracy, these data highlight the idea that downstream consequences of empathy cannot be reduced to a single empathic process, but rather require understanding how empathic components interact and combine.

The relationship among mentalizing, experience sharing, and prosocial motivation, though powerful, is by no means simple or monotonic. For instance, although experience sharing often compels perceivers to help targets, it can do so in ways that are demonstrably suboptimal. This is because experience sharing is most often elicited by the perception of clear (i.e., nonambiguous), nonverbal cues about individuals' joy or suffering (e.g., facial expressions). As such, this process can skew perceivers toward helping only when they have direct access to such cues. This produces a number of biases, such as perceivers' tendency to feel more empathy for the suffering of one person than the suffering of a group (the "identifiable victim effect"; Small & Loewenstein, 2003). These biases have spurred some theorists to argue that experience sharing constitutes an unreliable source of moral and prosocial behavior (Bloom, 2013; Prinz, 2011).

Mentalizing likewise has a complex relationship with prosociality. Consider the case of intergroup interactions. In some instances, taking the perspective of an outgroup target can increase perceivers' prosociality (Sturmer et al., 2005). However, in more fraught intergroup contexts, mentalizing with targets can promote *antisocial* behavior or attitudes. For instance, perceivers who mentalize about a target with whom they are competing may realize that target is likely to take advantage of them, and preempt their own losses by first acting antisocially themselves (Epley, Caruso, & Bazerman, 2006; Pierce, Kilduff, Galinsky, & Sivanathan, 2013). For individuals from low-power groups entangled in conflict (e.g., Palestinians), mentalizing about higher-power conflict groups (e.g., Israelis) can likewise intensify, not soften, their conflict-related negative attitudes (Bruneau & Saxe, 2012). Together, these data suggest that both experience sharing and mentalizing can support prosociality, but by no means always do so.

New Directions in Empathy Research

Having sketched the basic mechanisms underlying empathy and their interactions with one another, we now turn to two emerging, interconnected themes we see as important to the future of empathy research and theory.

The Motivated Nature of Empathy

One common assumption about empathy, and experience sharing in particular, is that it is deployed automatically in the presence of target emotions, and generally "happens to" perceivers. This view also constitutes a common thread uniting early and contemporary theories of empathy (see Zaki, 2014, for a review). Automatic models draw support from many demonstrations (some described above) that experience sharing and mimicry indeed occur quickly and outside of awareness. Any of us who have been unlucky enough to witness someone suffer a horrible injury, for instance, can attest to the seemingly unstoppable nature of vicarious distress. However, the fact that a process can be deployed automatically does not mean that perceivers have no recourse to alter empathic episodes based on their desires and motives.

Instead, ample evidence suggests that—as with emotions more generally (Tamir, 2009)—people have strong motives surrounding their experience of empathy.[2] For instance, perceivers often want to *avoid* empathy when it promises to be painful or costly, or when they interact with outgroup targets, or to *approach* empathy when it facilitates important social goals like relationship formation and maintenance. Also like with other emotions, perceivers carry out their motives to feel or not feel empathy through a number of regulatory strategies (Ochsner & Gross, 2005). For instance, if a perceiver anticipates that interacting with a target (e.g., a terminally ill patient) will provoke painful amounts of empathy, he or she can avoid that target altogether, in an interpersonal analogue of "situation selection" (Gross, 2002). Likewise, perceivers often cannily change their perception of targets' affective states, for instance, by reducing their attention to or reappraising the suffering of outgroup targets, thus making it easier to harm those targets (see Zaki, 2014, for a systematic review of empathic regulatory strategies).

Acknowledging empathy's motivated nature extends prior models, for instance, suggesting that some cases of empathic failure (e.g., in clinical populations and intergroup contexts) do not necessarily signal *inabilities* to empathize, but rather reduced motivation to do so. This further suggests that intervention approaches aiming to increase empathy should focus not only on training empathic skills, but also on changing perceivers' motives to feel empathy, for instance, by emphasizing social norms or personal values that encourage empathy (Arieli, Grant, & Sagiv, 2013; Tarrant, Dazeley, & Cottom, 2009). In a recent, allied approach, Schumann, Zaki, and Dweck (2014) induced individuals to believe either that empathy is a stable and unchangeable trait (an *entity mind-set*), or that empathy varies as a function of effort (an *incremental mind-set*). In prior research, incremental, as compared with entity, mind-sets increase individuals' motivation to expend effort under challenging situations (Dweck, 2006). Consistent with a motivated approach to empathy, incremental mind-sets likewise increased perceivers' willingness to engage with targets under challenging circumstances, for instance, when empathy promised to be affectively painful, or when perceivers encountered outgroup targets. In the future, motivated models should complement automatic views to build scientific understanding of when empathy fails and how it can be increased.

There Is No Ideal "Set Point" for Empathic Experience

A second evolving idea in the world of empathy research concerns the assumption that empathy is always desirable. People by and large believe that empathy ranks among other positive traits (on par with, e.g., friendliness or intelligence) in qualifying someone as a good person (Schumann et al., 2014). And indeed, empathy provides a vital emotional underpinning for all manner of adaptive social behavior. However, this does not imply that empathy is always a positive force, either for social perceivers or targets. This is especially true when empathic components are divorced from one another. As described above, psychopathy and intergroup competition mark two cases in which perceivers who deploy mentalizing in the absence of experience sharing can use their understanding of targets to cajole, manipulate, or even maximally harm other people (Konrath et al., 2013; Nozaki & Koyasu, 2013). Likewise, experience sharing can often backfire, for instance, allowing perceivers in competitive interactions to be taken advantage of (Gilin, Maddux, Carpenter, & Galinsky, 2013).

In addition to not always aiding interpersonal interactions, empathy can also be emotionally exhausting for perceivers. Imagine, for instance, walking down a Manhattan street while vicariously experiencing the affective states of everyone around you. This state of affairs would become unsustainable in minutes. Many people in careers that require common contact with others' suffering exemplify how difficult empathy can be for perceivers. Although it has yet to be studied rigorously, caretakers, clinicians, and medical professionals report widespread "empathy fatigue," or a sense of being overwhelmed by others' suffering (Figley, 1995, 2002).

We believe that the potentially deleterious effects of empathy should receive more attention in both basic and applied research. Consider the growing movement of interventions aimed at modulating empathy. Almost all such interventions seek to increase individuals' empathic responses, using methods derived from theory, religious practices, and/or basic science (Gordon, 2009; Weng et al., 2013). Such efforts are crucially important, but should be complemented by efforts to modulate empathic experience in other ways. In particular, we believe that perceivers could benefit from training in how to *regulate* empathy, increasing it when it is needed but also decreasing it when it proves overwhelming or maladaptive. Such regulation will be served by understanding that empathy—although a vital and powerful affective force—does not have an ideal set point.

Relationships between Empathy and Other Emotional States

One deep but unanswered question surrounds the extent to which empathy resembles—or can be reduced to—other, "intrapersonal" emotions. At first blush, experiencing an emotion one's self and observing that emotion in someone else appear dissociable in at least two ways. First, emotion experience, but not observation, appears to include *components*—such as visceral arousal—that can only be experienced in the first person. If this is the case, empathic experiences should require an inferential step that personal emotion does not. Second, personal emotion and empathy appear responsive to different *sources*: one's own experiences in the case of personal emotion versus a social target's emotion in the case of empathy. As Hoffman (1984) put it, empathy represents an emotional reaction in a perceiver that is more appropriate to a target's experience than to the perceiver's own. These apparent distinctions play into the relatively distinct treatment that emotion *experience* and emotion *perception* have received in existing research and theory.

Upon closer examination, however, these distinctions break down. Like other distinctions between self- and other-perception (Bem, 1967; Nisbett & Wilson, 1977), personal emotion might not feature privileged insight into one's own internal states. Indeed, appraisal and conceptual act theories hold that emotional experience occurs through a process of interpretation, through which people apply concepts to decipher core affective cues such as arousal (Barrett, 2013; Scherer, Schorr, & Johnstone, 2001). Similar processes characterize perception of others' emotions (Barrett, Lindquist, & Gendron, 2007; Nook, Lindquist, & Zaki, 2015) and empathy more broadly. In fact, experience sharing and mentalizing tightly parallel core affect and conceptualization as laid out in Barrett's conceptual act theory (Barrett, 2013). In particular, experience sharing provides initial affective and visceral inputs, which perceivers combine with conceptual information they glean through mentalizing to draw inferences about targets' states. In addition to its basic structure, empathy shares parallels with personal emotions in domains of motives and regulation. As described above, individuals desire to feel (or not feel) empathy just as they do with other emotional states (Tamir, 2009; Zaki, 2014), and likewise regulate empathic states in ways that parallel so-called intrapersonal emotion regulation (Ochsner & Gross, 2005; Zaki & Williams, 2013).

Broadly, empathy shares many features with other forms of emotion, but existing work has yet to directly compare the structure of personal emotional experiences with that of interpersonal affect. This will be an exciting and—we hope—synthetic direction for future research.

Conclusions

The study of empathy represents a centuries-old tradition that nonetheless continues changing rapidly through the advent of both new techniques and ideas. Further uncovering the cognitive and affective structure of this phenomenon will be crucial to understanding the ways in which interpersonal affect shapes social interactions.

Notes

1. The use of self-projection does not, of course, *always* lead perceivers astray. For instance, when perceivers and targets are highly similar, perceivers are more likely to project their own states onto targets (Ames, 2004), and more likely to accurately understand targets by doing so (Neyer et al., 1999). This type of projection, however, is less robust to context than mentalizing.
2. Importantly, motives—and the way they are carried out—operate at both explicit and implicit levels, and individuals often experience and act on even nonconscious motives (Gyurak, Gross, & Etkin, 2011; Williams, Bargh, Nocera, & Gray, 2009).
